ENTER HUNT MODE	Forces the asynchronous HDLC controller to close the current RxBD, if it is in use, and enter hunt mode. Reception resumes after the controller finds a frame preceded by one or more opening flags.
CLOSE RXBD	Not supported by the asynchronous HDLC controller.
INIT RX PARAMETERS	Initializes all Rx parameters in the channel's parameter RAM to reset state. Issue only when the receiver is disabled. The INIT TX AND RX PARAMETERS command resets both Tx and Rx parameters.

25.17 Handling Errors in the Asynchronous HDLC Controller

The asynchronous HDLC controller reports frame reception and transmission error conditions using the channel BDs and the asynchronous HDLC event register (UCCE). Table 25-20 describes transmit errors.

Table 25-20. Transmit Errors

Error	Description
$\overline{\text{CTS}}$ Lost during Frame Transmission	The channel stops sending the buffer, closes it, sets UCCE[TXE] and TxBD[CT]. The channel resumes sending from the next TxBD after a RESTART TRANSMIT command is issued.

Table 25-21 describes reception errors.

Table 25-21. Receive Errors

Error	Description
Overrun	Overrun occurs when the RISC cannot keep up with the data rate or the SDMA channel cannot write the received data to memory. The previous data byte and frame status are lost. The controller closes the buffer and sets RxBD[OV] and UCCE[RXF]. The receiver then looks for the next frame.
$\overline{\text{CD}}$ Lost during Frame Reception	The channel stops receiving frames, closes the buffer, and sets UCCE[RXF] and RxBD[CD]. This error has highest priority. The rest of the frame is lost and other errors are not checked in that frame. The receiver then searches for the next frame once $\overline{\text{CD}}$ is reasserted.
Abort Sequence	When an abort sequence (0x7D, 0x7E for PPP) is detected, the channel closes the buffer by setting UCCE[RXF] and RxBD[AB]. CRC error status is not checked on aborted frames. If no frame is being received, the next BD is opened and then closed with RxBD[AB] set.
CRC	The channel writes the received cyclic redundancy check to the buffer, closes the buffer, and sets UCCE[RXF] and RxBD[CR]. After receiving this error, the receiver prepares to receive the next frame.
Break Sequence Received	The receiver detected the first character in a break sequence. The channel closes the buffer and sets UCCE[RXF] and RxBD[BRK]. CRC error status is not checked. UCCE[BRKS] is set when the first break of a sequence is found; UCCE[BRKE] is set when an idle bit is received after a break sequence.

25.18 UCC Asynchronous HDLC Registers

The following sections describe the UCC registers when in asynchronous HDLC mode.

25.18.1 Asynchronous HDLC Event Register (UCCE)/ Asynchronous HDLC Mask Register (UCCM)

The UCC event register (UCCE) is used as the asynchronous HDLC event register to generate interrupts and report events recognized by the asynchronous HDLC channel. When an event is recognized, the asynchronous HDLC controller sets the corresponding UCCE bit. Interrupts can be masked by clearing the appropriate bit in the asynchronous HDLC mask register (UCCM). UCCE bits, shown in Figure 25-17, are cleared by writing ones—writing zeros has no effect. Unmasked UCCE bits must be cleared before the QUICC Engine module clears the internal interrupt request.

Address: UCC_base + 0x10 (UCCE), UCC_base + 0x14 (UCCM) Access: Read/Write

	0–2	3	4	5–6	7	8	9	10	11	12	13	14	15
R W	—	GLR	GLT	—	IDL	—	BRKE	BRKS	TXE	RXF	BSY	TXB	RXB
Reset	All zeros												

Figure 25-17. Asynchronous HDLC Event Register (UCCE)/Asynchronous HDLC Mask Register (UCCM)

Table 25-22 describes UCCE/UCCM fields.

Table 25-22. UCCE/UCCM Field Descriptions

Bits	Name	Description
0–2	—	Reserved, should be cleared.
3	GLR	Glitch on Rx. Set when the UCC finds a Rx clock glitch.
4	GLT	Glitch on Tx. Set when the UCC finds a Tx clock glitch.
5–6	—	Reserved, should be cleared.
7	IDL	Idle sequence status changed. Set when serial line status changes. Real-time status can be read in UCCS[ID].
8	—	Reserved, should be cleared.
9	BRKE	Break end. Marks the end of a break sequence—set when an idle bit is detected after a break sequence.
10	BRKS	Break start. Set when the first break character of a break sequence is received. Only one BRKS event occurs per break sequence, no matter the length of the sequence.
11	TXE	Tx error. Set when an error occurs on the transmitter channel.
12	RXF	Rx frame. Set when the number of frames specified in RFTHR are received. RXF is set no sooner than when the midpoint of the closing flag's stop bit arrives.
13	BSY	Busy condition. Set when a frame is received and discarded due to a buffer shortage.

Table 25-22. UCCE/UCCM Field Descriptions (continued)

Bits	Name	Description
14	TXB	Transmit buffer. Set when a buffer with TxBD[I] set is sent on the channel, not before the last bit of the closing flag begins its transmission if the buffer is the last one in the frame. Otherwise, TXB is set after the last byte of the buffer is written to the Tx FIFO.
15	RXB	Rx buffer. Set when a buffer with RxBD[I] set and RxBD[L] cleared is received over the channel.

25.18.2 UCC Asynchronous HDLC Status Register (UCCS)

The UCC asynchronous HDLC status register (UCCS), shown in Figure 25-18, monitors the real-time status of RXD. The real-time status of $\overline{\text{CTS}}$ and $\overline{\text{CD}}$ is part of the parallel I/O.

Address: Access: Read/Write

	0–2	3	4	5–6	7	8	9	10	11	12	13	14	15
R W	—	GLR	GLT	—	IDL	—	BRKE	BRKS	TXE	RXF	BSY	TXB	RXB
Reset	All zeros												

Figure 25-18. Asynchronous HDLC Event Register (UCCE)/Asynchronous HDLC Mask Register (UCCM)

Table 25-9 describes asynchronous HDLC UCCS fields.

Table 25-23. Asynchronous HDLC UCCS Field Descriptions

Bits	Name	Description
0–6	—	Reserved, should be cleared.
7	ID	Idle status. Set when RXD has been a logic one for at least a full character time. 0 The line is not idle. 1 The line is idle.

25.18.3 Asynchronous HDLC Mode Register (UPSMR)

When the UCC is in asynchronous HDLC mode, the UPSMR, shown in Figure 25-19, acts as the asynchronous HDLC mode register.

Address: Access: Read/Write

	0	1	2–3	4–15
R W	FLC	—	CHLN	—
Reset	All zeros			

Figure 25-19. Asynchronous HDLC Mode Register (UPSMR)

Table 25-24 describes UPSMR fields.

Table 25-24. UPSMR Field Descriptions

Bits	Name	Description
0	FLC	Flow control 0 Normal operation ($\overline{\text{CTS}}$ negation regarded as an error condition). 1 Asynchronous flow control. When $\overline{\text{CTS}}$ is negated, the transmitter stops at the end of the current character. If $\overline{\text{CTS}}$ remains negated past the middle of the character, the next full character is sent before transmission stops. If $\overline{\text{CTS}}$ is reasserted, transmission resumes from where it stopped and no $\overline{\text{CTS}}$ lost error is reported. Only idle characters are sent while $\overline{\text{CTS}}$ is negated.
1	—	Reserved, should be cleared.
2–3	CHLN	Character length. On other protocols CHLN is the number of data bits in a character. For asynchronous HDLC mode, CHLN must be set to 0b11 (indicating a character length of 8 bits).
4–15	—	Reserved, should be cleared.

25.19 UCC Asynchronous HDLC RxBDs

The QUICC Engine module uses the RxBD, shown in Figure 25-20, to report on received data.

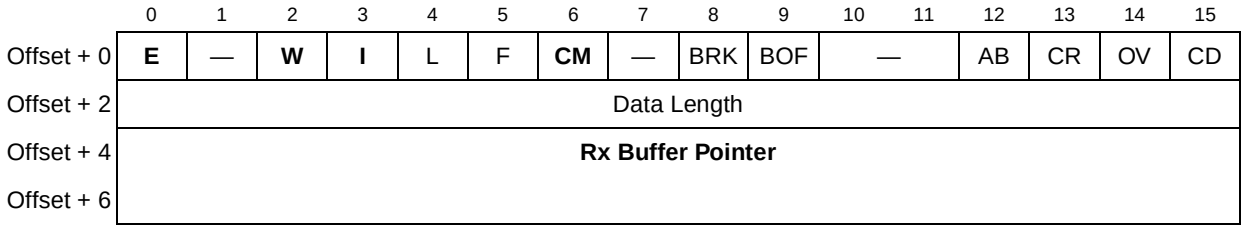

Figure 25-20. UCC Asynchronous HDLC RxBDs

Table 25-25 describes the UCC asynchronous HDLC RxBD status and control fields.

Table 25-25. Asynchronous HDLC RxBD Status and Control Field Descriptions

Bits	Name	Description
0	**E**	Empty. 0 The buffer is full or stops receiving because of an error. The core can read or update any fields of this RxBD. The QUICC Engine module cannot reuse this BD while E = 0. 1 The buffer is not full. The RISC controls the BD and buffer. The core should not update the BD.
1	—	Reserved, should be cleared.
2	**W**	Wrap (last BD in table). 0 Not the last BD in the table. 1 Last BD in the table. After this buffer is used, the QUICC Engine module receives incoming data using the BD pointed to by RBASE. The number of RxBDs in a table is determined by the W bit.
3	**I**	Interrupt. 0 UCCE[RXB] is not set after this buffer is used. UCCE[RXF] is unaffected. 1 UCCE[RXB] or UCCE[RXF] is set when this buffer is used by the asynchronous HDLC controller.

Table 25-25. Asynchronous HDLC RxBD Status and Control Field Descriptions (continued)

Bits	Name	Description
4	L	Last in frame. 0 Not the last buffer in a frame. 1 Set by UCC when a buffer is the last in a frame which happens when a closing flag or error is received. If an error occurs, one or more of the BRK, CD, OV, BOF, CR, and AB bits are set. The UCC updates RxBD[Data Length].
5	F	First in frame. Set by the UCC when this buffer is the first in a frame. 0 Not the first buffer in a frame. 1 First buffer in a frame.
6	**CM**	Continuous mode. 0 Normal operation. 1 The RISC does not clear E after the BD is closed allowing a buffer to be overwritten when the RISC next accesses the BD. However, E is cleared if an error other than CRC occurs during reception, regardless of CM.
7	—	Reserved, should be cleared.
8	BRK	Break character received. Set when a frame is closed because a break character is received.
9	BOF	Beginning of frame. Set when a frame is closed because a BOF character is received instead of the expected EOF.
10–11	—	Reserved, should be cleared.
12	AB	Rx abort sequence. Set when an abort sequence or framing error terminates a frame.
13	CR	Rx CRC error. Set when a frame has a CRC error. Received CRC bytes are written to the buffer.
14	OV	Overrun. Set when a receiver overrun occurs during frame reception.
15	CD	Carrier detect lost. Set when $\overline{CD}$ is negated during frame reception.

Because asynchronous HDLC is a frame-based protocol, RxBD[Data Length] of the last buffer of a frame contains the total number of frame bytes, including the 2 or 4 bytes for CRC.

25.20 UCC Asynchronous HDLC TxBDs

The QUICC Engine module uses the TxBD, shown in Figure 25-21, to confirm transmissions and indicate error conditions.

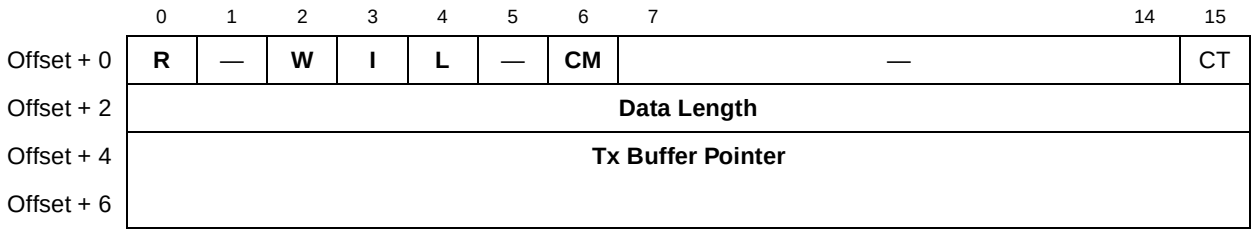

Figure 25-21. UCC Asynchronous HDLC TxBDs

Table 25-26 describes the UCC asynchronous HDLC TxBD status and control fields.

Table 25-26. Asynchronous HDLC TxBD Status and Control Field Descriptions

Bits	Name	Description
0	**R**	Ready. 0 The buffer is not ready for transmission; the BD and the buffer can be updated. The QUICC Engine module clears R after the buffer is sent or after an error condition. 1 The buffer is ready but is not sent or is being sent. Do not update the BD while R =1.
1	—	Reserved, should be cleared.
2	**W**	Wrap (last BD in table). 0 Not the last BD in the table. 1 The last BD in the table. After this buffer is used, the QUICC Engine module sends incoming data using the BD pointed to by TBASE. The number of TxBDs in this table are determined only by the W bit.
3	**I**	Interrupt. 0 UCCE[TXB] is not set after this buffer is sent. 1 UCCE[TXB] is set when this buffer is sent by the asynchronous HDLC controller.
4	**L**	Last. 0 Not the last buffer in the current frame. 1 Last buffer in the current frame. The proper CRC and closing flag are sent after the last byte.
5	—	Reserved, should be cleared.
6	**CM**	Continuous mode. 0 Normal operation. 1 The RISC does not clear R after this BD is closed, allowing its buffer to be resent when the RISC next accesses this BD. However, R is cleared if an error occurs during transmission, regardless of CM.
7–14	—	Reserved, should be cleared.
15	CT	$\overline{\text{CTS}}$ lost. In NMSI mode, $\overline{\text{CTS}}$ is lost during frame transmission. If more than one buffer has data in the FIFO when this error occurs, CT is set in the currently open TxBD. Written by the asynchronous HDLC controller after it finishes sending the buffer.

25.21 Differences Between HDLC and Asynchronous HDLC

The basic differences between HDLC and asynchronous HDLC modes are as follows:

- Asynchronous HDLC does not support the GRACEFUL STOP TRANSMIT command.
- Because asynchronous HDLC has no maximum received frame length counter, it receives all characters between opening and closing flags. There is no way to keep it from writing to memory. This does not affect the number of bytes received into a specific BD. A frame over the maximum length is received into memory in its entirety.
- If an error causes a frame to stop being received, the character being received at the moment the error occurred is not written into memory. For example, if a $\overline{\text{CD}}$ lost error occurs, the frame is closed and the partial character is not written to memory. Thus, the octet count reflects only the number of bytes written to memory.
- The automatic error counters in the HDLC controller are not implemented in the asynchronous HDLC controller.
- Noisy characters (characters for which all three samples are not identical) are not accounted for in the asynchronous HDLC controller. It is assumed that the CRC catches any data integrity problems.

25.22 Asynchronous HDLC Multi-User RAM Usage

The multiuser RAM consumption is dependent on several parameters. This section presents the way the multiuser RAM usage can be calculated according to the setting of these parameters.

Table 25-27 and Table 25-28 present the various parameters that impact the multi-user RAM usage.

Table 25-27. Tx and Rx Parameter RAM Usage

Data structure	Size [bytes]	Multiply by
Global Parameter RAM	256	1

Table 25-28. Internal Buffer Descriptors

Data structure	Size [bytes]	Multiply by
Tx buffer descriptors	8	Number of Tx Buffer Descriptors
Rx buffer descriptors	8	Number of Rx Buffer Descriptors

Table 25-29 presents the overall usage of multi-user RAM.

Table 25-29. Asynchronous HDLC Multi-user RAM Usage

Data structure	example size [bytes]
Parameter RAM usage	256
Tx buffer descriptors	8 × number of Tx BD's
Rx buffer descriptors	8 × number of Rx BD's
Total MRAM usage	256 + 8 × (Tx + Rx BD's)

Chapter 26
UCC BISYNC Mode

26.1 Introduction

A UCC can be configured as a BISYNC controller. A BISYNC controller communicates using the byte-oriented BISYNC protocol. This protocol was developed by IBM for use in networking products. There are three classes of BISYNC frames—transparent[1], nontransparent with header, and nontransparent without header, shown in Figure 26-1. Transparent BISYNC mode allows full binary data to be sent with any possible character pattern. Each class of frame starts with a standard two-octet synchronization pattern and ends with a block check code (BCC). The end-of-text character (ETX) is used to separate the text and BCC fields.

Nontransparent with Header

SYN1	SYN2	SOH	Header	STX	Text	ETX	BCC

Nontransparent without Header

SYN1	SYN2	STX	Text	ETX	BCC

Transparent

SYN1	SYN2	DLE	STX	Transparent Text	DLE	ETX	BCC

Figure 26-1. Classes of BISYNC Frames

The bulk of a frame is divided into fields whose meaning depends on the frame type. The BCC is a 16-bit CRC (Cyclic Redundancy Check) format if 8-bit characters are used; and is a combination longitudinal (sum check) and vertical (parity) redundancy check if 7-bit characters are used. In transparent operation, a special character (DLE) is defined that tells the receiver that the next character is text, allowing BISYNC control characters to be valid text data in a frame. A DLE sent as data must be preceded by a DLE character. This is sometimes called byte-stuffing. The physical layer of the BISYNC communications link must synchronize the receiver and transmitter, usually by sending at least one pair of synchronization characters before each frame.

BISYNC protocol is unique in that TBNR underrun (Transmit Buffer Not Ready and the previous TxBD was with “Last=0”) does not cause an underrun error. If a TBNR underrun event occurs, a synchronization pattern is sent until data is again ready. In nontransparent operation, the receiver discards additional synchronization characters (SYNCs) as they are received. In transparent mode, DLE-SYNC pairs are discarded. Normally, for proper transmission, an underrun must not occur between the DLE and its following character. This failure mode cannot occur with the PowerQUICC II Pro.

1.The transparent frame in BISYNC is not related to the transparent mode, discussed in Chapter 28, “Transparent Controller”

A UCC can be configured as a BISYNC controller to handle basic BISYNC protocol in normal and transparent modes. The controller can work with the time-slot assigner (TSA) or with the non-multiplexed serial interface (NMSI). The controller has separate transmit and receive sections whose operations are asynchronous with the CPU, and either synchronous or asynchronous with other UCCs.

26.1.1 BISYNC Block Diagram

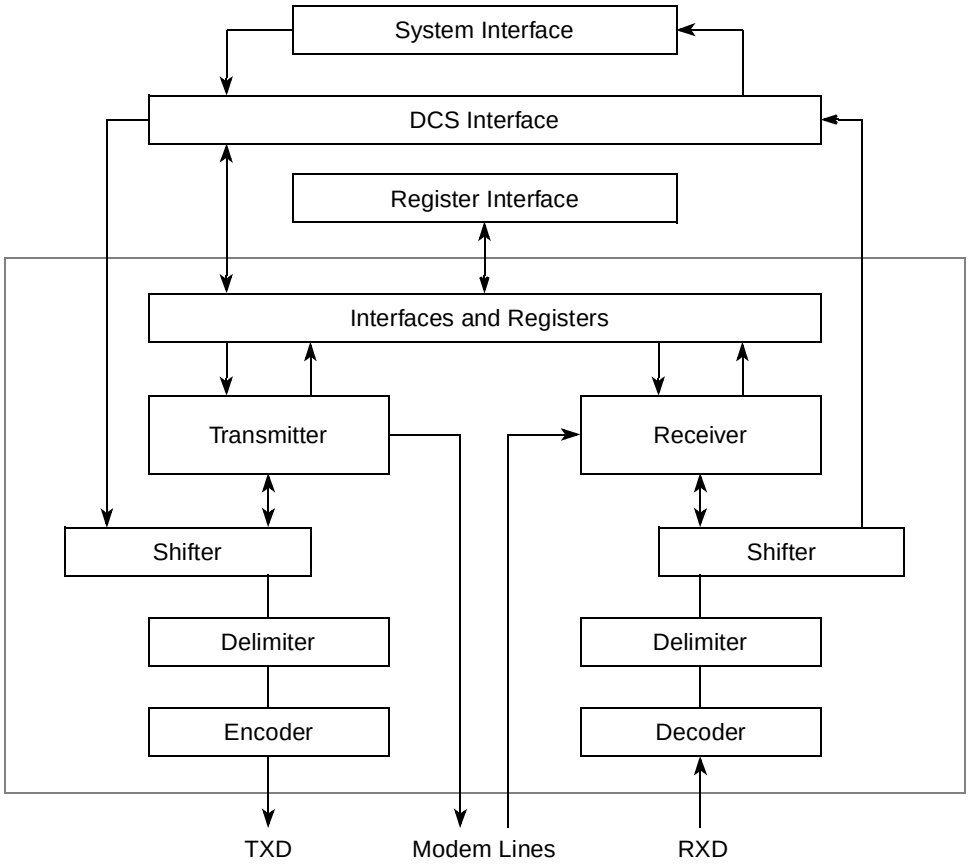

Figure 26-2. BISYNC Block Diagram

26.1.2 Features

The following list summarizes the main features of a UCC when used as a BISYNC controller:

- Flexible data buffers
- Eight control character recognition registers
- Automatic SYNC1–SYNC2 detection
- 16-bit pattern (BISYNC)
- 8-bit pattern (MONOSYNC)
- 4-bit pattern (NIBBLESYNC)
- External SYNC pin support
- SYNC/DLE stripping and insertion

- CRC16 and LRC (sum check) generation/checking
- VRC (parity) generation/checking
- Supports BISYNC transparent operation
- Maintains parity error counter
- Reverse data mode capability

26.1.3 Modes of Operation

The UCC as a BISYNC controller works with two major modes:

- Transparent mode
- Nontransparent mode

26.2 External Signal Descriptions

The UCC as a BISYNC controller has five signals which include the data and modem line signals. These are described in Table 26-1 below:

Table 26-1. Signal Properties

Name	Function	I/O	Reset
$\overline{\text{CD}}$	Carrier detect	I	1
$\overline{\text{CTS}}$	Clear to send	I	1
$\overline{\text{RTS}}$	Ready to send	O	1
RXD	Receive data line	I	—
TXD	Transmit data line	O	1

26.2.1 Detailed Signal Descriptions

When the GUMR_Lx[DIAG] bit field is programmed for normal operation, $\overline{\text{CD}}$ and $\overline{\text{CTS}}$ are controlled by the UCC. In the following sections, it is assumed that the GUMR_Lx[TCI] bit is zero, implying normal transmit clock operation.

Table 26-2. Interface A—Detailed Signal Descriptions

Signal	I/O	Description	
$\overline{\text{CD}}$	I	Carrier detect should encapsulate data in certain configurations	
		Timing	Assertion—according to TCLK (transmitter clock). Negation—according to TCLK (transmitter clock).
$\overline{\text{CTS}}$	I	$\overline{\text{CTS}}$ can be used to control reception and transmission in the same manner as the synchronous protocols.	
		Timing	Assertion—$\overline{\text{CTS}}$ transitions must occur while the Tx clock is low. Negation—$\overline{\text{CTS}}$ transitions must occur while the Tx clock is low.

Table 26-2. Interface A—Detailed Signal Descriptions (continued)

Signal	I/O	Description	
$\overline{\text{RTS}}$	O	Ready To Send signal asserted, when UCC has data to transmit.	
		Timing	Assertion—the delay between $\overline{\text{RTS}}$ and data is 0 bit times.
TXD	O	Serial data out line	
		Timing	Assertion/Negation—according to SERIAL CLK TCLK for transmitter.
RXD	I	Serial data In line	
		Timing	Assertion/Negation—according to SERIAL CLK RCLK for receiver.

26.3 Memory Map/Register Definition

26.3.1 Overview

Table 26-3. UCC BISYNC Register Summary

Offset [1]	Register	Access	Reset Value	Section/Page
0x0	General UCC Mode Register (GUEMR)	R/W	0x0000_0000	24.2.2/24-2
0x8	UPSMR BISYNC Mode Register	R/W	0x0000_0000	26.3.2.5/26-9
0xC	UCC Data Synchronization Register (UDSR)	R/W	0x7E_7E	24.2.3/24-7
0x10	UCCE UCC BISYNC Event Register	R/W	0x0000_0000	26.3.2.8/26-14
0x14	UCCM UCC BISYNC Mask Register	R/W	0x0000_0000	26.3.2.8/26-14

[1] From UCC*x* base address

26.3.2 Register Descriptions

26.3.2.1 UCC BISYNC Parameter RAM

For BISYNC mode, the protocol-specific area of the UCC parameter RAM is mapped as shown in Table 26-4. Fields shown in bold text must be initialized by the user.

Table 26-4. UCC BISYNC Parameter RAM Memory Map

Offset [1]	Name	Width	Description
0x30	—	Word	Reserved
0x34	**CRCC**	Word	CRC constant temp value
0x38	**PRCRC**	Hword	Preset receiver/transmitter CRC16/LRC. These values should be preset to all ones or zeros, depending on the BCS used.
0x3A	**PTCRC**	Hword	
0x3C	**PAREC**	Hword	Receive parity error counter. This 16-bit (modulo 2^{16}) counter maintained by the QUICC Engine module counts parity errors on receive if the parity feature of BISYNC is enabled. Initialize PAREC while the channel is disabled.

Table 26-4. UCC BISYNC Parameter RAM Memory Map (continued)

Offset [1]	Name	Width	Description
0x3E	**BSYNC**	Hword	BISYNC SYNC register. Contains the value of the SYNC to be sent as the second byte of a DLE–SYNC pair in an TBNR underrun condition and stripped from incoming data on receive once the receiver synchronizes to the data using the DSR and SYN1–SYN2 pair. See Section 26.3.2.3, "BISYNC SYNC Register (BSYNC)".
0x40	**BDLE**	Hword	BISYNC DLE register. Contains the value to be sent as the first byte of a DLE–SYNC pair and stripped on receive. See Section 26.3.2.4, "UCC BISYNC DLE Register (BDLE)".
0x42	**CHARACTER1**	Hword	Control character 1–8. These values represent control characters that the BISYNC controller recognizes. See Section 26.3.2.2, "UCC BISYNC Control Character Recognition (in the parameter RAM)".
0x44	**CHARACTER2**	Hword	
0x46	**CHARACTER3**	Hword	
0x48	**CHARACTER4**	Hword	
0x4A	**CHARACTER5**	Hword	
0x4C	**CHARACTER6**	Hword	
0x4E	**CHARACTER7**	Hword	
0x50	**CHARACTER8**	Hword	
0x52	**RCCM**	Hword	Receive control character mask. Masks CHARACTER*n* comparison so control character classes can be defined. Setting a bit enables and clearing a bit masks comparison. See Section 26.3.2.2, "UCC BISYNC Control Character Recognition".
0x54	—	Word	Reserved. Should be cleared.
0x58	—	Word	Reserved. Should be cleared.
0x5c	—	Word	Reserved. Should be cleared.
0x60	—	Word	Reserved. Should be cleared.
0x64	—	Word	Reserved. Should be cleared.
0x68	—	Word	Reserved. Should be cleared.
0x6C	—	Byte	Reserved. Should be cleared.
0x6D-0x100	—	—	Reserved. Should be cleared.

[1] From UCC*x* page base address.

GUMR[MODE] determines the protocol for each UCC. The SYN1-SYN2 synchronization characters are programmed in the DSR (see Section 24.2.3, "UCC Data Synchronization Register (UDSR)"). The BISYNC controller uses the same basic data structure as other modes; receive and transmit errors are reported through their respective BDs.

There are two basic ways to handle BISYNC channels:

- The controller inspects the data on a per-byte basis and interrupts the CPU each time a byte is received.

- The controller can be programmed so software handles the first 2 or 3 bytes. The controller directly handles subsequent data without interrupting the CPU.

26.3.2.2 UCC BISYNC Control Character Recognition

The BISYNC controller recognizes special control characters that customize the protocol implemented by the BISYNC controller and aid its operation in a DMA-oriented environment. They are used for receive buffers longer than 1 byte. In single-byte buffers, each byte can be easily inspected, so control character recognition should be disabled.

The control character table lets the BISYNC controller recognize the end of the current block. Because the controller imposes no restrictions on the format of BISYNC blocks, software must respond to received characters and inform the controller of mode changes and of certain protocol events, such as resetting the BCS. Using the control character table correctly allows the remainder of the block to be received without interrupting software.

Up to eight control characters can be defined to inform the BISYNC controller that the end of the current block is reached and whether a BCS is expected after the character. For example, the end-of-text character (ETX) implies an end-of-block (ETB) with a subsequent BCS. An enquiry (ENQ) character designates an end of block without a subsequent BCS. All the control characters are written into the data buffer. The BISYNC controller uses a table of 16-bit entries to support control character recognition. Each entry consists of the control character, an end-of-table bit (E), a BCS expected bit (B), and a hunt mode bit (H). The RCCM entry defines classes of control characters that support masking option. The control character table and RCCM are shown in Figure 26-3.

Offset[1]	0	1	2	3 — 7	8 — 15
0x42	E	B	H	—	CHARACTER1
0x44	E	B	H	—	CHARACTER2
0x46	E	B	H	—	CHARACTER3
0x48	E	B	H	—	CHARACTER4
0x4A	E	B	H	—	CHARACTER5
0x4D	E	B	H	—	CHARACTER6
0x4E	E	B	H	—	CHARACTER7
0x50	E	B	H	—	CHARACTER8
0x52	1	1	1	—	MASK VALUE(RCCM)

Figure 26-3. Control Character Table and RCCM

[1] From UCC*x* page base address

Table 26-5 describes control character table and RCCM fields.

Table 26-5. Control Character Table and RCCM Field Descriptions

Offset[1]	Bits	Name	Description
0x42–0x50	0	E	End of table 0 This entry is valid. The lower 8 bits are checked against the incoming character. In tables with eight control characters, E should be zero in all eight positions. 1 The entry is not valid. No other valid entries exist beyond this entry.
	1	B	BCS expected. A maskable interrupt is generated after the buffer is closed. 0 The character is written into the receive buffer and the buffer is immediately closed. 1 The character is written into the receive buffer. The receiver waits for 1 LRC or 2 CRC bytes of BCS and then closes the buffer. This should be used for ETB, ETX, and ITB.
	2	H	Hunt mode. Enables hunt mode when the current buffer is closed. 0 The BISYNC controller maintains character synchronization after closing this buffer. 1 The BISYNC controller enters hunt mode after closing the buffer. When the B bit is set, the controller enters hunt mode after receiving the BCS.
	3–7	—	Reserved
	8–15	CHARACTER*n*	Control character 1–8. When using 7-bit characters with parity, include the parity bit in the character value.
0x52	0–2	—	All ones
	3–7	—	Reserved
	8–15	RCCM	Received control character mask. Masks comparison of CHARACTER*n*. Each bit of RCCM masks the corresponding bit of CHARACTER*n*. 0 Mask this bit in the comparison of the incoming character and CHARACTER*n*. 1 The address comparison on this bit proceeds normally and no masking occurs. If RCCM is not set, erratic operation can occur during control character recognition.

1 From UCC*x* page base address

26.3.2.3 BISYNC SYNC Register (BSYNC)

BSYNC, shown in Figure 26-4, defines BISYNC stripping and SYNC character insertion. When a TBNR underrun occurs, the BISYNC controller inserts SYNC characters until the next buffer is available for transmission. If the receiver is not in hunt mode when a SYNC character is received, it discards this character if the valid bit (BSYNC[V]) is set. When using 7-bit characters with parity, the parity bit should be included in the SYNC register value.

Offset[1]	0	1	2	3	4	5	6	7	8 … 15
0x3e	V	DIS	0	0	0	0	0	0	SYNC

Figure 26-4. BISYNC SYNC (BSYNC)

1 From UCC*x* page base address

Table 26-6 describes BSYNC fields.

Table 26-6. BSYNC Field Descriptions

Bits	Name	Description
0	V	Valid. If V = 1 and the receiver is not in hunt mode when a SYNC character is received, this character is discarded.
1	DIS	Disable BSYNC stripping 0 Normal mode 1 BSYNC stripping disabled (BISYNC transparent mode only)
2–7	—	All zeros
8–15	SYNC	SYNC character

26.3.2.4 UCC BISYNC DLE Register (BDLE)

BDLE, shown in Figure 26-5, defines the BISYNC stripping and insertion of DLE characters. When a TBNR underrun occurs while a message is being sent in transparent mode, the BISYNC controller inserts DLE-SYNC pairs until the next buffer is available for transmission.

In transparent mode, the receiver discards any DLE character received and excludes it from the BCS if the valid bit (BDLE[V]) is set. If the second character is SYNC, the controller discards it and excludes it from the BCS. If it is a DLE, the controller writes it to the buffer and includes it in the BCS. If it is not a DLE or SYNC, the controller examines the control character table and acts accordingly. If the character is not in the table, the buffer is closed with the DLE follow character error bit set. If the valid bit is not set, the receiver treats the character as a normal character. When using 7-bit characters with parity, the parity bit should be included in the DLE register value.

Offset[1]	0	1	2	3	4	5	6	7	8 … 15
0x40	V	DIS	0	0	0	0	0	0	DLE

Figure 26-5. BISYNC DLE (BDLE)

1 From UCC*x* page base address

Table 26-7 describes the BDLE fields.

Table 26-7. BDLE Field Descriptions

Bits	Name	Description
0	V	Valid. If V = 1 and the receiver is not in hunt mode when a SYNC character is received, this character is discarded.
1	DIS	Disable DLE stripping 0 Normal mode 1 DLE stripping disabled. When DIS is enabled in BDLE and on BSYNC the following cases occur: DLE-DLE sequence. Both characters are written to memory. The BCS is calculated only on the second DLE. DLE-SYNC sequence. Both characters are written to memory, but neither are included in the BCS calculation. DLE-ETX, DLE-ITB, DLE-ETB sequence, both characters are written to memory. The BCS is calculated only on the second character.

Bits	Name	Description
2–7	—	All zeros
8–15	DLE	DLE character

26.3.2.4.1 Sending and Receiving the Synchronization Sequence

The BISYNC channel can be programmed to send and receive a synchronization pattern defined in the DSR. GUMR_H[SYNL] defines the pattern length, as shown in Table 26-8. The receiver synchronizes on this pattern. Unless SYNL is zero (external sync), the transmitter always sends the entire DSR contents, lsb first, before each frame—the chosen 4- or 8-bit pattern can be repeated in the lower-order bits.

Table 26-8. Receiver SYNC Pattern Lengths of the DSR

GUMR_H[SYNL] Setting	Bit Assignments															
	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
00	An external SYNC signal is used instead of the SYNC pattern in the DSR															
01	4-bit															
10	8-bit															
11	16-bit															

26.3.2.5 BISYNC Mode Register (UPSMR)

UPSMR is shown in Figure 26-6. UPSMR[NOS, RBCS, RTR, RPM, TPM] can be modified on-the-fly.

Address: UCC_BASE + 0x8 Access: Read/Write

	0–3	4–5	6	7	8	9	10–11	12–13	14–15
R W	NOS	CRC	RBCS	RTR	RVD	DRT	—	RPM	TPM
Reset	All zeros								

Figure 26-6. Protocol-Specific Mode Register for BISYNC (UPSMR)

Table 26-9 describes UPSMR fields.

Table 26-9. UPSMR Field Descriptions

Bits	Name	Description
0–3	NOS	Minimum number of SYN1-SYN2 pairs (defined in DSR) sent between or before messages. 0000 one pair is sent. 0001 two pairs are sent. . . . 1111 16 pairs are sent. The entire pair is always sent, regardless of how GUMR[SYNL) is set. NOS can be modified on-the-fly.
4–5	CRC	CRC selection x0 Reserved 01 CRC16 (BISYNC). X16 + X15 + X2 + 1. PRCRC and PTCRC should be initialized to all zeros or all ones before the channel is enabled. In either case, the transmitter sends the calculated CRC noninverted and the receiver checks the CRC against zero. Eight-bit data characters (without parity) are configured when CRC16 is chosen. 11 LRC (sum check). (BISYNC). For even LRC, initialize PRCRC and PTCRC to zeros before the channel is enabled; for odd LRC, they should be initialized to ones. Note that the receiver checks character parity when BCS is programmed to LRC and the receiver is not in transparent mode. The transmitter sends character parity when BCS is programmed to LRC and the transmitter is not in transparent mode. Use of parity in BISYNC assumes that 7-bit data characters are being used.
6	RBCS	Receive BCS. The receiver internally stores two BCS calculations separated by an 8-serial clock delay to allow examination of a received byte to determine whether it should used in BCS calculation. 0 Disable receive BCS 1 Enable receive BCS. Should be set (or reset) within the time taken to receive the following data byte. When RBCS is reset, BCS calculations exclude the latest fully received data byte. When RBCS is set, BCS calculations continue as normal.
7	RTR	Receiver transparent mode 0 Normal receiver mode with SYNC stripping and control character recognition. 1 Transparent receiver mode. SYNCs, DLEs, and control characters are recognized only after a leading DLE character. The receiver calculates the CRC16 sequence even if it is programmed to LRC while in transparent mode. Initialize PRCRC to the CRC16 preset value before setting RTR.
8	RVD	Reverse data 0 Normal operation 1 Any portion of this UCC defined to operate in BISYNC mode operates by reversing the character bit order and sending the msb first.
9	DRT	Disable receiver while sending. DRT should not be set for typical BISYNC operation. 0 Normal operation 1 As the UCC sends data, the receiver is disabled and gated by the internal $\overline{\text{RTS}}$ signal. This helps if the BISYNC channel is being configured onto a multidrop line and the user does not want to receive its own transmission. Although BISYNC usually uses a half-duplex protocol, the receiver is not actually disabled during transmission. **Note:** If DRT = 1, GUMR_H[CDS] should be cleared unless both of the following are true: the same clock is used for TCLK and RCLK, and $\overline{\text{CTS}}$ either has synchronous timing or is always asserted.
10–11	—	Reserved, should be cleared

Table 26-9. UPSMR Field Descriptions (continued)

Bits	Name	Description
12–13	RPM	Receiver parity mode. Selects the type of parity check that the receiver performs. RPM can be modified on-the-fly and is ignored unless CRC = 11 (LRC). Receive parity errors cannot be disabled but can be ignored. 00 Odd parity. The transmitter counts ones in the data word. If the sum is not odd, the parity bit is set to ensure an odd number. An even sum indicates a transmission error. 01 Low parity. If the parity bit is not low, a parity error is reported. 10 Even parity. An even number must result from the calculation performed at both ends of the line. 11 High parity. If the parity bit is not high, a parity error is reported.
14–15	TPM	Transmitter parity mode. Selects the type of parity the transmitter performs and can be modified on-the-fly. TPM is ignored unless CRC = 11 (LRC). 00 Odd parity 01 Force low parity (always send a zero in the parity bit position) 10 Even parity 11 Force high parity (always send a one in the parity bit position)

26.3.2.6 UCC BISYNC Receive BD (RxBD)

The QUICC Engine module uses BDs to report on each buffer received. It closes the buffer, generates a maskable interrupt, and starts receiving data into the next buffer after any of the following:

- A user-defined control character is received
- An error is detected
- A full receive buffer is detected
- The ENTER HUNT MODE command is issued

Figure 26-7 shows the UCC BISYNC RxBD.

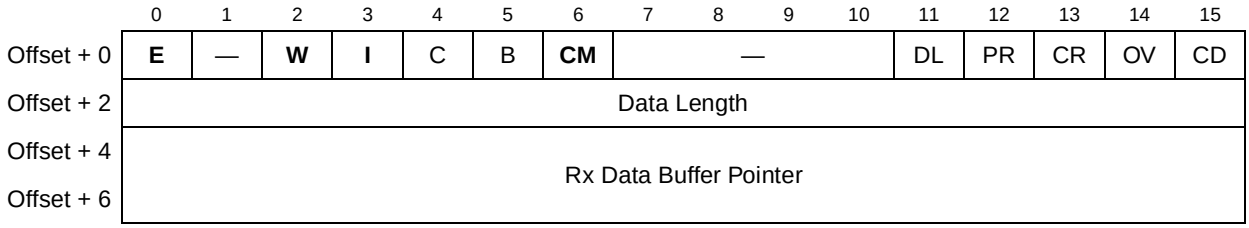

Figure 26-7. UCC BISYNC RxBD

Table 26-10 describes UCC BISYNC RxBD status and control fields. Fields shown in bold type must be initialized by the user.

Table 26-10. UCC BISYNC RxBD Status and Control Field Descriptions

Bits	Name	Description
0	**E**	Empty 0 The buffer is full or stopped receiving because of an error. The cpu can read or write any fields of this RxBD. The QUICC Engine module does not use this BD as long as the E bit is zero. 1 The buffer is not full. The QUICC Engine module controls this BD and buffer. The cpu should not update this BD.
1	—	Reserved, should be cleared
2	**W**	Wrap (last BD in table) 0 Not the last BD in the table 1 Last BD in the table. After this buffer is used, the QUICC Engine module receives incoming data into the first BD that RBASE points to. The number of BDs in this table is determined by the W bit and by overall space constraints of the multi-user RAM.
3	**I**	Interrupt 0 No interrupt is generated after this buffer is used 1 UCCE[RXB] is set when the controller closes this buffer, which can cause an interrupt if it is enabled.
4	C	Control Character. The last byte in the buffer is a user-defined control character. 0 The last byte of this buffer does not contain a control character. 1 The last byte of this buffer contains a control character.
5	B	BCS received. The last byte in the buffer contain the received BCS. 0 This buffer does not contain the BCS. 1 This buffer contains the BCS. A control character may also reside one byte prior to BCS.
6	**CM**	Continuous mode. 0 Normal operation 1 The QUICC Engine module does not clear E after this BD is closed; the buffer is overwritten when the QUICC Engine module accesses this BD next. However, E is cleared if an error occurs during reception, regardless of how CM is set.
7–10	—	Reserved, should be cleared
11	DL	DLE follow character error. While in transparent mode, a DLE character was received, and the next character was not DLE, SYNC, or a valid entry in the control characters table.
12	PR	Parity error. Set when a character with parity error is received. Upon a parity error, the buffer is closed; thus, the corrupted character is the last byte of the buffer. A new Rx buffer receives subsequent data.
13	CR	BCS error. Updated every time a byte is written to the buffer. The CR bit includes the calculation for the current byte. By clearing PSMR[RBCS] within eight serial clocks, the user can exclude the current character from the massage BCS calculation. The data length field may be read to determine the current character's position.
14	OV	Overrun. Set when a receiver overrun occurs during frame reception.
15	CD	Carrier detect lost. Indicates when the carrier detect signal, $\overline{\text{CD}}$, is negated during frame reception.

Data length and buffer pointer fields are described in Section 24.3, "UCC Buffer Descriptors (BDs)." Data length represents the number of octets the QUICC Engine module writes into this buffer, including the BCS. For BISYNC mode, clear these bits. It is incremented each time a received character is written to the buffer.

26.3.2.7 UCC BISYNC Transmit BD (TxBD)

The QUICC Engine module arranges data to be sent on a UCC channel in buffers referenced by the channel TxBD table. The QUICC Engine module uses BDs to confirm transmission or indicate errors so the CPU knows buffers have been serviced. The QUICC Engine module configures status and control bits before transmission, but the QUICC Engine module sets them after the buffer is sent.

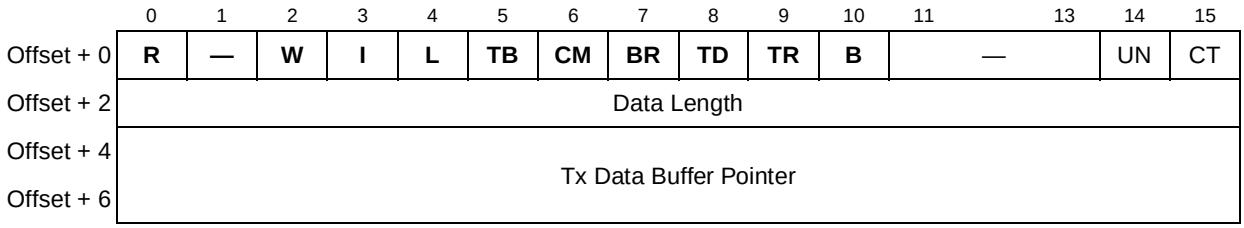

Figure 26-8. UCC BISYNC Transmit BD (TxBD)

Table 26-11 describes UCC BISYNC TxBD status and control fields. Fields shown in bold type must be initialized by the user.

Table 26-11. UCC BISYNC TxBD Status and Control Field Descriptions

Bits	Name	Description
0	**R**	Ready 0 The buffer is not ready for transmission. The current BD and buffer can be updated. The QUICC Engine module clears R after the buffer is sent or after an error condition. 1 The user-prepared buffer has not been sent or is being sent. This BD cannot be updated while R = 1.
1	—	Reserved, should be cleared
2	**W**	Wrap (last BD in table) 0 Not the last BD in the table 1 Last BD in the table. After this buffer is used, the QUICC Engine module sends data using the BD pointed to by TBASE. The number of TxBDs in this table is determined only by the W bit and overall space constraints of the multi-user RAM.
3	**I**	Interrupt 0 No interrupt is generated after this buffer is serviced. 1 UCCE[TXB] or UCCE[TXE] is set after the QUICC Engine module services this buffer, which can cause an interrupt.
4	**L**	Last in message 0 The last character in the buffer is not the last character in the current block. 1 The last character in the buffer is the last character in the current block. The transmitter enters and stays in normal mode after sending the last character in the buffer and the BCS, if enabled.
5	**TB**	Transmit BCS. Valid only when the L bit is set. 0 Send an SYN1–SYN2 or idle sequence (specified in GUMR[RTSM]) after the last character in the buffer. 1 Send the BCS sequence after the last character. The controller also resets the BCS generator after sending the BCS.
6	**CM**	Continuous mode 0 Normal operation 1 The QUICC Engine module does not clear R after this BD is closed, so the buffer is resent when the QUICC Engine module next accesses this BD. However, R is cleared if an error occurs during transmission, regardless of how CM is set.

Table 26-11. UCC BISYNC TxBD Status and Control Field Descriptions (continued)

Bits	Name	Description
7	**BR**	BCS reset. Determines whether transmitter BCS accumulation is reset before sending the data buffer. 0 BCS accumulation is not reset 1 BCS accumulation is reset before sending the data buffer
8	**TD**	Transmit DLE 0 No automatic DLE transmission can occur before the data buffer. 1 The transmitter sends a DLE character before sending the buffer, which saves writing the first DLE to a separate buffer in transparent mode. See TR for information on control characters.
9	**TR**	Transparent mode 0 The transmitter enters and stays in normal mode after sending the buffer. The transmitter automatically inserts SYNCs if a TBNR underrun condition occurs. 1 The transmitter enters or stays in transparent mode after sending the buffer. It automatically inserts DLE–SYNC pairs if a TBNR underrun occurs (the controller finishes a buffer with L = 0 and the next BD is not available). It also checks all characters before sending them. If a DLE is detected, another DLE is sent automatically. Insert a DLE or program the controller to insert one before each control character. The transmitter calculates the CRC16 BCS even if UPSMR[BCS] is programmed to LRC. Initialize PTCRC to CRC16 before setting TR.
10	**B**	BCS enable 0 The buffer consists of characters that are excluded from BCS accumulation. 1 The buffer consists of characters that are included in BCS accumulation.
11–13	—	Reserved, should be cleared
14	UN	Underrun. Set when the BISYNC controller encounters a transmitter underrun error while sending the associated data buffer. The QUICC Engine module writes UN after it sends the associated buffer.
15	CT	$\overline{\text{CTS}}$ lost. The QUICC Engine module sets CT when $\overline{\text{CTS}}$ is lost during message transmission after it sends the data buffer.

Data length and buffer pointer fields are described in Section 24.3, “UCC Buffer Descriptors (BDs).” Although it is never modified by the QUICC Engine module, data length should be greater than zero. The QUICC Engine module writes these fields after it finishes sending the buffer.

26.3.2.8 BISYNC Event Register (UCCE)/BISYNC Mask Register (UCCM)

The BISYNC controller uses UCCE to report events recognized by the BISYNC channel and to generate interrupts, as shown in Figure 26-9. When an event is recognized, the controller sets the corresponding UCCE bit. Interrupts are enabled by setting, and masked by clearing the equivalent bits in UCCM. UCCE bits are reset by writing ones; writing zeros has no effect. Unmasked bits must be reset before the QUICC Engine module negates the internal interrupt request signal.

Address: UCC_base + 0x10 (UCCE), UCC_base + 0x14 (UCCM) Access: Read/Write

	0–7	8	9	10	11	12	13	14	15
R W	—	GRA	—		TXE	RCH	BSY	TXB	RXB
Reset	All zeros								

Figure 26-9. BISYNC Event Register (UCCE)/BISYNC Mask Register (UCCM)

Table 26-12 describes UCCE and UCCM fields.

Table 26-12. UCCE/UCCM Field Descriptions[1]

Bits	Name	Description
0–7	—	Reserved, should be cleared. Refer to note 1 below.
8	GRA	Graceful stop complete. Set as soon the transmitter finishes any message in progress when a GRACEFUL STOP TRANSMIT is issued (immediately if no message is in progress).
9–10	—	Reserved, should be cleared. Refer to note 1 below.
11	TXE	Tx Error. Set when an error occurs on the transmitter channel.
12	RCH	Receive character. Set when a character is received and written to the buffer.
13	BSY	Busy. Set when a character is received and discarded due to a lack of buffers. The receiver resumes reception after an ENTER HUNT MODE command.
14	TXB	Tx buffer. Set when a buffer is sent. TXB is set as the last bit of data or the BCS begins transmission.
15	RXB	Rx buffer. Set when the QUICC Engine module closes the receive buffer on the BISYNC channel.

1 Reserved bits in the UCCE should not be masked in the UCCM register.

26.4 Functional Description

26.4.1 UCC BISYNC Channel Frame Transmission

The BISYNC transmitter is designed to work with almost no CPU intervention. When the transmitter is enabled, it starts sending SYN1-SYN2 pairs in the data synchronization register (DSR) or idles as programmed in the GUMR. The BISYNC controller polls the first BD in the channel's TxBD table. If there is a message to send, the controller fetches the message from memory and starts sending it after the SYN1-SYN2 pair. The entire pair is always sent, regardless of GUMR[SYNL].

After a buffer is sent, if the last (TxBD[L]) and the Tx block check sequence (TxBD[TB]) bits are set, the BISYNC controller appends the CRC16/LRC and then writes the message status bits in TxBD status and control fields and clears the ready bit, TxBD[R]. It then starts sending the SYN1-SYN2 pairs or idles, according to GUMR[RTSM]. If the end of the current BD is reached and TxBD[L] is not set, only TxBD[R] is cleared. In both cases, an interrupt is issued according to TxBD[I]. TxBD[I] controls whether interrupts are generated after transmission of each buffer, a specific buffer, or each block. The controller then proceeds to the next BD.

If no additional buffers have been sent to the controller for transmission, an in-frame TBNR underrun is detected and the controller starts sending syncs or idles. If the controller is in transparent mode, it sends DLE-sync pairs. Characters are included in the block check sequence (BCS) calculation on a per-buffer basis. Each buffer can be programmed independently to be included or excluded from the BCS calculation; thus, excluded characters must reside in a separate buffer. The controller can reset the BCS generator before sending a specific buffer. In transparent mode, the controller inserts a DLE before sending a DLE character, so that only one DLE is used in the calculation.

26.4.2 UCC BISYNC Channel Frame Reception

Although the receiver is designed to work with almost no CPU intervention, the user can intervene on a per-byte basis if necessary. The receiver performs CRC16, longitudinal (LRC) or vertical redundancy (VRC) checking, sync stripping in normal mode, DLE-sync stripping, stripping of the first DLE in DLE-DLE pairs in transparent mode, and control character recognition. Control characters are discussed in Section 26.3.2.2, "UCC BISYNC Control Character Recognition."

When enabled, the receiver enters the hunt mode where the data is shifted into the receiver shift register 1 bit at a time and the contents of the shift register are compared to the contents of DSR[SYN1, SYN2]. If the two are unequal, the next bit is shifted in and the comparison is repeated. When registers match, the hunt mode is terminated and character assembly begins. The controller is character-synchronized and performs SYNC stripping and message reception. It reverts to the hunt mode when it receives an ENTER HUNT MODE command, an error condition, or an appropriate control character.

When receiving data, the controller updates the CR bit in the BD for each byte transferred. When the buffer is full, the controller clears the E bit in the BD and generates an interrupt if the I bit in the BD is set. If incoming data exceeds the buffer length, the controller fetches the next BD; if E is zero, reception continues to its buffer.

When a BCS is received, it is checked and written to the buffer. The BISYNC controller sets the last bit, writes the message status bits into the BD, clears the E bit, and then generates a maskable interrupt; indicating that a block of data was received and is in memory. The BCS calculations do not include SYNCs (in nontransparent mode) or DLE-SYNC pairs (in transparent mode).

26.4.3 UCC BISYNC Commands

Transmit and receive commands are issued to the QUICC Engine module command register (CPCR). Transmit commands are described in Table 26-13.

Table 26-13. Transmit Commands

Command	Description
STOP TRANSMIT	After hardware or software is reset and the channel is enabled in the GUMR, the channel is in transmit enable mode and starts polling the first BD every 64 transmit clocks. This command stops transmission after a maximum of 64 additional bits without waiting for the end of the buffer and the transmit DCS to be flushed. TBPTR is not advanced, no new BD is accessed, and no new buffers are sent for this channel. SYNC-SYNC or DLE-SYNC pairs are sent continually until a RESTART TRANSMIT is issued. A STOP TRANSMIT can be used when an EOT sequence should be sent and transmission should stop. After transmission resumes, the EOT sequence should be the first buffer sent to the controller. Note that the controller remains in transparent or normal mode after it receives a STOP TRANSMIT or RESTART TRANSMIT command.
GRACEFUL STOP TRANSMIT	Stops transmission after the current frame finishes sending or immediately if there is no frame being sent. UCCE[GRA] is set once transmission stops. Then BISYNC transmit parameters and TxBDs can be modified. The TBPTR points to the next TxBD. Transmission resumes when the R bit of the next BD is set and a RESTART TRANSMIT is issued.

Table 26-13. Transmit Commands (continued)

Command	Description
RESTART TRANSMIT	Lets characters be sent on the transmit channel. The BISYNC controller expects it after a STOP TRANSMIT or a GRACEFUL STOP TRANSMIT command is issued, after a transmitter error occurs, or after a STOP TRANSMIT is issued and the channel is disabled in its UCCM. The controller resumes transmission from the current TBPTR in the channel's TxBD table.
INIT TX PARAMETERS	Initializes all transmit parameters in the serial channel's parameter RAM to their reset state. Issue only when the transmitter is disabled. INIT TX AND RX PARAMETERS resets transmit and receive parameters.

Receive commands are described in Table 26-14.

Table 26-14. Receive Commands

Command	Description
RESET BCS CALCULATION	Immediately resets the receive BCS accumulator. It can be used to reset the BCS after recognizing a control character, thus signifying that a new block is beginning.
ENTER HUNT MODE	After hardware or software is reset and the channel is enabled in UCCM, the channel is in receive enable mode and uses the first BD. This command forces the controller to stop receiving and enter hunt mode, during which the controller continually scans the data stream for an SYN1-SYN2 sequence as programmed in the DSR. After receiving the command, the current receive buffer is closed and the BCS is reset. Message reception continues using the next BD.
INIT RX PARAMETERS	Initializes receive parameters in this serial channel's parameter RAM to reset state. Issue only when the receiver is disabled. An INIT TX and RX PARAMETERS resets transmit and receive parameters.

26.4.4 Handling Errors in the UCC BISYNC

The controller reports message transmit and receive errors using the channel BDs, error counters, and the UCCE. Modem lines can be directly monitored via the parallel port pins. Table 26-15 describes transmit errors.

Table 26-15. Transmit Errors

Error	Description
Transmitter underrun	The channel stops sending the buffer, closes it, sets TxBD[UN], and generates a TXE interrupt if it is enabled. The channel resumes transmission after a RESTART TRANSMIT command is received. Underrun cannot occur between frames or during a DLE–*XXX* pair in transparent mode.
$\overline{\text{CTS}}$ lost during message transmission	The channel stops sending the buffer, closes it, sets TxBD[CT], and generates a TXE interrupt if not masked. Transmission resumes when a RESTART TRANSMIT command is received.

Table 26-16 describes receive errors.

Table 26-16. Receive Errors

Error	Description
Overrun	The controller maintains a receiver DCS for receiving data. The QUICC Engine module begins programming the SDMA channel (if the buffer is in external memory) and updating the CRC when the first byte is received in the Rx DCS. If an Rx DCS overrun occurs, the controller writes the received byte over the previously received byte. The previous character and its status bits are lost. The channel then closes the buffer, sets RxBD[OV], and generates the RXB interrupt if it is enabled. Finally, the receiver enters hunt mode.
$\overline{\text{CD}}$ Lost during Message Reception	The channel stops receiving, closes the buffer, sets RxBD[CD], and generates the RXB interrupt if not masked. This error has the highest priority. If the rest of the message is lost, no other errors are checked in the message. The receiver immediately enters hunt mode. When GUMR[SYNL] = 1x (8-bit sync or 16-bit sync), and $\overline{\text{CD}}$ lost during syncs or first data byte, data doesn't transferred to Rx FIFO.
Parity	The channel writes the received character to the buffer and sets RxBD[PR]. The channel stops receiving, closes the buffer, sets RxBD[PR], and generates the RXB interrupt if it is enabled. The channel also increments PAREC and the receiver immediately enters hunt mode.
CRC	The channel updates the CR bit in the BD every time a character is received with a byte delay of eight serial clocks between the status update and the CRC calculation. When control character recognition is used to detect the end of the block and cause CRC checking, the channel closes the buffer, sets the CR bit in the BD, and generates the RXB interrupt if it is enabled.

26.5 Initialization Information

26.5.1 Programming the UCC BISYNC Controller

Software has two ways to handle data received by the BISYNC controller. The simplest is to allocate single-byte receive buffers, request an interrupt on reception of each buffer, and implement BISYNC protocol entirely in software on a byte-by-byte basis. This flexible approach can be adapted to any BISYNC implementation. The obvious penalty is the overhead caused by interrupts on each received character.

A more efficient method is to prepare and link multi-byte buffers in the RxBD table and use software to analyze the first 2 to 3 bytes of the buffer to determine the type of block received. When this is determined, reception continues without further software intervention until it encounters a control character, which signifies the end of the block and causes software to revert to byte-by-byte reception.

To accomplish this, set UCCM[RCH] to enable an interrupt on every received byte so software can analyze each byte. After analyzing the initial characters of a block, either set UPSMR[RTR] or issue a RESET BCS CALCULATION command. For example, if a DLE-STX is received, enter transparent mode. By setting the appropriate UPSMR bit, the controller strips the leading DLE from DLE-character sequences. Thus, control characters are recognized only when they follow a DLE character. UPSMR[RTR] should be cleared after a DLE-ETX is received.

Alternatively, after an SOH is received, a RESET BCS CALCULATION should be issued to exclude SOH from BCS accumulation and reset the BCS. Notice that UPSMR[RBCS] is not needed because the controller automatically excludes SYNCs and leading DLEs.

After the type of block is recognized, UCCE[RCH] should be masked. The CPU does not interrupt data reception until the end of the current block, which is indicated by the reception of a control character matching the one in the receive control character table. Using Table 26-17, the control character table should be set to recognize the end of the block.

Table 26-17. Control Characters

Control Characters	E	B	H
ETX	0	1	1
ITB	0	1	0
ETB	0	1	1
ENQ	0	0	0
Next entry	0	X	X

After ETX, a BCS is expected; then the buffer should be closed. Hunt mode should be entered when a line turnaround occurs. ENQ characters are used to stop sending a block and to designate the end of the block for a receiver, but no CRC is expected. After control character reception, set UCCM[RCH] to reenable interrupts for each byte of data received.

Chapter 27
UCC for Fast Protocols

NOTE

Read Chapter 23, "Unified Communications Controllers (UCCs)," before reading this chapter.

The QUICC Engine block unified communications controller (UCC) implements a wide range of protocols and interfaces that are divided into fast and slow protocols. This chapter provides a general overview of the UCC when used for fast protocols and the common programming model. The fast protocols include ATM over UTOPIA L2, high-speed serials (Ethernet, HDLC, HDLC bus, Transparent), and Ethernet for the first Mile (EFM). Slow protocols (UART and asynchronous HDLC, BISYNC, and QMC) are described in their respective chapters. For a detailed description of the feature set and the protocol-specific programming model, refer to their respective UCC chapter.

UCC key features for fast protocols include the following:

- Supports the following interfaces
  - UTOPIA L2, POS-PHY L2 at 50 MHz (assuming QUICC Engine frequency above 100 MHz[1]).
  - MII/RMII (assuming QUICC Engine frequency above 100 MHz).
  - GMII/RGMII/TBI/RTBI (assuming QUICC Engine frequency above 250 MHz).
  - High speed serial interface[2] with modem control.
  - Serial or nibble-parallel data interface through TDM[3].
- Supports ATM, Ethernet and HDLC protocols. Assuming a 400 -MHz QE clock, the UCC supports the following:
  - Full 10/100 Mbps, full-duplex/half-duplex Ethernet/IEEE 802.3x/VLAN through MII/RMII
  - Full 1000 Mbps, full-duplex Ethernet/IEEE 802.3x/VLAN through GMII/RGMII
  - Full OC-12 rate full-duplex ATM AAL5 segmentation and reassembly (SAR) through UTOPIA L2
  - Up to 70 Mbps HDLC/ HDLC bus and/or totally transparent protocols data rates
- UCC clock can be derived from a baud-rate generator or an external signal.
- Supports $\overline{\text{RTS}}$, $\overline{\text{CTS}}$, and $\overline{\text{CD}}$ modem control signals
- Uses bursts to improve bus usage
- Multibuffer data structure for received and transmit
- Buffers and buffer descriptors (BDs) may reside anywhere in system memory.

1. Note that this is the minimal QE frequency for H/W operation. The actual QE frequency to meet the protocol performance target will be higher.
2. The QE frequency must be higher then the data bit-rate multiplied by 8/3.
3. The QE frequency must be higher then the data bit-rate multiplied by 24 (Rev1.x) or by 16 (Rev2.x).

- Programmable size-virtual FIFO buffers
- Fully transparent option for one half of the UCC (receiver/transmitter) while HDLC/SDLC protocols execute on the other half (transmitter/receiver)
- Echo and local loopback modes for testing
- Routing to any TDM through the TSA in serial or nibble data port size

27.1 Overview

The UCC protocol is chosen by programming the mode bits in the GUMR register (see Section 27.4.2.1, "GUMR in Fast Mode"). For a fast protocol mode such as ATM, Ethernet, HDLC/ HDLC bus or Transparent, the UCC must first be configured to work in the fast mode by configuring GUEMR register.

FCC compatibility is provided for the following protocols:

- HDLC
- Transparent

Subsequent chapters in this book describe extended features. UCC initialization code is slightly different from FCC or SCC code. Differences are emphasized throughout the manual.

NOTE: Backward-Compatibility

The UCC is backward-compatible to the FCC in HDLC or Transparent modes.

In 10/100BaseT Ethernet mode, some of the mode bits in the FCC programming model moved to other registers in the UCC Ethernet Controller (UEC). The data structures (buffer descriptors) are the same as in the MPC8260 FCC (and TSEC). The UCC parameter RAM is very similar to the FCC in Ethernet mode. The manual specifies the differences. In ATM mode, the programming model for configuring the UTOPIA bus interface is described in the UPC chapter.

The UCC block diagram is shown in Figure 27-1.

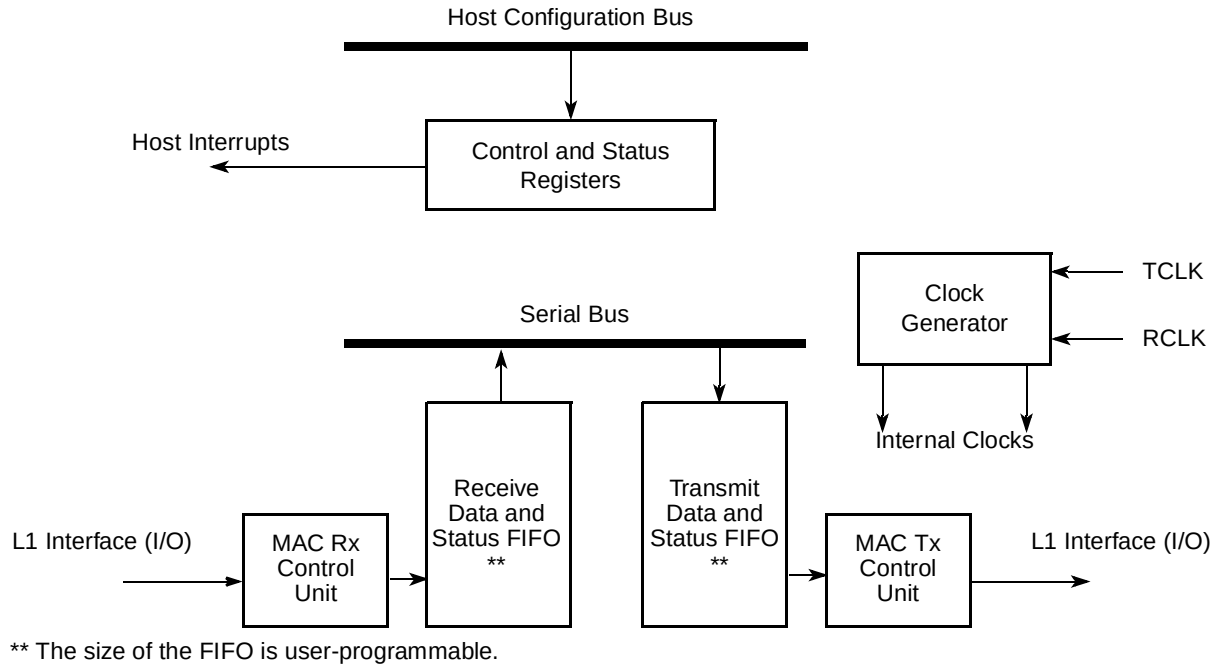

Figure 27-1. UCC Block Diagram

27.2 UCC Virtual FIFOs

NOTE: Backward Compatibility

Users who are familiar with the PowerQUICC II should note the following change in the UCC compared with the FCC.

Fast protocols require larger FIFO depth than slow ones. Sufficient FIFO size is important for increasing the QUICC Engine block's performance by eliminating overrun and underrun conditions. Each protocol has an optimized FIFO size that depends not only on the bit rate, but also on other parameters such as packet or frame size. The UCC, when configured for fast protocols, extends the HW FIFO by using the QUICC Engine block's internal MURAM. This extension is called virtual FIFO or VFIFO, because its size and location within the MURAM are programmable according to the specific protocol. The FIFO as shown in Figure 27-1 is constructed of a real HW FIFO embedded in the UCC and its extension to a virtual FIFOs in the QUICC Engine block's MURAM. This flexible FIFO structure enables the QUICC Engine block to sustain maximum data rates by allocating larger FIFO memory when required.

The size of the virtual FIFO is user-programmable (see Section 27.5, "Fast Protocol FIFO Configuration Registers"). The actual size that is needed depends on a number of factors, especially the following:

- Maximum packet size
- Protocols running on the UCC
- Memory bus latency

27.3 UCC Parameter RAM for Fast Protocols

The QUICC Engine block maintains a section of MURAM called the parameter RAM, which contains many parameters for the operation of the UCCs. UCC base addresses are described in Section 23.3.2, "General UCC Extended Mode Register (GUEMR)."

The UCC Parameter RAM base addresses are programmable using the CECR command register, see Section 20.3.1, "QUICC Engine Command Register (CECR)."

Some parameter RAM values must be initialized before the UCC is enabled. The QUICC Engine block initializes or writes other values. Once initialized, most parameter RAM values need not be accessed by user software, because most activity centers around the TxBDs and RxBDs rather than the parameter RAM. However, if the parameter RAM is accessed, note the following:

- Parameter RAM can be read at any time.
- Tx parameter RAM can be written only when the transmitter is disabled (that is, after a STOP TRANSMIT command and before a RESTART TRANSMIT command or after the buffer/frame finishes transmitting after a GRACEFUL STOP TRANSMIT command and before a RESTART TRANSMIT command).
- Rx parameter RAM can be written only when the receiver is disabled. Note the CLOSE RX BD command does not stop reception, but it does allow the user to extract data from a partially full Rx buffer.

NOTE: Backward-Compatibility

After power-on reset, UCC1–UCC3 are backward-compatible to FCC1–FCC3, and UCC5–UCC8 are backward-compatible to SCC1–SCC4 in their parameter RAM base address.

In the 82xx family of devices, the parameter RAM for each serial controller is located at a fixed address in the internal memory space for the device. In the QUICC Engine architecture there is a default setting for the parameter RAM pages (see Section 23.3.2, "General UCC Extended Mode Register (GUEMR)"), but the user may relocate the pages to allow improved optimization of the memory space.

27.4 Programming Model

The following sections discuss the programming model.

27.4.1 UCC Memory Map for Fast Protocols

Table 27-1. UCC Memory Map (Fast Mode)

Address[1]	Use	Size	Access
0x00	General UCC mode register (GUMR)	4	R/W
0x04	UCC protocol specific mode register (UPSMR)[2, 3]	4	R/W
0x08	UCC transmit on demand register (UTODR)	2	R/W

Table 27-1. UCC Memory Map (Fast Mode) (continued)

Address[1]	Use	Size	Access
0x0C	UCC data synchronization register (UDSR)	2	R/W
0x10	UCC event register (UCCE)	4	R/W
0x14	UCC mask register (UCCM)	4	R/W
0x18	UCC status register (UCCS) [3]	1	R
	Virtual FIFO Registers		
0x20	UCC receive virtual FIFO base (URFB)	4	R/W
0x24	UCC receive virtual FIFO size (URFS)	2	R/W
0x28	UCC receive virtual FIFO emergency threshold (URFET)	2	R/W
0x2A	UCC receive virtual FIFO Special emergency threshold (URFSET)	2	R/W
0x2C	UCC transmit virtual FIFO base (UTFB)	4	R/W
0x30	UCC transmit virtual FIFO size (UTFS)	2	R/W
0x34	UCC transmit virtual FIFO emergency threshold (UTFET)	2	R/W
0x38	UCC transmit virtual FIFO, transmit threshold (UTFTT)	2	R/W
	Timer/Counter Registers		
0x3C	UCC transmit polling timer (UTPT)[4]	2	R/W
0x40	UCC retry counter register (URTRY)	4	R
0x44–0x7F	Reserved	12	
	Extended mode register		
0x90	General UCC extended mode register (GUEMR)	1	R/W
0x94–0xFF	Reserved	12	
0x100–0x1BF	Ethernet MAC specific registers		R/W
0x1C0–0x1FF	Reserved	12	

1 Offset from UCCx base

2 In Ethernet RMII mode include also Loopback and CLK that are configured in the GUMR, see Section 27.4.2.1, “GUMR in Fast Mode.”

3 Protocol specific register, described in the specific protocols’ chapters.

4 See Chapter 23, “Unified Communications Controllers (UCCs).”

27.4.2 UCC Registers in Fast Mode

The following sections discuss UCC registers in fast mode.

27.4.2.1 GUMR in Fast Mode

GUMR configures the protocol and interface of the UCC and is compatible with the PowerQUICC II general FCC mode register (GFMR). The GUMR mode defines the programming model for the UCC and the meaning of the remaining bits of this register. In this chapter the following fast protocols are described:

- HDLC
- Transparent
- Ethernet
- ATM

NOTE: Backward-Compatibility

GUMR[14–15] are modes taken from the PowerQUICC II SCC. For backward-compatibility with the PowerQUICC II FCC, they should be cleared.

Offset UCC base + 0x00 Access: Read/Write

Figure 27-2. General UCC Mode Register (Fast Protocols)

Table 27-2. GUMR (in Fast Mode) Register Field Descriptions

Bits	Name	Description
0–1	DIAG	Diagnostic mode 00 Normal operation—Receive data enters through RXD, and transmit data is shifted out through TXD. The UCC uses the modem signals ($\overline{CD}$ and $\overline{CTS}$) to enable and disable transmission and reception automatically. Timings are shown in Section 23.5.1, "Synchronous Protocols" and in Section 23.5.2, "Asynchronous Protocols". 01 Local loopback mode—The transmitter output is connected internally to the receiver input; the receiver and transmitter operate normally. RXD is ignored. Data can be programmed to appear on TXD, or TXD can remain high by programming the appropriate parallel port register. RTS can be disabled in the appropriate parallel I/O register. In TDM modes, L1TXDx and L1RQx can be programmed either to be asserted normally or to remain inactive by programming the serial interface mode register (SIMODE). The transmitter and receiver must use the same clock source; thus, the same BRG or the same external CLKx signal can be used. Separate CLKx signals can be used as long as they are connected to the same external clock source. **Note:** If external loopback is preferred, DIAG should be set for normal operation and TXD and RXD should be connected externally. Clocks can be generated externally or they can be generated internally by a baud-rate generator. The user can physically connect the appropriate control signals (RTS connected to CD, and CTS grounded), or the parallel port register can be used to cause CD and CTS to be asserted to the UCC permanently. 10 Automatic echo mode—The channel automatically retransmits received data, using the receive clock provided. The receiver operates normally and receives data if CD is asserted. The transmitter simply transmits received data. In this mode, CTS is ignored. The echo function can also be accomplished in software by receiving buffers from a UCC, linking them to TxBDs and transmitting them back out of that UCC. **Note:** For correct ECHO operation the Rx and Tx clocks should be identical. 11 Loopback and echo mode—Loopback and echo operation occur simultaneously. $\overline{CD}$ and $\overline{CTS}$ are ignored. Refer to the loopback bit description for clocking requirements. **Note:** For correct ECHO operation the Rx and Tx clocks should be identical.
2	TCI	Transmit clock invert 0 Normal operation (For Ethernet and ATM the transmitter is triggered by the rising edge of the UCC Tx clock, for HDLC and Transparent the UCC inverts the reference clock so it can clock data out one-half clock earlier). 1 The UCC inverts the internal transmit clock. (For HDLC and Transparent protocols data is clocked out on the rising edge of the UCC Tx clock). **Note:** It is recommended to set TCI when the reference clock frequency is above 20 MHz (also in internal loopback) **Note:** This bit should be cleared if this UCC is used with the TSA. **Note:** TCI does not apply for Ethernet and ATM protocols.
3	TRX	Transparent receiver. The UCCs offer totally transparent operation. However, to increase flexibility, totally transparent operation is configured with the TTX and TRX bits instead of the MODE bits. This mode lets the user implement unique applications such as a UCC transmitter configured to HDLC and a receiver configured to totally transparent operation. To do this, program MODE = HDLC, TTX = 0, and TRX = 1. 0 Normal operation 1 The receiver operates in totally transparent mode, regardless of the protocol selected for the transmitter in the MODE bits. **Note:** If full-duplex, totally transparent operation for a UCC is obtained by setting both TTX and TRX. Attempting to operate a UCC with Ethernet or ATM on its transmitter and transparent operation on its receiver causes erratic behavior. In other words, unless MODE = HDLC, TTX must equal TRX.

Table 27-2. GUMR (in Fast Mode) Register Field Descriptions (continued)

Bits	Name	Description
4	TTX	Transparent transmitter. The QUICC Engine UCCs offer totally transparent operation. However, to increase flexibility, totally transparent operation is configured with the TTX and TRX bits instead of the MODE bits. This mode lets the user implement unique applications, such as configuring a UCC receiver to HDLC and a transmitter to totally transparent operation. To do this, program MODE = HDLC, TTX = 1, and TRX = 0. 0 Normal operation. 1 The transmitter operates in totally transparent mode, regardless of the receiver protocol selected in the MODE bits. **Note:** If full-duplex, totally transparent operation for a UCC is obtained by setting both TTX and TRX. Attempting to operate a UCC with Ethernet or ATM on its transmitter and transparent operation on its receiver causes erratic behavior. In other words, unless MODE = HDLC, TTX must equal TRX.
5	CDP	$\overline{CD}$ pulse (transparent mode only) 0 Normal operation (envelope mode). $\overline{CD}$ should envelope the frame; the negation of $\overline{CD}$ while receiving causes a $\overline{CD}$ lost error. 1 Pulse mode. When $\overline{CD}$ is asserted (high to low transition), synchronization has been achieved, and further transitions of $\overline{CD}$ do not affect reception. **Note:** This bit must be set if this UCC is used with the TSA.
6	CTSP	$\overline{CTS}$ pulse 0 Normal operation (envelope mode). $\overline{CTS}$ should envelope the frame; the negation of $\overline{CTS}$ while transmitting causes a $\overline{CTS}$ lost error. 1 Pulse mode. $\overline{CTS}$ is asserted when synchronization is achieved; further transitions of $\overline{CTS}$ do not affect transmission. **Note:** This bit must be set if this UCC is used with the TSA, except for ISDN D-channel in IDL circuits, for which normal (envelope) mode must be selected. **Note:** This bit must be cleared if this UCC is used in internal loopback.
7	CDS	$\overline{CD}$ sampling 0 The $\overline{CD}$ input is assumed to be asynchronous with the data. The UCC synchronizes it internally before data is received. (This mode is illegal in transparent mode when SYNL = 0b00.) 1 The $\overline{CD}$ input is assumed to be synchronous with the data, giving faster operation. In this mode, $\overline{CD}$ must transition while the receive clock is in the low state. When $\overline{CD}$ goes low, data is received. This mode is useful when connecting CEs in transparent mode since it allows the $\overline{RTS}$ signal of one QUICC Engine block to be connected directly to the $\overline{CD}$ signal of another QUICC Engine block. **Note:** This bit must be set if this UCC is used with the TSA. **Note:** This bit must be set if this UCC is used in internal loopback.
8	CTSS	$\overline{CTS}$ sampling 0 The $\overline{CTS}$ input is assumed to be asynchronous with the data. When it is internally synchronized by the UCC, data is sent after no more than two serial clock delays. 1 The $\overline{CTS}$ input is assumed to be synchronous with the data, giving faster operation. In this mode, $\overline{CTS}$ must transition while the transmit clock is in the low state. As soon as $\overline{CTS}$ is low, data transmission begins. This mode is useful when connecting QUICC Engine block in transparent mode because it allows the $\overline{RTS}$ signal of one QUICC Engine block to be connected directly to the $\overline{CTS}$ signal of another QUICC Engine block. **Note:** This bit must be set if this UCC is used with the TSA.
9–13	—	Reserved. Should be cleared.

Table 27-2. GUMR (in Fast Mode) Register Field Descriptions (continued)

Bits	Name	Description
14	TXSY	Transmitter synchronized to the receiver. Intended for X.21 applications where the transmitted data must begin an exact multiple of 8-bit periods after the received data arrives. 0 No synchronization between receiver and transmitter (default). 1 The transmit bit stream is synchronized to the receiver. Additionally, if RSYN = 1, transmission in totally transparent mode does not occur until the receiver synchronizes with the bit stream and $\overline{CTS}$ is asserted to the UCC. Assuming $\overline{CTS}$ is asserted, transmission begins 8 clocks after the receiver starts receiving data. **Note**: Should be cleared in all protocols except for transparent operation. Can be set only in serial (1 bit data width) interface. **Note**: For backward compatibility with the PowerQUICC II FCC, this bit should be cleared.
15	RSYN	Receive synchronization timing (totally transparent mode only). 0 Normal operation 1 If CDS = 1, $\overline{CD}$ should be asserted on the second bit of the Rx frame rather than on the first. **Note**: Should be cleared in all protocols except for transparent operation. Can be set only in serial (1 bit data width) interface. **Note**: For backward compatibility with the PowerQUICC II FCC, this bit should be cleared. **Note:** This bit must be cleared if this UCC is used in internal loopback.
16–17	SYNL	Sync length (transparent mode only). Determines the operation of a UCC receiver configured for totally transparent operation only. 00 The sync pattern in the UDSR is not used. An external sync signal is used instead ($\overline{CD}$ signal asserted: high to low transition). 01 Automatic sync (assumes always synchronized, ignores $\overline{CD}$ signal). 10 8-bit sync. The receiver synchronizes on an 8-bit sync pattern stored in the UDSR. The negation of $\overline{CD}$ causes CD lost error. Transmitter is not affected from this mode. 11 16-bit sync. The receiver synchronizes on a 16-bit sync pattern stored in the UDSR. The Negation of $\overline{CD}$ causes CD lost error. Transmitter is not affected from this mode.
18	RTSM	RTS mode. 0 Send idles between frames as defined by the protocol. $\overline{RTS}$ is negated between frames (default). 1 Send flags/syncs between frames according to the protocol. $\overline{RTS}$ is asserted whenever the UCC is enabled.
19–20	RENC	Receiver decoding method. The user should set RENC = TENC in most applications. 00 NRZ 01 NRZI (one bit mode HDLC or transparent only) 1x Reserved
21	REVD	Reverse data (valid for a totally transparent channel only) 0 Normal operation 1 The totally transparent channels on this UCC (either the receiver, transmitter, or both, as defined by TTX and TRX) reverse bit order, transmitting the MSB of each octet first.
22–23	TENC	Transmitter encoding method. The user should set TENC = RENC in most applications. 00 NRZ 01 NRZI (one bit mode HDLC or transparent only) 1x Reserved

Table 27-2. GUMR (in Fast Mode) Register Field Descriptions (continued)

Bits	Name	Description
24–25	TCRC	Transparent CRC (totally transparent channel only). Selects the type of frame checking provided on the transparent channels of the UCC (either the receiver, transmitter, or both, as defined by TTX and TRX). This configuration selects a frame check type; the decision to send the frame check is made in the TxBD. Thus, it is not required to send a frame check in transparent mode. If a frame check is not used, the user can ignore any frame check errors generated on the receiver. 00 16-bit CCITT CRC (HDLC). (X16 + X12 + X5 + 1) 01 Reserved 10 32-bit CCITT CRC (Ethernet and HDLC) (X32 + X26 + X23 + X22 + X16 + X12 + X11 + X10 + X8 + X7 + X5 + X4 + X2 + X1 +1) 11 Reserved
26	ENR	Enable receive. Enables the receiver hardware state machine for this UCC. 0 Reset the UCC receiver. The receiver is disabled and any data in the receive FIFO buffer is lost. 1 The receiver is enabled. **Note:** The UCC provides other tools for controlling reception—the enter hunt mode command, close rx bd command, and RxBD[E]. **Note:** When working in Ethernet mode, set the MACCFG1 bit 29 (Enable Receiver) also.
27	ENT	Enable transmit. Enables the transmitter hardware state machine for this UCC. 0 Reset the UCC transmitter. The transmitter is disabled. If ENT is cleared during transmission, the transmitter aborts the current character and TXD returns to idle state. Data in the TxFIFOs is flushed. 1 The transmitter is enabled. **Note:** The UCC provides other tools for controlling transmission besides the ENT bit—the stop transmit, graceful stop. **Note:** When working in Ethernet mode need to Set also MACCFG1 bit 31(Enable Transmitter)
28–31	MODE	Channel protocol mode: 0000 HDLC 0001 Reserved 0010 Reserved (QMC) 0011 Reserved 0100 Reserved (UART) 0101 Reserved 0110 Reserved 0111 Reserved 1000 Reserved (BISYNC) 1001 Reserved 1010 ATM 1011 Reserved 1100 Ethernet 1101 Reserved 1110 1111 Reserved

27.4.3 UCC Transmit Polling Timer (UTPT)

Refer to Section 23.3.3, “UCC Transmit Polling Timer (UTPT).”

27.4.4 UCC Transmit On Demand Register (UTODR)

Refer to Section 23.3.4, “UCC Transmit-On-Demand Register (UTODR).”

27.4.5 UCC Data Synchronization Register (UDSR)

NOTE: Backward-Compatibility

The UDSR is backward-compatible with the FCC FDSR for HDLC and transparent protocols. It is not used for Ethernet protocol in the QUICC Engine block.

Each UCC has a UDSR to specify the pattern used in the frame synchronization procedure of the synchronous protocols. In the totally transparent protocol, the UDSR should be programmed with the preferred SYNC pattern. At reset, UDSR defaults to 0x7E7E (two HDLC flags) and need not be written for HDLC mode. The UDSR contents are always sent lsb first.

Offset UCC base + 0x0C — Access: Read/Write

Figure 27-3. UCC Data Synchronization Register (Fast Protocols)

27.4.6 Bus Mode Registers (RBMR and TBMR)

There are separate bus mode registers for Rx buffers (RBMR) and for Tx buffers (TBMR). On the MPC826x devices, these were called function code registers, RFCR and TFCR. The bus mode registers contain the transaction specification associated with SDMA channel accesses to external memory. Figure 27-4 shows the register format. Boldfaced entries must be initialized by the user.

Offset UCC base + 0x04 (RBMR*x*)
UCC base + 0x05 (TBMR*x*) — Access: Read/Write

	0	1	2	3	4	5	6	7
R W	—		**GBL**	**BO**		**CETM**	**DTB**	**BDB**

Table 27-3 describes RBMR*x*/TBMR*x* fields.

Table 27-3. RBMR*x*/TBMR*x* Field Descriptions

Bits	Name	Description
0–1	—	Reserved, should be cleared.
2	**GBL**	Global. Indicates whether the memory operation should be snooped. 0 Snooping on the Coherent System Bus (CSB) is disabled. 1 Snooping on the Coherent System Bus (CSB) is enabled. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."

Table 27-3. RBMR*x*/TBMR*x* Field Descriptions (continued)

Bits	Name	Description
3–4	**BO**	Byte ordering. Set BO to select the required byte ordering for the buffer. If BO is changed on-the-fly, it takes effect at the beginning of the next frame (Ethernet and transparent) or at the beginning of the next BD. 00,01,11 Reserved modes. 10 Big-endian byte ordering. As data is sent onto the serial line from the data buffer, the MSB of the buffer word contains data to be sent earlier than the LSB of the same buffer word. These bits must be set to 10 value.
5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1and Section 5.4.3.7, “Debug Configuration.”
6	**DTB**	Indicates on what bus the data is located. 0 On the coherent system bus (CSB) 1 On the QUICC Engine secondary bus. The programming of this bit must be consistent with the System Configuration. See Figure 19-11 in System Interface chapter.
7	**BDB**	Indicates on what bus the BDs are located. 0 On the coherent system bus (CSB). 1 On the QUICC Engine secondary bus. The programming of this bit must be consistent with the System Configuration. SeeFigure 19-1 in System Interface chapter.

27.4.7 UCC Event Register (UCCE)

Refer to Section 23.3.5, “UCC Event Register (UCCE),” and to the protocol specific chapters of the user manual.

27.4.8 UCC Mask Register (UCCM)

Refer to Section 23.3.6, “UCC Mask Register (UCCM),” and to the protocol specific chapters of the user manual.

27.4.9 UCC Status Register

Refer to Section 23.3.7, “UCC Status Register,” and to the protocol specific chapters of the user manual.

27.5 Fast Protocol FIFO Configuration Registers

The following sections discuss fast protocol FIFO configuration registers.

27.5.1 Receive Virtual FIFO Base Register (URFB)

URFB configures the receive virtual FIFO base address relative to the multi-user RAM base address.

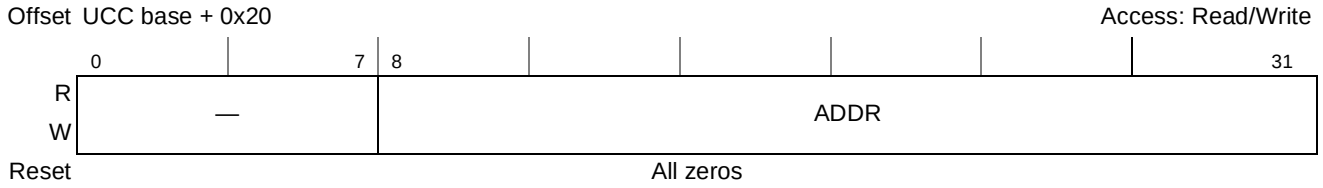

Figure 27-5. Receive Virtual FIFO Base Register (Fast Protocols)

Table 27-4. URFB Register Field Descriptions

Bits	Name	Description
0–7	—	Reserved. Should be cleared by the user.
8–31	ADDR	Receive FIFO base address[1]. Address 0x0 is restricted and can not be used.

1 Address must be aligned to 8 bytes (3 lsb cleared)

27.5.2 Receive Virtual FIFO Size Register (URFS)

URFS configures the receive virtual FIFO size in bytes, allocated to data and status in the multi-user RAM.

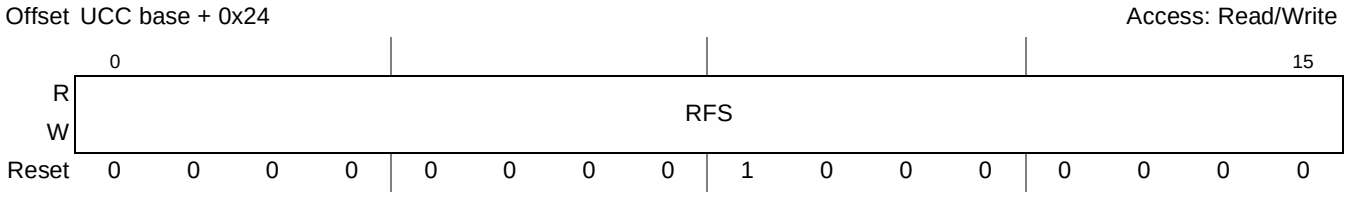

Figure 27-6. Receive Virtual FIFO Size Register (Fast Protocols)

Table 27-5. URFS (in Fast Mode) Register Field Descriptions

Bits	Name	Description
0–15	RFS[1]	Receive virtual FIFO's size (in bytes). The following values are the per-protocol minimum values for RFS: • Gigabit Ethernet 2048 bytes • Fast Ethernet 512 bytes • HDLC/Transparent up to 10Mbps128 bytes • HDLC/Transparent above 10Mbps 256 bytes • ATM OC-12 Rate: 1024 bytes • ATM OC-3 Rate: 256 bytes

1 Size must be aligned to 8 bytes.

NOTE

The register descriptions contain recommended values for the different protocols, assuming the UCC is used in a system where accessing the external memory is the bottleneck of the system. These values may differ if the memory bus is not the bottleneck.

27.5.3 Receive Virtual FIFO Emergency Threshold (URFET)

URFET configures the lower emergency threshold level of the receive virtual FIFO, which is the minimum amount of bytes in virtual FIFO for which RISC requests for data handling get emergency priority.

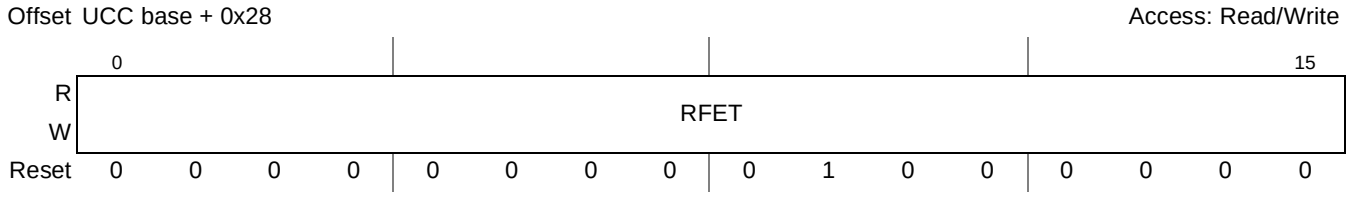

Figure 27-7. Receive Virtual FIFO Emergency Threshold (Fast Protocols)

Table 27-6. URFET (in Fast Mode) Register Field Descriptions

Bits	Name	Description
0–15	RFET[1]	Receive Virtual FIFO Emergency Threshold (in bytes). The recommended value for RFET (for most applications) is 1/2 of the FIFO size. To disable the emergency state, program this threshold to a value which exceeds the FIFOs size.

[1] Must be aligned to 8 bytes.

27.5.4 Receive Virtual FIFO Special Emergency Threshold (URFSET)

URFSET configures the upper threshold level of the receive virtual FIFO. The UCC enters a special emergency state when the virtual FIFO's level exceeds RSFET, and exits this state when the virtual FIFO fill level drops below RFET (the normal emergency threshold programmed in URFET register). In Ethernet protocol, during the special emergency state, the UCC transmits pause flow control frames to the link partner, see Section 30.11.7.6, "AN Advertisement Register (ANA)." In ATM protocol, during the special emergency state the ATM transmitter may pause transmit.

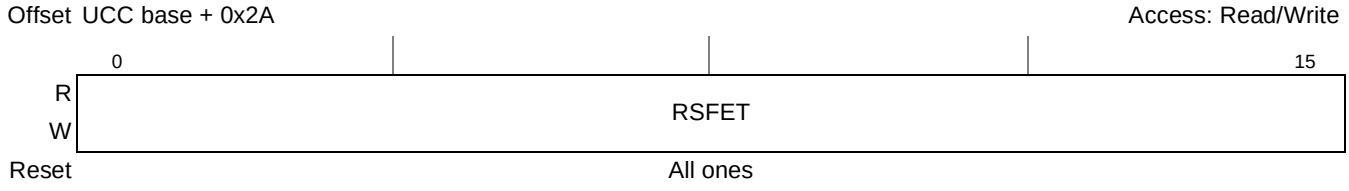

Figure 27-8. Receive Virtual FIFO Special Emergency Threshold (Fast Protocols)

Table 27-7. URFSET (in Fast Mode) Register Field Descriptions

Bits	Name	Description
0–15	RSFET[1]	Receive Virtual FIFO Special Emergency Threshold (in bytes). RSFET should always be larger then RFET. Recommended for use in Gigabit Ethernet and ATM at rates above OC-3. The recommended value for RSFET in order to enable the special emergency state (for most applications) is 3/4 of the FIFO size. To disable the special emergency state, program this threshold to a value which exceeds the FIFOs size (disabled by default at reset).

1 Must be 8 aligned to 8 bytes.

27.5.5 Transmit Virtual FIFO Base Register (UTFB)

UTFB configures the transmit virtual FIFO base address relative to the multiuser RAM base address.

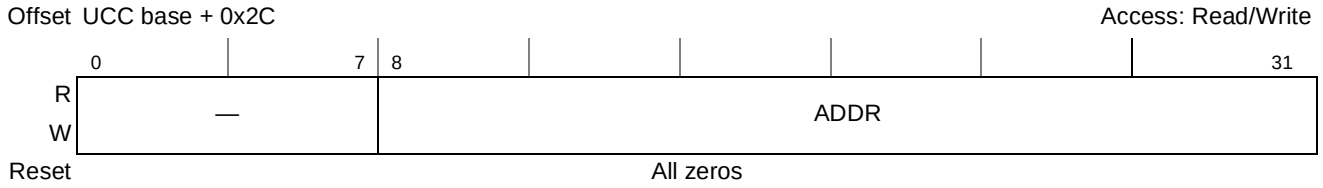

Figure 27-9. Transmit Virtual FIFO Base Register (Fast Protocols))

Table 27-8. UTFB Register Field Descriptions

Bits	Name	Description
0–7	—	Reserved. Should be cleared.
8–31	ADDR	Transmit virtual FIFO base address[1]. Address 0x0 is restricted.

1 Address must be aligned to 8 bytes (3 lsb cleared).

27.5.6 Transmit Virtual FIFO Size Register (UTFS)

NOTE

UTFS configures the transmit virtual FIFO size in bytes, allocated to data and status in the multiuser RAM.

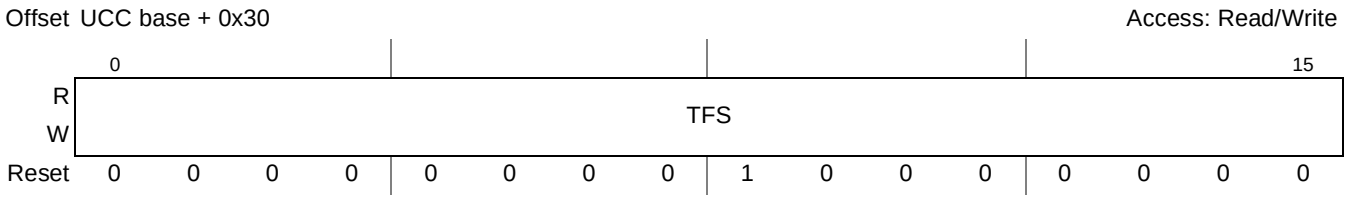

Figure 27-10. Transmit Virtual FIFO Size Register (Fast Protocols)

Table 27-9. UTFS Register Field Descriptions

Bits	Name	Description
0–15	TFS[1]	Transmit Virtual FIFO Size (in Bytes) The following values are the per-protocol minimal values for TFS: • Gigabit Ethernet 2048 bytes • Fast Ethernet 512 bytes • HDLC/Transparent up to 10Mbps128 bytes • HDLC/Transparent up to 10Mbps 256 bytes • ATM OC-12 Rate 1024 bytes • ATM OC-3 Rate 256 bytes

1 Size must be aligned to 8 bytes.

NOTE

The register descriptions contain recommended values for the different protocols, assuming the UCC is used in a system where accessing the external memory is the bottleneck of the system. These values may differ if the memory bus is not the bottleneck.

27.5.7 Transmit Virtual FIFO Emergency Threshold (UTFET)

UTFET configures the threshold level of the transmit emergency state (high priority). When the number of bytes in the virtual FIFO drops below this watermark the UCC transmitter enters emergency state.

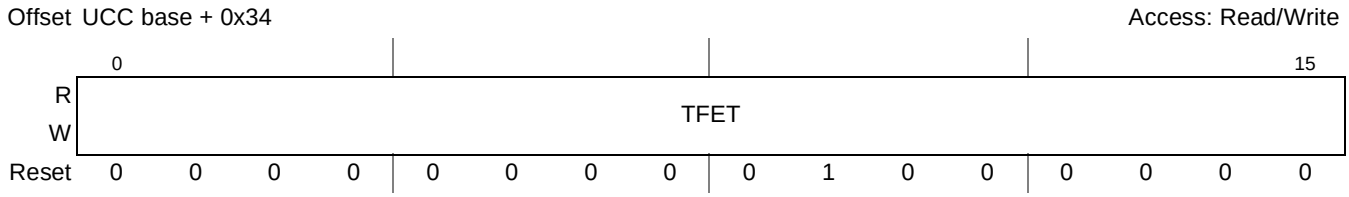

Figure 27-11. Transmit Virtual FIFO Emergency Threshold

Table 27-10. UTFET (in Fast Mode) Register Field Descriptions

Bits	Name	Description
0–15	TFET	Transmit virtual FIFO Emergency Threshold (in bytes). It is recommended to set this value to 1/2 the FIFO size.

27.5.8 Transmit Virtual FIFO Transmit Threshold (UTFTT)

UTFTT configures the threshold level of the transmit virtual FIFO. This threshold represents the amount of bytes that should be in the virtual FIFO before transmission starts (transmission will start before

reaching that watermark if the entire frame is in the virtual FIFO). This a condition is checked for each frame.

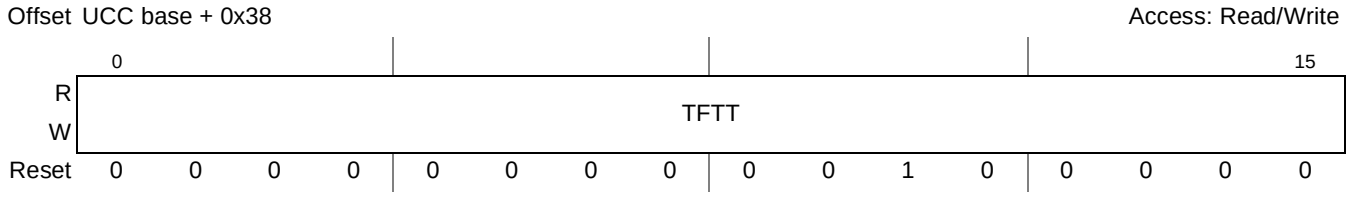

Figure 27-12. Transmit Virtual FIFO Transmit Threshold

Table 27-11. UTFTT (in Fast Mode) Register Field Descriptions

Bits	Name	Description
0–15	TFTT[1]	Transmit virtual FIFO transmit threshold (in bytes). The recommended value (for most applications) is 0x40 bytes, or up to 1/4 of the FIFO size. This threshold represents the amount of bytes that should be in virtual FIFO before transmission starts (transmission will start before reaching that watermark if the entire frame is in the virtual FIFO).

[1] Must be 8 aligned to 8 bytes.

27.5.9 UCC Transmit Retry Counter (URTRY)

URTRY counts the number of retransmission attempts of the UCC. Retransmission can happen for Ethernet half duplex or for HDLC bus protocols. The retry counter is cleared by writing to it (any value).

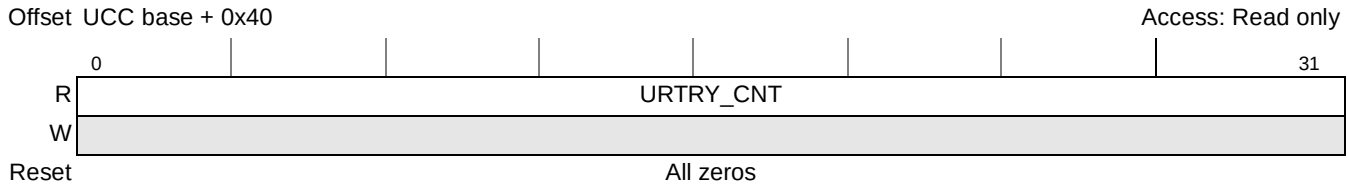

Figure 27-13. DCS Retry Counter Register (URTRY)

Table 27-12. URTRY Register Field Descriptions

Bits	Name	Description
0–31	URTRY_CNT	The number of retransmissions. Read only, cleared by any write to it.

Chapter 28
Transparent Controller

The UCC transparent controller, shown in Figure 28-1, functions as a high-speed serial-to-parallel and parallel-to-serial converter. Transparent mode provides a clear channel on which the UCC performs no bit-level manipulation; implementing higher-level protocols requires software. Transparent mode is also referred to as a totally transparent or promiscuous operation.

Basic applications for a UCC in transparent mode include the following:

- Moving data serially, such as voice, without the need for protocol processing
- For board-level applications, such as chip-to-chip communications, requiring a serial-to-parallel and parallel-to-serial conversion
- For applications requiring the switching of data paths without altering the protocol encoding itself, such as a multiplexer, in which data from a high-speed TDM serial stream is divided into multiple low-speed data streams

A UCC transmitter and receiver can be programmed in transparent mode independently. Setting GUMR*x*[TTx] enables the transparent transmitter; setting GUMR*x*[TRx] enables the transparent receiver. Both bits must be set for full-duplex transparent operation. If only one bit is set, the other half of the UCC operates with the protocol programmed in GUMR*x*[MODE]. This allows loopback modes to transfer data from one memory location to another using DMA, while the data is converted to a specific serial format. Transparent controllers are the only ones that can be split in this way.

The UCC in transparent mode can work with the TSA or NMSI and support modem lines using the general-purpose I/O signals. The data can be transmitted and received with msb or lsb first in each octet. The UCC consists of separate transmit and receive sections whose operations are asynchronous with the core and can either be synchronous or asynchronous with respect to the other UCCs. Each clock can be supplied from the internal BRG bank or provided by external signals.

28.1 Block Diagram

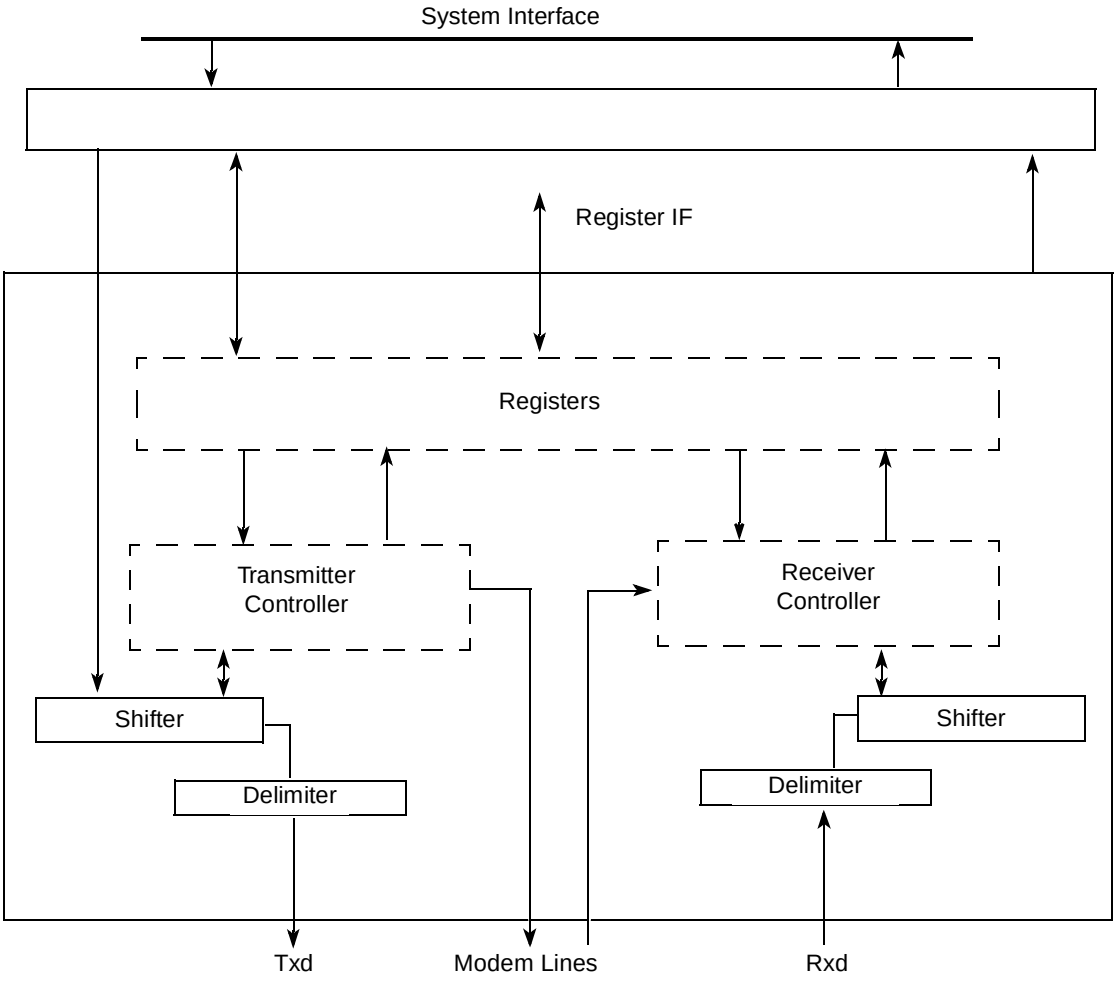

Figure 28-1. Transparent Block Diagram

28.2 Features

The main features of the transparent controller are as follows:

- Flexible data buffers
- Automatic SYNC detection on receive
  - 16-bit pattern
  - 8-bit pattern
  - Automatic sync (always synchronized)
  - External sync signal support
- CRCs can optionally be transmitted and received
- Supports transparent nibble/octal modes (4/8 bits per clocks)
- Reverse data mode

- Another protocol can be performed on the UCC's other half (transmitter or receiver) during transparent mode
- External BD table

28.3 Modes of Operation

The transparent protocol modes of operation are determined by the GUMR register and UPSMR register (1 bit/nibble/octal mode).

28.3.1 Carrier Detection Pulse or Normal mode

Normal operation (GUMR[CDP] = 0)

- The $\overline{CD}$ (carrier detection) signal should envelope the frame. Negation of $\overline{CD}$ during frame receiving causes a receiver error ($\overline{CD}$ lost). When this error occurs the receiver will ignore the remaining current frame and wait for the next valid frame arrival. The receiver will set the RxBD[CD] bit.

Pulse mode (GUMR[CDP] = 1)

- Once $\overline{CD}$ is asserted, synchronization has been achieved. Further transitions of $\overline{CD}$ do not affect reception.

28.3.2 Reverse Data Mode

Normal Operation (GUMR[REVD] = 0)

Reverse data (GUMR[REVD] = 1)

- Reverse data modes supported are 1 bit and nibble.
  - **1 Bit mode**: The totally transparent channels on this UCC reverse the bit order, transmitting the msb of each octet first. This can be programmed to happen on the receiver, transmitter, or both, as defined by TTX and TRX.
  - **Nibble mode**: The totally transparent channels on this UCC reverse the nibble order, transmitting the 4 msb's of each octet first. This can be programmed to happen on the receiver, transmitter, or both, as defined by TTX and TRX.

28.3.3 Synchronization Pattern Modes

Determines the operation of a UCC receiver configured for totally transparent operation only.

- GUMR[SYNL] = 00

  The sync pattern in the UDSR is not used. An external sync signal is used instead ($\overline{CD}$ signal asserted: high to low transition).
- GUMR[SYNL] = 01

  Automatic sync (assumes always synchronized, ignores $\overline{CD}$ signal).

  GUMR[SYNL] = 10

8-bit sync. The receiver synchronizes on an 8-bit sync pattern stored in the UDSR. Negation of $\overline{CD}$ causes $\overline{CD}$ lost error.

- GUMR[SYNL] = 11

  16-bit sync. The receiver synchronizes on a 16-bit sync pattern stored in the UDSR. Negation of $\overline{CD}$ causes $\overline{CD}$ lost error.

28.4 Memory Map/Register Definition

28.4.1 Overview

Table 28-1. UCC Transparent Register Summary

Offset[1]	Register	Access	Reset Value	Section/Page
0x0	General UCC Mode Register (GUMR)	R/W		27.4.2.1/27-6
0x4	UCC Transparent Mode Register (UPSMR)	R/W	0	28.4.2.2/28-6
0x8	Transmit On Demand Register (UTODR)	R/W		23.3.4/23-7
0xC	UCC Data Synchronization Register (UDSR)	R/W		27.4.5/27-11
0x10	UCC Transparent Event Register (UCCE)[2]	R/W	0	28.4.2.5/28-10
0x14	UCC Transparent Mask Register (UCCM)	R/W	0	28.4.2.5/28-10

1 From UCC Base.

2 Set by QUICC Engine module, cleared by host.

28.4.2 Register Descriptions

28.4.2.1 UCC Transparent Parameter RAM

When a UCC operates in transparent mode, the protocol area of the UCC parameter RAM is mapped with the transparent parameters in Table 28-2.

Table 28-2. UCC Transparent Parameter RAM Memory Map

Offset[1]	Name	Width	Description
0x00	**RIPTR**	Hword	Receive internal temporary data pointer. Used by microcode as a temporary buffer for data. Must be 32-byte aligned and the size of the internal buffer must be 32 bytes unless it is stated otherwise in the protocol specification.
0x02	**TIPTR**	Hword	Transmit internal temporary data pointer. Used by microcode as a temporary buffer for data. Must be 32-byte aligned and the size of the internal buffer must be 32 bytes unless it is stated otherwise in the protocol specification.
0x04	—	Hword	Reserved, should be cleared.

Table 28-2. UCC Transparent Parameter RAM Memory Map (continued)

Offset[1]	Name	Width	Description
0x06	**MRBLR**	Hword	Maximum receive buffer length (a multiple of 32 for all modes). The number of bytes that the UCC receiver writes to a receive buffer before moving to the next buffer. The receiver can write fewer bytes to the buffer than MRBLR if a condition such as an error or end-of-frame occurs, but it never exceeds the MRBLR value. Therefore, user-supplied buffers should be at least as large as the MRBLR. Note that UCC transmit buffers can have varying lengths by programming TxBD[Data Length], as needed, and are not affected by the value in MRBLR. MRBLR is not intended to be changed dynamically while an UCC is operating. Change MRBLR only when the UCC receiver is disabled.
0x08	**RSTATE**	Word	Receive internal state. The high byte, RSTATE[0–7], contains the bus mode register, see Section 27.4.6, “Bus Mode Registers (RBMR and TBMR).” RSTATE[8–31] is used by the QUICC Engine module and must be cleared initially.
0x0C	**RBASE**	Word	RxBD base address (must be divisible by eight). Defines the starting location in the memory map for the UCC RxBDs. This provides great flexibility in how UCC RxBDs are partitioned. By selecting RBASE entries for all UCCs and by setting the W bit in the last BD in each BD table, the user can select how many BDs to allocate for the receive side of every UCC. The user must initialize RBASE before enabling the corresponding channel. Furthermore, the user should not configure BD tables of two enabled UCCs to overlap or erratic operation occurs.
0x10	RBDSTAT	Hword	RxBD status and control. Reserved for QUICC Engine module use only.
0x12	RBDLEN	Hword	RxBD data length. A down-count value initialized by the QUICC Engine module with MRBLR and decremented with every byte written by the SDMA channels.
0x14	RDPTR	Word	RxBD data pointer. Updated by the SDMA channels to show the next address in the buffer to be accessed.
0x18	**TSTATE**	Word	Tx internal state. The high byte, TSTATE[0–7], contains the bus mode register, see Section 27.4.6, “Bus Mode Registers (RBMR and TBMR).” TSTATE[8–31] is used by the QUICC Engine module and must be cleared initially.
0x1C	**TBASE**	Word	TxBD base address (must be divisible by eight). Defines the starting location in the memory map for the UCC TxBDs. This provides great flexibility in how UCC TxBDs are partitioned. By selecting TBASE entries for all UCCs and by setting the W bit in the last BD in each BD table, the user can select how many BDs to allocate for the transmit side of every UCC. The user must initialize TBASE before enabling the corresponding channel. Furthermore, the user should not configure BD tables of two enabled UCCs to overlap or erratic operation occurs.
0x20	TBDSTAT	Hword	TxBD status and control. Reserved for QUICC Engine module use only.
0x22	TBDLEN	Hword	TxBD data length. A down-count value initialized with the TxBD data length and decremented with every byte read by the SDMA channels.
0x24	TDPTR	Word	TxBD data pointer. Updated by the SDMA channels to show the next address in the buffer to be accessed.
0x28	RBPTR	Word	RxBD pointer. Points to the next BD that the receiver transfers data to when it is in idle state or to the current BD during frame processing. After a reset or when the end of the BD table is reached, the QUICC Engine module sets RBPTR = RBASE. Although the user need never write to RBPTR in most applications, the user can modify it when the receiver is disabled or when no receive buffer is in use.

Table 28-2. UCC Transparent Parameter RAM Memory Map (continued)

Offset[1]	Name	Width	Description
0x2C	TBPTR	Word	TxBD pointer. Points either to the next BD that the transmitter transfers data from when it is in idle state or to the current BD during frame transmission. After a reset or when the end of the BD table is reached, the QUICC Engine module sets TBPTR = TBASE. Although the user need never write to TBPTR in most applications, the user can modify it when the transmitter is disabled or when no transmit buffer is in use (after a STOP TRANSMIT or GRACEFUL STOP TRANSMIT command is issued and the frame completes transmission).
0x30	RCRC	Word	Temporary receive CRC
0x34	—	Word	Reserved
0x38	TCRC	Word	Temporary transmit CRC
0x3C	—	2 Words	Reserved
0x44	**C_MASK**	Word	CRC constant. For the 16-bit CRC-CCITT, initialize C_MASK to 0x0000_F0B8. For the 32-bit CRC-CCITT, initialize C_MASK to 0xDEBB_20E3.
0x48	**C_PRES**	Word	CRC preset. For the 16-bit CRC-CCITT, initialize C_PRES to 0x0000_FFFF. For the 32-bit CRC-CCITT, initialize C_PRES to 0xFFFF_FFFF.
0x4C	**DISFC**[2]	Hword	Discard frame counter. Counts error-free frames discarded due to lack of buffers.
0x4E	**CRCEC**[2]	Hword	CRC error counter. Counts frames not addressed to the user or frames received in the BSY condition, but does not include overrun, $\overline{CD}$ lost, or abort errors.
0x58	—	4 words	Reserved, should be cleared.
0x68	TS_TMP	Hword	Temporary storage
0x6A	TMP_MB	Hword	Temporary storage

1 From UCC*x* page base address

2 DISFC and CRCEC—These 16-bit (modulo 216) counters are maintained by the QUICC Engine module. The user should initialize them while the channel is disabled.

28.4.2.2 UCC Transparent Mode Register (UPSMR)

UPSMR is shown in Figure 28-2. When a UCC is configured for HDLC and transparent, the UPSMR is used as the HDLC mode register, shown in Section 29.2.2.2, “HDLC Mode Register (UPSMR).”

Figure 28-2. UCC Transparent Mode Register (UPSMR)

The UPSMR fields are described in Table 28-3.

Table 28-3. UPSMR Field Descriptions

Bits	Name	Description
0–14	—	Reserved, should be cleared.
15–16	NBO	Mode of operation 00 normal mode (1 bit of data per clock). 01 nibble mode (4 bits of data per clock). 10 octal mode (8 bits of data per clock). 11 Reserved
17–31	—	Reserved, should be cleared.

28.4.2.3 UCC Transparent Receive Buffer Descriptor (RxBD)

Figure 28-3 shows the UCC Transparent RxBD.

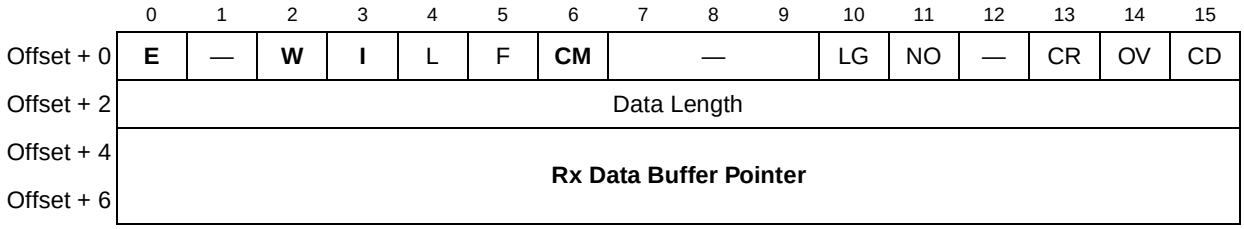

Figure 28-3. UCC Transparent Receive Buffer Descriptor (RxBD)

Table 28-4 describes RxBD fields.

Table 28-4. UCC Transparent RxBD Field Descriptions

Bits	Name	Description
0	**E**	Empty 0 The buffer is full of received data or data reception stopped because of an error. The core can read or write to any fields of this RxBD. The CP does not use this BD while E = 0. 1 The buffer associated with this BD is empty. This RxBD and its associated receive buffer are owned by the CP. Once E is set, the core should not write any fields of this RxBD.
1	—	Reserved, should be cleared.
2	**W**	Wrap (final BD in table) 0 Not the last BD in the RxBD table. 1 Last BD in the RxBD table. After this buffer is used, the CP receives incoming data into the first BD that RBASE points to in the table. The number of RxBDs in this table is programmable and is determined only by the W bit and the overall space constraints of the multi-user RAM. The RxBD table must contain more than one BD in transparent mode.
3	**I**	Interrupt 0 The RXB bit is not set after this buffer is used, but RXF operation remains unaffected. 1 UCCE[RXB] or UCCE[RXF] is set when the transparent controller uses this buffer. These two bits can cause interrupts if they are enabled.

Table 28-4. UCC Transparent RxBD Field Descriptions (continued)

Bits	Name	Description
4	L	Last in frame. Set by the transparent controller when this buffer is the last one in a frame. This implies the reception of a closing flag or reception of an error, in which case one or more of the CD, OV, and/or LG bits are set. The transparent controller writes the number of frame octets to the data length field. 0 Not the last buffer in a frame. 1 Last buffer in a frame.
5	F	First in frame. Set by the transparent controller when this buffer is the first in a frame. 0 Not the first buffer in a frame. 1 First buffer in a frame.
6	**CM**	Continuous mode 0 Normal operation. 1 The E bit is not cleared by the CP after this BD is closed, allowing the associated data buffer to be automatically overwritten the next time the CP accesses this BD. However, the E bit is cleared if an error occurs during reception, regardless of the CM bit.
7–10	—	Reserved, should be cleared.
11	NO	Rx nonoctet-aligned frame. Set when a received frame contains a number of bits not divisible by eight.
12	—	Reserved, should be cleared.
13	CR	Rx CRC error. This frame contains a CRC error. Received CRC bytes are written to the receive buffer.
14	OV	Overrun. Set when a receiver overrun occurs during frame reception.
15	CD	Carrier detect lost. $\overline{CD}$ has negated during frame reception. This bit is valid only for NMSI mode.

The RxBD status bits are written by the transparent controller after receiving the associated data buffer.

28.4.2.4 Transparent Transmit Buffer Descriptor (TxBD)

Data is presented to the transparent controller for transmission on a UCC channel by arranging it in buffers referenced by the channel TxBD table. The transparent controller confirms transmission (or indicates errors) using the BDs to inform the core that the buffers have been serviced. Figure 28-4 shows the UCC Transparent TxBD.

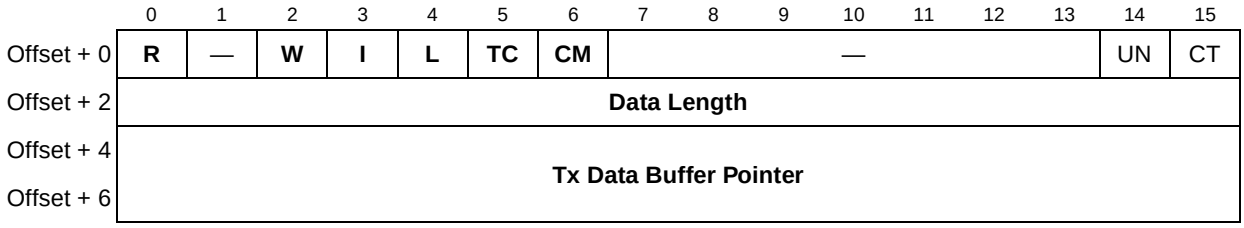

Figure 28-4. UCC Transparent Transmit Buffer Descriptor (TxBD)

Table 28-5 describes Transparent TxBD fields.

Table 28-5. Transparent TxBD Field Descriptions

Bits	Name	Description
0	**R**	Ready 0 The buffer associated with this BD is not ready for transmission. The user can manipulate this BD or its associated buffer. The CP clears R after the buffer has been sent or an error occurs. 1 The buffer is ready to be sent. The transmission may have begun, but it has not completed. The user cannot set fields in this BD once R is set.
1	—	Reserved, should be cleared.
2	**W**	Wrap (final BD in table) 0 Not the last BD in the TxBD table. 1 Last BD in the TxBD table. After this buffer has been used, the CP sends data from the first BD that TBASE points to in the table. The number of TxBDs in this table is determined only by the W bit and the overall space constraints of the multi-user RAM.
3	**I**	Interrupt 0 No interrupt is generated after this buffer is serviced. 1 Either UCCE[TXB] or UCCE[TXE] is set when this buffer is serviced by the transparent controller. These bits can cause interrupts if they are enabled.
4	**L**	Last 0 Not the last buffer in the frame. 1 Last buffer in the current frame.
5	**TC**	Tx CRC.Valid only when the L bit is set. Otherwise, it is ignored. 0 Transmit the closing flag after the last data byte. This setting can be used to send a bad CRC after the data for testing purposes. 1 Transmit the CRC sequence after the last data byte.
6	**CM**	Continuous mode 0 Normal operation. 1 The R bit is not cleared by the CP after this BD is closed, allowing the buffer to be retransmitted automatically the next time the CP accesses this BD. However, the R bit is cleared if an error occurs during transmission, regardless of the CM bit.
7–13	—	Reserved, should be cleared.
14	UN	Underrun. The transparent controller encounters a transmitter underrun condition while sending the buffer. The transparent controller writes UN after sending the buffer.
15	CT	$\overline{\text{CTS}}$ lost. Set when $\overline{\text{CTS}}$ is lost during frame transmission in NMSI mode. If data from more than one buffer is in the FIFO buffer when this error occurs, CT is set in the currently open TxBD. The transparent controller writes CT after sending the buffer.

The TxBD status bits are written by the transparent controller after sending the associated data buffer.

The remaining TxBD parameters are as follows:

- Data length is the number of bytes the transparent controller should transmit from this data buffer; it is never modified by the RISC. The value of this field should be greater than zero.
- Tx data buffer pointer. The transmit buffer pointer, which contains the address of the associated data buffer, can be even or odd. The buffer can reside in internal or external memory. This value is never modified by the RISC.

28.4.2.5 UCC Transparent Event Register (UCCE)/Mask Register (UCCM)

UCCE reports events recognized by the transparent channel and generates interrupts. On recognition of an event, the transparent controller sets the corresponding UCCE bit. UCCE bits are cleared by writing ones; writing zeros does not affect bit values. All unmasked bits must be cleared before the RISC clears the internal interrupt request. Interrupts generated by the UCCE can be masked in the UCCM, which has the same bit format as UCCE. If a UCCM bit = 1, the corresponding interrupt in the event register is enabled. If the bit is 0, the interrupt is masked. Figure 28-7 represents the UCCE/UCCM.

Address: UCC_base + 0x10 (UCCE), UCC_base + 0x14 (UCCM) Access: User Read/Write

	0–7	8	9–10	11	12	13	14	15
R/W	—	GRA	—	TXE	RXF	BSY	TXB	RXB
Reset	All zeros							

Figure 28-5. UCC Transparent Mode Register (UPSMR)

Table 28-6 describes UCCE/UCCM fields.

Table 28-6. Transparent UCCE/UCCM Field Descriptions

Bits	Name	Description
0–7	—	Reserved, should be cleared.
8	GRA	Graceful stop complete. A graceful stop, which was initiated by the GRACEFUL STOP TRANSMIT command, is now complete. GRA is set as soon as the transmitter finishes transmitting any frame that is in progress when the command was issued. It is set immediately if no frame is in progress when the command is issued.
9–10	—	Reserved, should be cleared.
11	TXE	Tx error. An error ($\overline{\text{CTS}}$ lost or underrun) occurs on the transmitter channel.
12	RXF	Rx frame. A complete frame is received on the Transparent channel. This bit is set no sooner than two clocks after receipt of the last bit of the closing flag.
13	BSY	Busy condition. A frame is received and discarded due to a lack of buffers.
14	TXB	Transmit buffer. Enabled by setting TxBD[I]. A buffer is sent on the Transparent channel. TXB is set no sooner than when the last bit of the closing flag begins its transmission if the buffer is the last one in the frame. Otherwise, TXB is set after the last byte of the buffer is written to the transmit FIFO buffer.
15	RXB	Receive buffer. Enabled by setting RxBD[I]. RXB is set when a buffer is filled, even if the buffer is the last in a frame.
16–31	—	Reserved, should be cleared.

28.4.2.6 UCC Transparent Commands

The following transmit and receive commands are issued to the RISC command register. Table 28-7 describes the transmit commands.

Table 28-7. Transmit Commands

Command	Description
STOP TRANSMIT	After hardware or software is reset and the channel is enabled in the GUMR, the channel is in transmit enable mode and starts polling the first BD every 64 clocks (or immediately if TODR[TOD] = 1). STOP TRANSMIT disables frame transmission on the transmit channel. If the transparent controller receives the command during frame transmission, transmission is aborted after a maximum of 64 additional bits and the transmit FIFO is flushed. The current TxBD pointer (TBPTR) is not advanced, no new BD is accessed and no new buffers are sent for this channel. The transmitter will send idles.
GRACEFUL STOP TRANSMIT	Stops transmission smoothly, rather than abruptly, in much the same way that the regular STOP TRANSMIT command functions. It stops transmission after the current frame finishes or immediately if no frame is being sent. A transparent frame is not complete until a BD with TxBD[L] set has its buffer completely sent. UCCE[GRA] is set once transmission stops. Transmit parameters and their BDs can then be modified. The current TxBD pointer (TBPTR) advances to the next TxBD in the table. Transmission resumes once TxBD[R] is set and a RESTART TRANSMIT command is issued.
RESTART TRANSMIT	Re-enables transmission of characters on the transmit channel. The transparent controller expects this after a STOP TRANSMIT command is issued at which point the channel is disabled in UCCM, or after a GRACEFUL STOP TRANSMIT command is issued, or after a transmitter error. The transparent controller resumes transmission from the current TBPTR in the channel TxBD table.
INIT TX PARAMETERS	Initializes all transmit parameters in the serial channel parameter RAM to the reset state. It should be issued only when the transmitter is disabled. INIT TX AND RX PARAMETERS resets receive and transmit parameters.

Table 28-8 describes receive commands.

Table 28-8. Receive Commands

Command	Description
ENTER HUNT MODE	After the hardware or software is reset and the channel is enabled in the UCC mode register, the channel is in receive enable mode and uses the first BD in the table. The ENTER HUNT MODE command is generally used to force the Transparent receiver to abort reception of the current frame and enter the hunt mode. In hunt mode, the Transparent controller continually scans the input data stream for the sync sequence. After receiving the command, the current receive buffer is closed, the error status flags and length field are cleared, RxBD[E] (the empty bit) is set, and the CRC calculation is reset. Further frame reception uses the current RxBD.
INIT RX PARAMETERS	Initializes all receive parameters in this serial channel parameter RAM to reset state. Issue only when the receiver is disabled. INIT TX AND RX PARAMETERS resets receive and transmit parameters.

28.4.2.7 Handling Errors in the Transparent Controller

The UCC reports message reception and transmission errors using the channel buffer descriptors, the error counters, and UCC Transparent Event Register (UCCE). Table 28-9 describes transmit errors.

Table 28-9. Transparent Transmission Errors

Error	Description
Transmitter Underrun	When this occurs, the channel stops sending the buffer, closes it, sets TxBD[UN], and generates a TXE interrupt if it is enabled. Transmission resumes after a RESTART TRANSMIT command is received. Underrun occurs after a transmit frame for which TxBD[L] was not set. In this case, only UCCE[TXE] is set. Underrun cannot occur between transparent frames.
$\overline{\text{CTS}}$ Lost During Frame Transmission	When this occurs, the channel stops sending the buffer, closes it, sets TxBD[CT], and generates the TXE interrupt if it is enabled. The channel resumes sending after RESTART TRANSMIT is received.

Table 28-10 describes receive errors.

Table 28-10. Transparent Reception Errors

Error	Description
Overrun Error	The transparent controller maintains an internal FIFO buffer for receiving data. The RISC begins programming the SDMA channel and updating the CRC whenever data is received in the FIFO buffer. When a receive FIFO overrun occurs, the channel writes the received data byte to the internal FIFO buffer over the previously received byte. The previous byte and the frame status are lost. The channel closes the buffer with RxBD[OV] set and generates the RXF interrupt if it is enabled. The receiver then enters hunt mode. Even if the overrun occurs during a frame whose address is not matched in the address recognition logic, an RxBD with data length two is opened to report the overrun and the RXF interrupt is generated if it is enabled.
$\overline{\text{CD}}$ Lost During Frame Reception	When this error occurs, the channel terminates frame reception, closes the buffer, sets RxBD[CD], and generates the RXF interrupt if it is enabled. This error has highest priority. The rest of the frame is lost and other errors are not checked in that frame. At this point, the receiver enters hunt mode. When GUMR[SYNL] = 1x (8-bit sync or 16-bit sync) and $\overline{\text{CD}}$ is lost during syncs or during first data byte, data does not transfer to the Rx FIFO.
Nonoctet Aligned Frame	When this error occurs, the channel writes the received data to the data buffer, closes the buffer, sets the Rx nonoctet aligned frame bit RxBD[NO], and generates the RXF interrupt (if it is enabled). The CRC error status should be disregarded on nonoctet frames. After a nonoctet aligned frame is received, the receiver enters hunt mode. An immediate back-to-back frame is still received. The nonoctet data portion may be derived from the last byte in the buffer by finding the least-significant set bit, which marks the end of valid data as follows:
CRC Error	When this error occurs, the channel writes the received CRC to the data buffer, closes the buffer, sets RxBD[CR], and generates the RXF interrupt (if it is enabled). The channel also increments the CRC error counter. After receiving a frame with a CRC error, the receiver enters hunt mode. An immediate back-to-back frame is still received. CRC checking cannot be disabled, but the CRC error can be ignored if checking is not required.

28.5 Functional Description

28.5.1 UCC Transparent Channel Frame Transmission Process

The transparent transmitter is designed to work with almost no intervention from the core. When the core enables the UCC transmitter in transparent mode, it starts sending idles, which are logic high or encoded ones, as programmed in GUMR[TEND]. The UCC polls the first BD in the TxBD table. When there is a message to send, the UCC fetches data from memory, loads the transmit FIFO, and waits for transmitter synchronization, which is achieved with $\overline{\text{CTS}}$ before the transmitter begins sending (see Section 28.5.3, "Achieving Synchronization in Transparent Mode"), or by waiting for the receiver to achieve synchronization, depending on GUMR[TXSY]. Transmission begins when transmitter synchronization is achieved.

When all BD data has been sent, if TxBD[L] is set, the UCC writes the message status bits into the BD, clears TxBD[R], and sends idles until the next BD is ready. If it is ready, some idles are still sent. The transmitter resumes sending only after it achieves synchronization.

If TxBD[L] is cleared when the end of the BD is reached, only TxBD[R] is cleared and the transmitter moves immediately to the next buffer to begin transmission with no gap on the serial line between buffers. Failure to provide the next buffer in time causes a transmit underrun which sets UCCE[TXE].

In both cases, an interrupt is issued according to TxBD[I]. By appropriately setting TxBD[I] in each BD, interrupts are generated after each buffer or group of buffers is sent. The UCC then proceeds to the next BD in the table and any whole number of bytes can be sent. If GUMR[REVD] is set, the bit order of each byte is reversed before being sent, the msb of each octet is sent first.

An optional CRC, selected in GUMR[TCRC], can be appended to each transparent frame if it is enabled in the TxBD.

When the time-slot assigner (TSA) is used with a transparent-mode channel, synchronization is provided by the TSA. There is a start-up delay for the transmitter, but delays will always be some whole number of complete TSA frames. This means that *n*-byte transmit buffers can be mapped directly into *n*-byte time slots in the TSA frames.

28.5.2 UCC Transparent Channel Frame Reception Process

When the core enables the UCC receiver in transparent mode, it waits to achieve synchronization before data is received. The receiver can be synchronized to the data by a synchronization pulse or SYNC pattern.

After a buffer is full, the UCC clears RxBD[E] and generates a maskable interrupt if RxBD[I] is set. It moves to the next RxBD in the table and begins moving data to its buffer. If the next buffer is not available, UCCE[BSY] signifies a busy signal that can generate a maskable interrupt. The receiver reverts to hunt mode when an ENTER HUNT MODE command or an error is received. If GUMR[REVD] is set, the bit order of each byte is reversed before it is written to memory.

The receiver always checks the CRC of the received frame, according to GUMR[TCRC]. If a CRC is not required, resulting errors can be ignored.

28.5.3 Achieving Synchronization in Transparent Mode

Once the UCC transmitter is enabled for transparent operation in the GUMR, the TxBD is prepared for the UCC, and the transmit FIFO is preloaded by the SDMA channel. Transmit synchronization must be established before data can be sent.

Similarly, once the UCC receiver is enabled for transparent operation in the GUMR and the RxBD is made empty for the UCC, receive synchronization must occur before data can be received. The synchronization process gives the user bit-level control of when the transmission and reception begins. The methods for this are as follows:

- An in-line synchronization pattern
- External synchronization signals
- Automatic sync

28.5.3.1 Synchronization in NMSI Mode

This section describes synchronization in NMSI mode.

28.5.3.1.1 In-Line Synchronization Pattern

The transparent channel can be programmed to transmit and receive a synchronization pattern if GUMR[SYNL] ≠ 0; see Section 27.4.2.1, “GUMR in Fast Mode.” The pattern is defined in the UDSR; see Section 27.4.5, “UCC Data Synchronization Register (UDSR).” GUMR[SYNL] defines the SYNC pattern length. The synchronization pattern is shown in Figure 28-6.

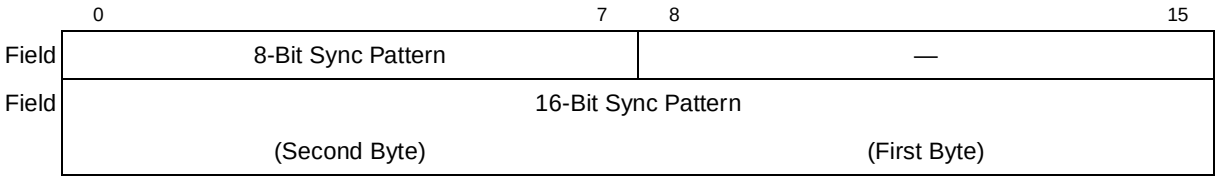

Figure 28-6. In-Line Synchronization Pattern

The receiver synchronizes on the synchronization pattern located in the UDSR. For instance, if an 8-bit SYNC is selected, reception begins as soon as these eight bits are received, beginning with the first bit following the 8-bit SYNC. This effectively links the transmitter synchronization to the receiver synchronization.

NOTE

The transparent controller does not automatically send the synchronization pattern; therefore, the synchronization pattern must be included in the transmit buffer.

28.5.3.1.2 External Synchronization Signals

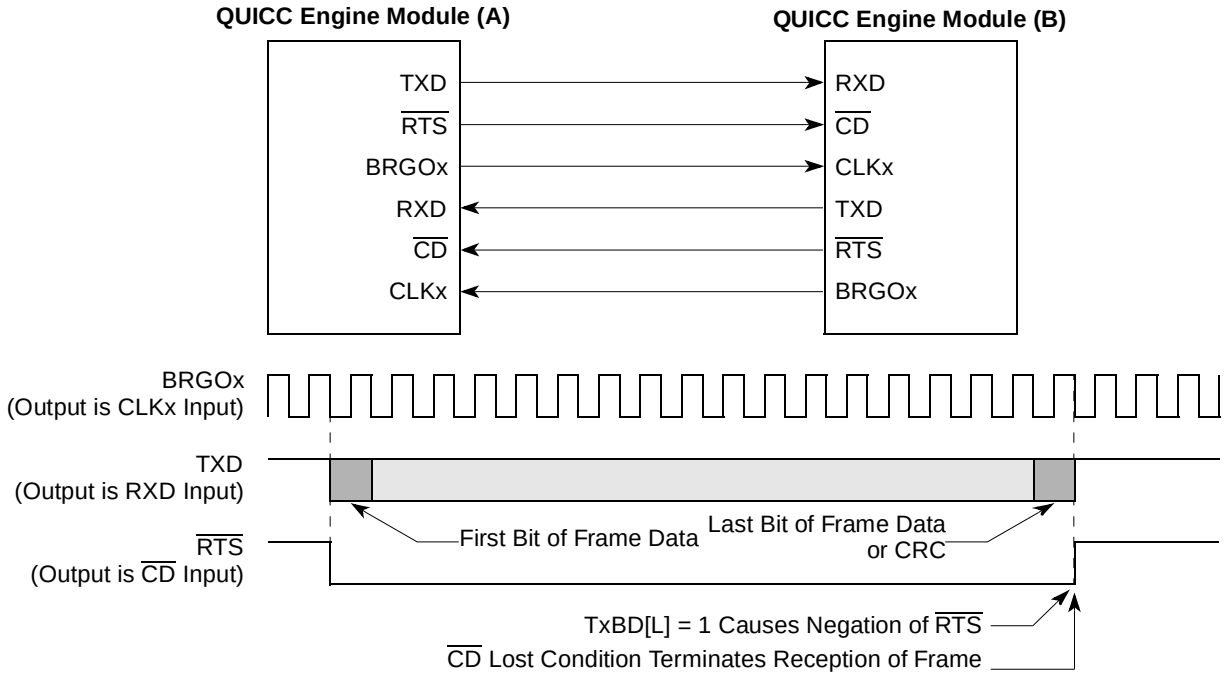
If GUMR[SYNL] = 00, an external signal is used to begin the sequence. $\overline{\text{CTS}}$ is used for the transmitter and $\overline{\text{CD}}$ is used for the receiver; these signals share the following sampling options.

- The pulse/envelope option determines whether $\overline{\text{CD}}$ or $\overline{\text{CTS}}$ needs to be asserted only once to begin reception/transmission or whether they must be asserted and stay that way for the duration of the transparent frame. This option is controlled by the CDP and CTSP bits of the GUMR. If the user expects a continuous stream of data without interruption, the pulse option should be used. However, if the user needs to identify frames of transparent data, the envelope mode of the these signals should be used.
- The sampling option determines the delay between $\overline{\text{CD}}$ and $\overline{\text{CTS}}$ being asserted and the resulting action by the UCC. These signals can be assumed to be asynchronous to the data and then internally synchronized by the UCC, or they can be assumed to be synchronous to the data giving faster operation. This option allows the $\overline{\text{RTS}}$ of one UCC to be connected to the $\overline{\text{CD}}$ of another UCC (on another device) and to have the data synchronized and bit aligned. It is also an option to link the transmitter synchronization to the receiver synchronization.

Diagrams for the pulse/envelope and sampling options are in Section 23.5, “Controlling UCC Timing with RTS, CTS, and CD.”

28.5.3.1.3 Transparent Synchronization Example

Figure 28-7 shows an example of synchronization using external signals.



Notes:

1. Each QUICC Engine module generates its own transmit clocks. If the transmit and receive clocks are the same, one can generate transmit and receive clocks for the other QUICC Engine device. For example, CLKx on QUICC Engine module (B) could be used to clock the transmitter and receiver.
2. $\overline{\text{CTS}}$ should be configured as always asserted in the parallel I/O port or connected to ground externally.
3. The required GUMR configurations are DIAG = 00, CTSS = 1, CTSP is a don't care, CDS = 1, CDP = 0, TTX = 1, and TRX = 1. REVD and TCRC are application-dependent.
4. The transparent frame contains a CRC if TxBD[TC] is set.
5. The transparent frame contains a CRC if TxBD[TC] is set.

Figure 28-7. Sending Transparent Frames Between QUICC Engine Modules or Other QUICC Engine Devices

QUICC Engine module (A) and QUICC Engine module (B) exchange transparent frames and synchronize each other using $\overline{\text{RTS}}$ and $\overline{\text{CD}}$. However, $\overline{\text{CTS}}$ is not required because transmission begins at any time. Thus, $\overline{\text{RTS}}$ is connected directly to the other QUICC Engine module's $\overline{\text{CD}}$. GUMR[SYNL] is not used and transmission and reception from each QUICC Engine module are independent.

28.5.3.1.4 Transparent Mode without Explicit Synchronization

If there is no need to synchronize the transparent controller at a specific point, the user can 'fake' synchronization in one of the following ways:

- Tie a parallel I/O pin to the $\overline{\text{CTS}}$ and $\overline{\text{CD}}$ lines. Then, after enabling the receiver and transmitter, provide a falling edge by manipulating the I/O pin in software.
- Enable the receiver and transmitter for the UCC in loopback mode and then change GUMR[DIAG] to 0b00 while the transmitter and receiver are enabled.

28.5.3.2 Synchronization and the TSA

A 1 bit transparent-mode UCC using the time-slot assigner can synchronize either on a user-defined inline pattern or by inherent synchronization. Note that when the TSA is used, a newly-enabled transmitter sends from 10 to 15 frames of idles before sending the actual transparent data due to startup requirements of the TDM. Therefore, when loopback testing through the TDM, expect to receive several bytes of 0xFF before the actual data.

28.5.3.2.1 Inline Synchronization Pattern

The receiver can be programmed to begin receiving data into the receive buffers only after a specified data pattern arrives. To synchronize on an inline pattern:

- Set GUMR[SYNL].
- Program the UDSR with the desired pattern.
- Clear GUMR[CDP].
- Set GUMR[CTSP, CTSS, CDS].

If GUMR[TXSY] is also used, the transmitter begins transmission eight clocks after the receiver achieves synchronization.

28.5.3.2.2 Inherent Synchronization

Inherent synchronization assumes synchronization by default when the channel is enabled; all data sent from the TDM to the UCC is received. To implement inherent synchronization, set GUMR[CDP, CDS, CTSP, CTSS]. If these bits are not set, the received bit stream is bit-shifted. The UCC loses the first received bit because $\overline{\text{CD}}$ and $\overline{\text{CTS}}$ are treated as asynchronous signals.

28.5.3.2.3 End of Frame Detection

An end of frame cannot be detected in the transparent data stream since there is no defined closing flag in transparent mode. Therefore, if framing is needed, the user must use the $\overline{\text{CD}}$ line to alert the transparent controller of an end of frame.

Chapter 29
HDLC Controller

29.1 Introduction

Layer 2 of the seven-layer OSI model is the data link layer (DLL), in which high level data link control (HDLC) is one of the most common protocols. The framing structure of HDLC is shown in Figure 29-12. HDLC uses a zero insertion/deletion process (commonly known as bit stuffing) to ensure that the bit pattern of the delimiter flag does not occur in the fields between flags. The HDLC frame is synchronous and therefore relies on the physical layer for a method of clocking and of synchronizing the transmitter/receiver.

Because the layer 2 frame can be transmitted over a point-to-point link, a broadcast network, or a packet-and-circuit switched system, an address field is needed for the frame's destination address. The length of this field is commonly 0, 8, or 16 bits, depending on the data link layer protocol. For instance, SDLC and LAPB use an 8-bit address and SS#7 has no address field because it is used always in point-to-point signaling links. LAPD further divides its 16-bit address into different fields to specify various access points within one device. It also defines a broadcast address. Some HDLC-type protocols also permit extended addressing beyond 16 bits.

The 8- or 16-bit control field provides a flow-control number and defines the frame type (control or data). The exact use and structure of this field depends upon the protocol using the frame. Data is transmitted in the data field, which can vary in length depending upon the protocol using the frame. Layer 3 frames are carried in this data field.

Error control is implemented by appending a cyclic redundancy check (CRC) to the frame, which in most protocols is 16-bits long but can be as long as 32-bits. In HDLC, the lsb of each octet is transmitted first and the msb of the CRC is transmitted first.

When GUMR[MODE] selects HDLC mode, that UCC functions as an HDLC controller. When a UCC in HDLC mode is used with a non multiplexed modem interface, the UCC outputs are connected directly to the external pins. Modem signals can be supported through the appropriate port pins. The receive and transmit clocks can be supplied either externally or from the bank of baud-rate generators. The HDLC controller can also be connected to one of the TDM channels of the serial interface and used with the TSA. The HDLC controller consists of separate transmit and receive sections whose operations are asynchronous with the core and can either be synchronous or asynchronous with other UCCs. The user can allocate external buffer descriptors (BDs) for receive and transmit tasks so many frames can be sent or received without core intervention.

29.1.1 Block Diagram

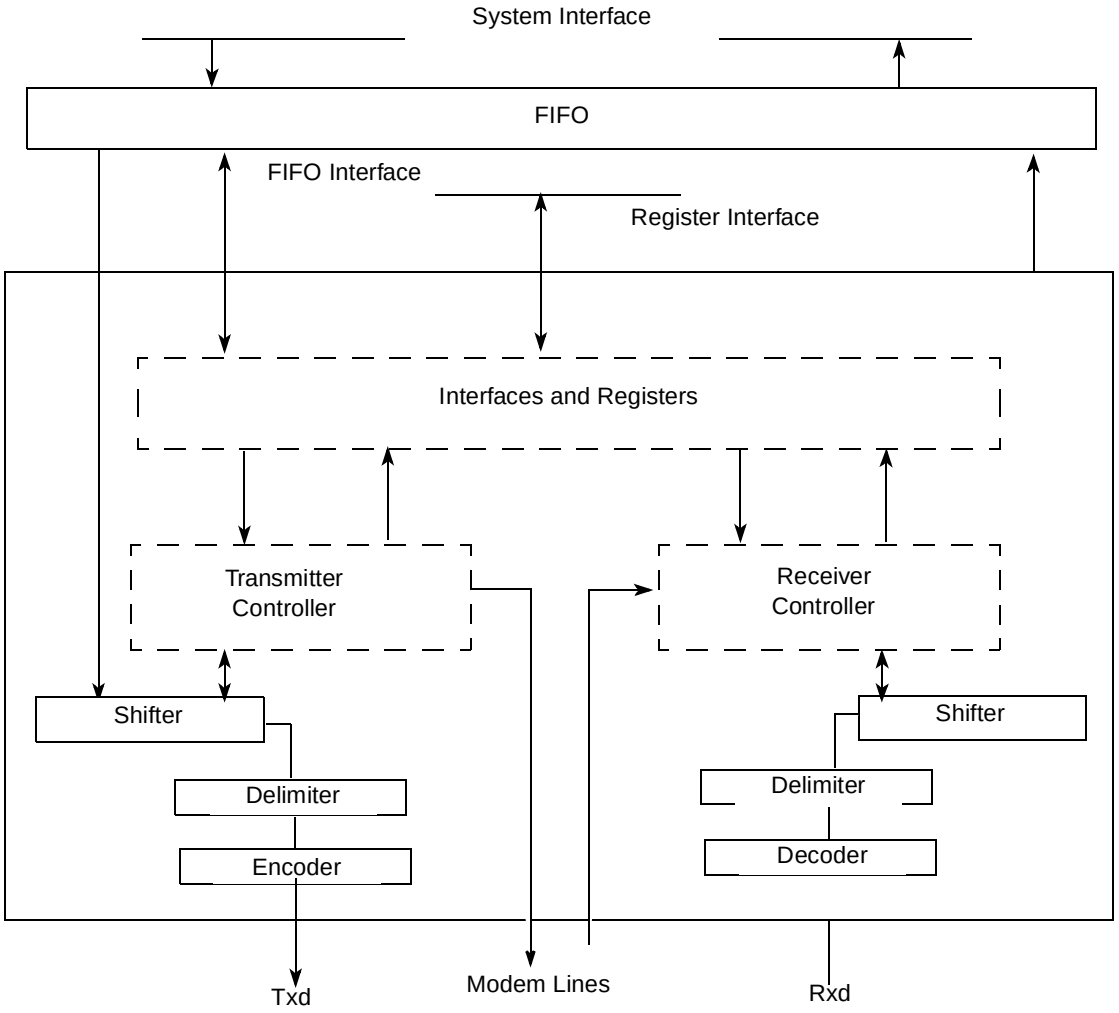


Figure 29-1. HDLC Block Diagram

29.1.2 Features

Key features of the HDLC include the following:

- Flexible data buffers with multiple buffers per frame
- Separate interrupts for frames and buffers (receive and transmit)
- Received frames threshold to reduce interrupt overhead
- Four address comparison registers with masks
- Maintenance of four 16-bit error counters
- Flag/abort/idle generation and detection
- Zero insertion/deletion
- 16- or 32-bit CRC-CCITT generation/checking
- Detection of nonoctet-aligned frames

- Detection of frames that are too long
- Programmable flags (0–15) between successive frames
- External BD table
- Up to 70Mbps rate
- Support of time stamp mode for Rx frames
- Support of nibble mode HDLC (4 bits per clock)
- Automatic retransmission in case of collision (HDLC bus).

29.1.3 Modes of Operation

The HDLC module can work with several modes of operation which are determined in the UPSMR register.

1. Normal operation (1 bit of data per clock)
2. Nibble mode (4 bits data per clock)
3. HDLC bus with collision detection

The HDLC controller includes an option for hardware collision detection and retransmission on an open-drain connected HDLC bus, referred to as HDLC bus mode. Most HDLC-based controllers provide only point-to-point communications, however HDLC bus enhancement allows implementation of an HDLC-based LAN and other point-to-multipoint configurations. The HDLC bus is based on techniques used in the CCITT ISDN I.430 and ANSI T1.605 standards for D-channel point-to-multipoint operation over the S/T interface. However, the HDLC bus does not fully comply with I.430 or T1.605 standards and cannot replace devices that implement these protocols. Instead, it is more suited to non-ISDN LAN and point-to-multipoint configurations.

29.2 Memory Map/Register Definition

29.2.1 Overview

Table 29-1. UCC HDLC Register Summary

Offset	Register	Access	Reset Value	Section/Page
General Registers				
0x4	UPSMR HDLC Mode Register	R/W	0x0000_0000	29.2.2.2/29-7
0x10	UCCE UCC HDLC Event Register	R/W	0x0000_0000	29.2.2.5/29-12
0x14	UCCM UCC HDLC Mask Register	R/W	0x0000_0000	29.2.2.5/29-12
0x18	UCCS UCC HDLC Status Register	R/W	0x0000_0000	29.2.2.6/29-15

29.2.2 Register Descriptions

29.2.2.1 HDLC Parameter RAM

When a UCC operates in HDLC mode, the protocol area of the UCC parameter RAM is mapped with the HDLC parameters as shown in Table 29-2.

Table 29-2. HDLC Parameter RAM Memory Map

Offset[1]	Name	Width	Description
0x00	**RIPTR**	Hword	Receive internal temporary data pointer. Used by microcode as a temporary buffer for data. Must be 32-byte aligned and the size of the internal buffer must be 32 bytes unless it is stated otherwise in the protocol specification.
0x02	**TIPTR**	Hword	Transmit internal temporary data pointer. Used by microcode as a temporary buffer for data. Must be 32-byte aligned and the size of the internal buffer must be 32 bytes unless it is stated otherwise in the protocol specification.
0x04	—	Hword	Reserved, should be cleared.
0x06	**MRBLR**	Hword	Maximum receive buffer length (a multiple of 32 for all modes). The number of bytes that the UCC receiver writes to a receive buffer before moving to the next buffer. The receiver can write fewer bytes to the buffer than MRBLR if a condition such as an error or end-of-frame occurs, but it never exceeds the MRBLR value. Therefore, user-supplied buffers should be at least as large as the MRBLR. Note that UCC transmit buffers can have varying lengths by programming TxBD[Data Length], as needed, and are not affected by the value in MRBLR. MRBLR is not intended to be changed dynamically while an UCC is operating. Change MRBLR only when the UCC receiver is disabled.
0x08	**RSTATE**	Word	Receive internal state. The high byte, RSTATE[0–7], contains the Bus Mode Register, see Section 27.4.6, “Bus Mode Registers (RBMR and TBMR).” RSTATE[8–31] is used by the QUICC Engine module and must be cleared initially.
0x0C	**RBASE**	Word	RxBD base address (must be divisible by eight). Defines the starting location in the memory map for the UCC RxBDs. This provides great flexibility in how UCC RxBDs are partitioned. By selecting RBASE entries for all UCCs and by setting the W bit in the last BD in each BD table, the user can select how many BDs to allocate for the receive side of every UCC. The user must initialize RBASE before enabling the corresponding channel. Furthermore, the user should not configure BD tables of two enabled UCCs to overlap or erratic operation occurs.
0x10	RBDSTAT	Hword	RxBD status and control. Reserved for QUICC Engine module use only.
0x12	RBDLEN	Hword	RxBD data length. A down-count value initialized by the QUICC Engine module with MRBLR and decremented with every byte written by the SDMA channels.
0x14	RDPTR	Word	RxBD data pointer. Updated by the SDMA channels to show the next address in the buffer to be accessed.
0x18	**TSTATE**	Word	Tx internal state. The high byte, TSTATE[0–7], contains the Bus Mode Register, see Section 27.4.6, “Bus Mode Registers (RBMR and TBMR).” TSTATE[8–31] is used by the QUICC Engine module and must be cleared initially.
0x1C	**TBASE**	Word	TxBD base address (must be divisible by eight). Defines the starting location in the memory map for the UCC TxBDs. This provides great flexibility in how UCC TxBDs are partitioned. By selecting TBASE entries for all UCCs and by setting the W bit in the last BD in each BD table, the user can select how many BDs to allocate for the transmit side of every UCC. The user must initialize TBASE before enabling the corresponding channel. Furthermore, the user should not configure BD tables of two enabled UCCs to overlap or erratic operation occurs.

Table 29-2. HDLC Parameter RAM Memory Map (continued)

Offset[1]	Name	Width	Description
0x20	TBDSTAT	Hword	TxBD status and control. Reserved for QUICC Engine module use only.
0x22	TBDLEN	Hword	TxBD data length. A down-count value initialized with the TxBD data length and decremented with every byte read by the SDMA channels.
0x24	TDPTR	Word	TxBD data pointer. Updated by the SDMA channels to show the next address in the buffer to be accessed.
0x28	RBPTR	Word	RxBD pointer. Points to the next BD that the receiver transfers data to when it is in idle state or to the current BD during frame processing. After a reset or when the end of the BD table is reached, the QUICC Engine module sets RBPTR = RBASE. Although the user need never write to RBPTR in most applications, the user can modify it when the receiver is disabled or when no receive buffer is in use.
0x2C	TBPTR	Word	TxBD pointer. Points either to the next BD that the transmitter transfers data from when it is in idle state or to the current BD during frame transmission. After a reset or when the end of the BD table is reached, the QUICC Engine module sets TBPTR = TBASE. Although the user need never write to TBPTR in most applications, the user can modify it when the transmitter is disabled or when no transmit buffer is in use (after a STOP TRANSMIT or GRACEFUL STOP TRANSMIT command is issued and the frame completes transmission).
0x30	RCRC	Word	Temporary receive CRC
0x34	—	Word	Reserved
0x38	TCRC	Word	Temporary transmit CRC
0x3C	—	2 Words	Reserved
0x44	**C_MASK**	Word	CRC constant. For the 16-bit CRC-CCITT, initialize C_MASK to 0x0000_F0B8. For the 32-bit CRC-CCITT, initialize C_MASK to 0xDEBB_20E3.
0x48	**C_PRES**	Word	CRC preset. For the 16-bit CRC-CCITT, initialize C_PRES to 0x0000_FFFF. For the 32-bit CRC-CCITT, initialize C_PRES to 0xFFFF_FFFF.
0x4C	**DISFC**[2]	Hword	Discard frame counter. Counts error-free frames discarded due to lack of buffers.
0x4E	**CRCEC**[2]	Hword	CRC error counter. Counts frames not addressed to the user or frames received in the BSY condition, but does not include overrun, $\overline{CD}$ lost, or abort errors.
0x50	**ABTSC**[2]	Hword	Abort sequence counter
0x52	**NMARC**[2]	Hword	Non-matching address Rx counter. Counts non-matching addresses received (error-free frames only). See the HMASK and HADDR[1–4] parameter description.
0x54	MAX_CNT	Word	Max_length counter. Temporary decrementing counter that tracks frame length.
0x58	**MFLR**	Hword	Max frame length register. If the HDLC controller detects an incoming HDLC frame that exceeds the user-defined value in MFLR, the rest of the frame is discarded and the LG (Rx frame too long) bit is set in the last BD belonging to that frame. The HDLC controller waits for the end of the frame and then reports the frame status and length in the last RxBD. MFLR includes all in-frame bytes between the opening and closing flags (address, control, data, and CRC).
0x5A	**RFTHR**	Hword	Received frames threshold. Used to reduce the interrupt overhead that might otherwise occur when a series of short HDLC frames arrives, each causing an RXF interrupt. By programming RFTHR, the user lowers the frequency of RXF interrupts, which occur only when the RFTHR value is reached. Note that the user should provide enough empty RxBDs to receive the number of frames specified in RFTHR.

Table 29-2. HDLC Parameter RAM Memory Map (continued)

Offset[1]	Name	Width	Description
0x5C	**RFCNT**	Hword	Received frames count. A decrementing counter used to implement this feature. Initialize this counter with RFTHR.
0x5E	**HMASK**	Hword	HMASK and HADDR[1–4]. The HDLC controller reads the frame address from the HDLC receiver, checks it against the four address register values, and masks the result with HMASK. In HMASK, a 1 represents a bit position for which address comparison should occur; 0 represents a masked bit position. When addresses match, the address and subsequent data are written into the buffers. When addresses do not match and the frame is error-free, the non-matching address received counter (NMARC) is incremented. Note that for 8-bit addresses, mask out (clear) the eight high-order bits in HMASK. The eight low-order bits and HADDRx should contain the address byte that immediately follows the opening flag. For example, to recognize a frame that begins 0x7E (flag), 0x68, 0xAA, using 16-bit address recognition, HADDRx should contain 0xAA68 and HMASK should contain 0xFFFF. See Figure 29-2.
0x60	**HADDR1**	Hword	
0x62	**HADDR2**	Hword	
0x64	**HADDR3**	Hword	
0x66	**HADDR4**	Hword	
0x68	TS_TMP	Hword	Temporary storage
0x6A	TMP_MB	Hword	Temporary storage
0x100	—	—	Reserved

1 Offset from UCC page base address.

2 DISFC, CRCEC, ABTSC, and NMARC—These 16-bit (modulo 216) counters are maintained by the RISC. The user can initialize them while the channel is disabled.

Figure 29-2 shows an example of using HMASK and HADDR[1–4].

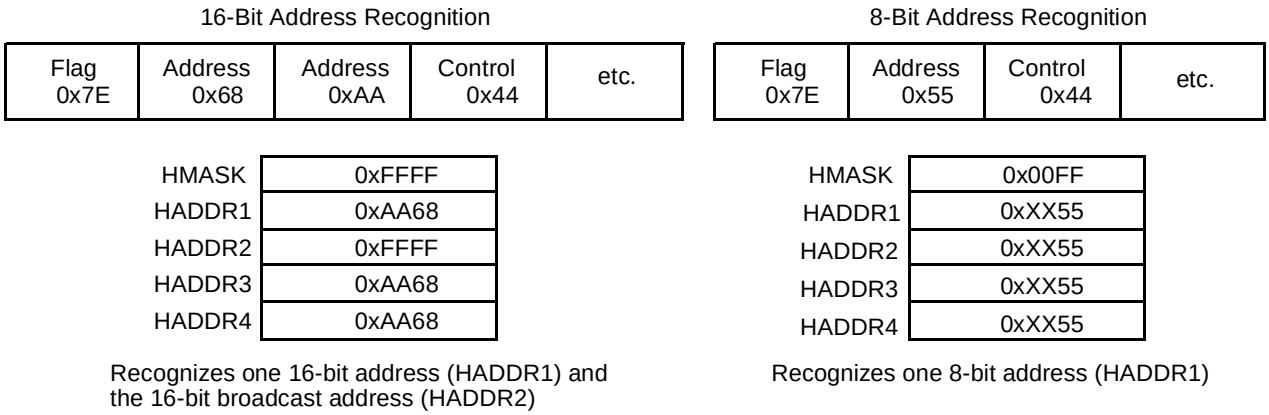

Figure 29-2. HDLC Address Recognition Example

29.2.2.2 HDLC Mode Register (UPSMR)

When a UCC is configured for HDLC mode, the UPSMR is used as the HDLC mode register, shown in Figure 29-3.

Address: UCC_base + 0x4 Access: User Read/Write

	0–3	4	5	6	7	8	9	10	11	12	13	14	15
R W	NOF	FSE	MFF	RTE	—		TS	BUS	BRM	—	DRT	—	NBO
Reset	All zeros												

	16	17–19	20–23	24	25	26–31
R W	NBO	CW	—	CRC		—
Reset	All zeros					

Figure 29-3. HDLC Mode Register (UPSMR)

Figure 29-4. HDLC Mode Register (UPSMR)

The UPSMR fields are described in Table 29-3.

Table 29-3. UPSMR Field Descriptions

Bits	Name	Description
0–3	NOF	Number of flags. Minimum number of flags between or before frames (0–15 flags). If NOF = 0000, no flags are inserted between the frames. Thus, for back-to-back frames, the closing flag of one frame is immediately followed by the opening flag of the next frame.
4	FSE	Flag sharing enable. This bit is valid only if GUMR[RTSM] is set. 0 Normal operation 1 If NOF = 0000, a single shared flag is transmitted between back-to-back frames. Other values of NOF are decremented by 1 when FSE is set. This is useful in signaling system #7 applications.
5	MFF	Multiple Frames in FIFO. When UPSMR[BUS] is set, MFF must be cleared. 0 Normal operation. The transmit FIFO buffer must never contain more than one HDLC frame. The $\overline{\text{CTS}}$ lost status is reported accurately on a per-frame basis. The receiver is not affected by this bit. 1 The transmit FIFO buffer can contain multiple frames, but lost $\overline{\text{CTS}}$ is not guaranteed to be reported on the exact buffer/frame it occurred on. This option, however, can improve the performance of HDLC transmissions for small back-to-back frames or if the user prefers to strongly limit the number of flags sent between frames. MFF does not affect the receiver.
6	RTE	Retransmit enable. When UPSMR[BUS] is set, RTE must be set. 0 No retransmission. 1 Automatic frame retransmission is enabled. Particularly useful in the HDLC bus protocol and ISDN applications where multiple HDLC controllers can collide. Note that retransmission occurs only if a lost $\overline{\text{CTS}}$ occurs on the first or second buffer of the frame.
7–8	—	Reserved, should be cleared.
9	TS	Time stamp 0 Normal operation. 1 A 32-bit time stamp is added at the beginning of the receive BD data buffer, thus the buffer pointer must be (32-byte aligned - 4). The BD's data length does not include the time stamp. See Section 20.3.9, "QUICC Engine Time-Stamp Control Register (CETSCR)." Note that when UPSMR[TS] is set, the timestamp used is CETSCR2.

Table 29-3. UPSMR Field Descriptions (continued)

Bits	Name	Description
10	BUS	HDLC bus mode. 0 Normal HDLC operation. 1 HDLC bus operation is selected. See Section 29.3.3, "HDLC Bus Mode with Collision Detection"
11	BRM	HDLC bus $\overline{\text{RTS}}$ mode. Valid only if BUS = 1. Otherwise, it is ignored. 0 Normal $\overline{\text{RTS}}$ operation during HDLC bus mode. $\overline{\text{RTS}}$ is asserted on the first bit of the Tx frame and negated after the first collision bit is received. 1 Special $\overline{\text{RTS}}$ operation during HDLC bus mode. $\overline{\text{RTS}}$ is delayed by one bit with respect to the normal case, which helps when the HDLC bus protocol is being run locally and sent over a long-distance line at the same time. The one-bit delay allows $\overline{\text{RTS}}$ to be used to enable the transmission line buffers so that the electrical effects of collisions are not sent over the transmission line.
12	—	Reserved, should be cleared.
13	DRT	Disable receiver while transmitting. 0 Normal operation. 1 As the UCC sends data, the receiver is disabled and gated by the internal $\overline{\text{RTS}}$. This helps if the HDLC channel is on a multidrop line and the UCC does not need to receive its own transmission. **Note:** If DRT is set and $\overline{\text{CTS}}$ is not connected to the external device, it is required to programmed the $\overline{\text{CTS}}$ PIO to default.
14	—	Reserved, should be cleared.
15–16	NBO	Mode of operation 00 normal mode (1 bit of data per clock). 01 nibble mode (4 bits of data per clock). 10 octal mode (8 bits of data per clock). 11 Reserved
17–19	CW	Collision window. Valid only if BUS = 1. The number of bytes (0-7) from the beginning of the frame, that a collision could occur. When CW = 000, the collision window is 1 byte. When CW = 111, the collision window is 8 bytes.
20–23	—	Reserved, should be cleared.
24–25	CRC	CRC selection 00 16-bit CCITT-CRC (HDLC). X16 + X12 + X5 + 1 01 Reserved 10 32-bit CCITT-CRC (Ethernet and HDLC). X32 + X26 + X23 + X22 + X16 + X12 + X11 + X10 + X8 + X7 + X5 + X4 + X2 + X1 +1 11 Reserved
26–31	—	Reserved, should be cleared.

29.2.2.3 HDLC Receive Buffer Descriptor (RxBD)

The HDLC controller uses the RxBD to report on data received for each buffer. Figure 29-5 shows an example of the RxBD process.

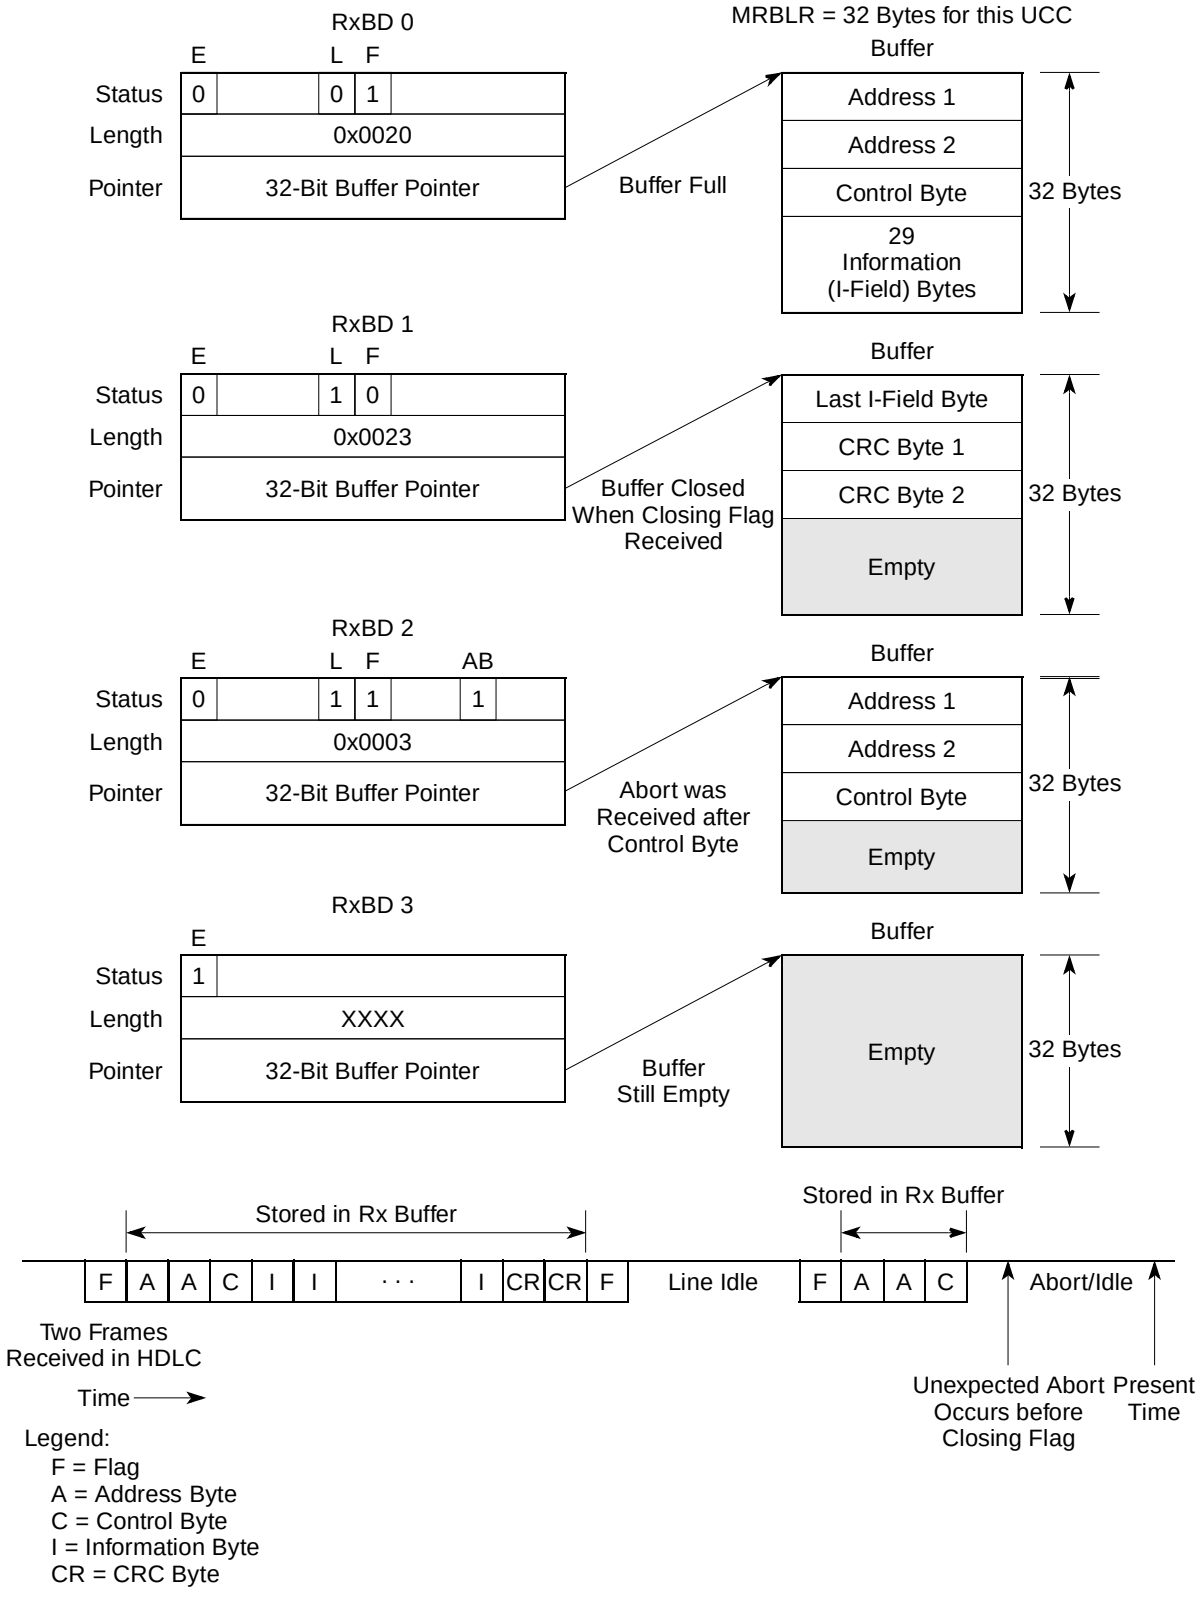

Figure 29-5. UCC HDLC Receiving Using RxBDs

Figure 29-6 shows the UCC HDLC RxBD.

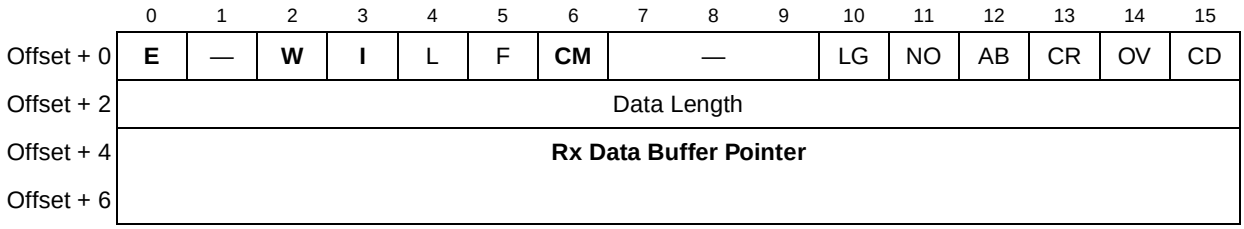

Figure 29-6. UCC HDLC Receive Buffer Descriptor (RxBD)

Table 29-4 describes RxBD fields.

Table 29-4. UCC HDLC RxBD Field Descriptions

Bits	Name	Description
0	**E**	Empty 0 The buffer is full with received data or data reception stopped because of an error. The core can read or write to any fields of this RxBD. The RISC does not use this BD while E = 0. 1 The buffer associated with this BD is empty. This RxBD and its associated receive buffer are owned by the RISC. Once E is set, the core should not write any fields of this RxBD.
1	—	Reserved, should be cleared.
2	**W**	Wrap (final BD in table) 0 Not the last BD in the RxBD table. 1 Last BD in the RxBD table. After this buffer is used, the RISC receives incoming data into the first BD that RBASE points to in the table. The number of RxBDs in this table is programmable and is determined only by the W bit and the overall space constraints of the multi-user RAM. The RxBD table must contain more than one BD in HDLC mode.
3	**I**	Interrupt 0 The RXB bit is not set after this buffer is used, but RXF operation remains unaffected. 1 UCCE[RXB] or UCCE[RXF] is set when the HDLC controller uses this buffer. These two bits can cause interrupts if they are enabled.
4	L	Last in frame. Set by the HDLC controller when this buffer is the last one in a frame. This implies the reception of a closing flag or reception of an error, in which case one or more of the CD, OV, AB, and LG bits are set. The HDLC controller writes the number of frame octets to the data length field. 0 Not the last buffer in a frame. 1 Last buffer in a frame.
5	F	First in frame. Set by the HDLC controller when this buffer is the first in a frame. 0 Not the first buffer in a frame. 1 First buffer in a frame.
6	**CM**	Continuous mode 0 Normal operation. 1 The E bit is not cleared by the RISC after this BD is closed, allowing the associated data buffer to be automatically overwritten the next time the RISC accesses this BD. However, the E bit is cleared if an error occurs during reception, regardless of the CM bit.
7–9	—	Reserved, should be cleared.
10	LG	Rx frame length violation. A frame length greater than the maximum defined for this channel is recognized, and only the maximum-allowed number of bytes (MFLR) is written to the data buffer. This event is not reported until the RxBD is closed, the RXF bit is set, and the closing flag is received. The number of bytes received between flags is written to the data length field of this BD.

Table 29-4. UCC HDLC RxBD Field Descriptions (continued)

Bits	Name	Description
11	NO	Rx nonoctet-aligned frame. Set when a received frame contains a number of bits not divisible by eight.
12	AB	Rx abort sequence. At least seven consecutive 1s are received during frame reception.
13	CR	Rx CRC error. This frame contains a CRC error. Received CRC bytes are written to the receive buffer.
14	OV	Overrun. A receiver overrun occurs during frame reception.
15	CD	Carrier detect lost. $\overline{CD}$ has negated during frame reception. This bit is valid only for NMSI mode.

The RxBD status bits are written by the HDLC controller after receiving the associated data buffer.

The remaining RxBD parameters are as follows:

- Data length is the number of octets the RISC writes into this BD's data buffer. It is written by the RISC once the BD is closed. When this is the last BD in the frame (L = 1), this field contains the total number of frame octets, including 2 or 4 bytes for CRC. The memory allocated for this buffer should be no smaller than the MRBLR value.
- Rx data buffer pointer. The receive buffer pointer, which always points to the first location of the associated data buffer, resides in internal or external memory and must be divisible by 32 unless UPSMR[TS] = 1 (see Table 29-3).

29.2.2.4 HDLC Transmit Buffer Descriptor (TxBD)

Data is presented to the HDLC controller for transmission on a UCC channel by arranging it in buffers referenced by the channel TxBD table. The HDLC controller confirms transmission (or indicates errors) using the BDs to inform the core that the buffers have been serviced. Figure 29-7 shows the UCC HDLC TxBD.

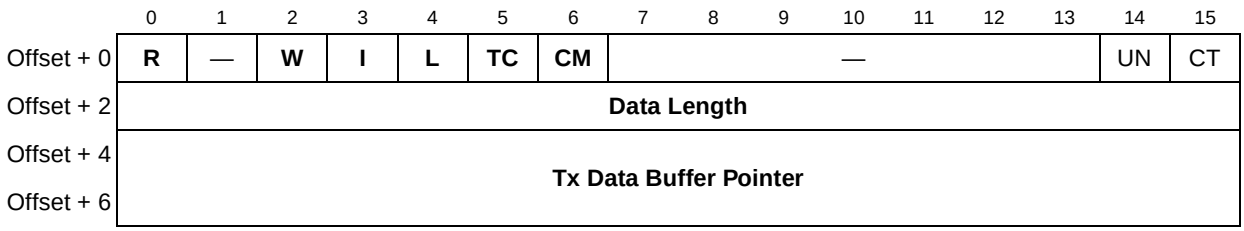

Figure 29-7. UCC HDLC Transmit Buffer Descriptor (TxBD)

Table 29-5 describes HDLC TxBD fields.

Table 29-5. UCC HDLC TxBD Field Descriptions

Bits	Name	Description
0	**R**	Ready 0 The buffer associated with this BD is not ready for transmission. The user can manipulate this BD or its associated buffer. The RISC clears R after the buffer has been sent or an error occurs. 1 The buffer is ready to be sent. The transmission may have begun, but it has not completed. The user cannot set fields in this BD once R is set.
1	—	Reserved, should be cleared.

Table 29-5. UCC HDLC TxBD (continued) Field Descriptions

Bits	Name	Description
2	**W**	Wrap (final BD in table) 0 Not the last BD in the TxBD table. 1 Last BD in the TxBD table. After this buffer has been used, the RISC sends data from the first BD that TBASE points to in the table. The number of TxBDs in this table is determined only by the W bit and the overall space constraints of the multi-user RAM.
3	**I**	Interrupt 0 No interrupt is generated after this buffer is serviced. 1 Either UCCE[TXB] or UCCE[TXE] is set when this buffer is serviced by the HDLC controller. These bits can cause interrupts if they are enabled.
4	**L**	Last 0 Not the last buffer in the frame. 1 Last buffer in the current frame.
5	**TC**	Tx CRC.Valid only when the L bit is set. Otherwise, it is ignored. 0 Transmit the closing flag after the last data byte. This setting can be used to send a bad CRC after the data for testing purposes. 1 Transmit the CRC sequence after the last data byte.
6	**CM**	Continuous mode 0 Normal operation. 1 The R bit is not cleared by the RISC after this BD is closed, allowing the buffer to be retransmitted automatically the next time the RISC accesses this BD. However, the R bit is cleared if an error occurs during transmission, regardless of the CM bit.
7–13	—	Reserved, should be cleared.
14	UN	Underrun. The HDLC controller encounters a transmitter underrun condition while sending the buffer. The HDLC controller writes UN after sending the buffer.
15	CT	$\overline{\text{CTS}}$ lost. Set when $\overline{\text{CTS}}$ is lost during frame transmission in NMSI mode. If data from more than one buffer is in the FIFO buffer when this error occurs, CT is set in the currently open TxBD. The HDLC controller writes CT after sending the buffer.

The TxBD status bits are written by the HDLC controller after sending the associated data buffer.

The remaining TxBD parameters are as follows:

- Data length is the number of bytes the HDLC controller should transmit from this data buffer; it is never modified by the RISC. The value of this field should be greater than zero.
- Tx data buffer pointer. The transmit buffer pointer, which contains the address of the associated data buffer, can be even or odd. The buffer can reside in internal or external memory. This value is never modified by the RISC.

29.2.2.5 HDLC Event Register (UCCE)/Mask Register (UCCM)

The UCCE is used as the HDLC event register when the UCC operates as an HDLC controller. The UCCE reports events recognized by the HDLC channel and generates interrupts. On recognition of an event, the HDLC controller sets the corresponding UCCE bit. UCCE bits are cleared by writing ones; writing zeros does not affect bit values. All unmasked bits must be cleared before the RISC clears the internal interrupt request.

Interrupts generated by the UCCE can be masked in the HDLC mask register (UCCM), which has the same bit format as UCCE. If a UCCM bit = 1, the corresponding interrupt in the event register is enabled. If the bit is 0, the interrupt is masked.

Figure 29-8 represents the UCCE/UCCM.

Address: UCC_base + 0x10 (UCCE), UCC_base + 0x14 (UCCM) Access: User Read/Write

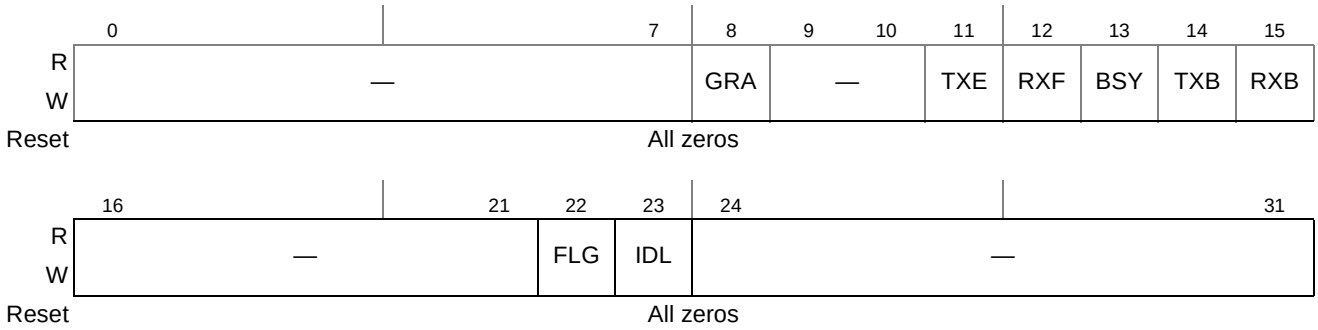

Figure 29-8. HDLC Event/Mask Register (UCCE/UCCM)

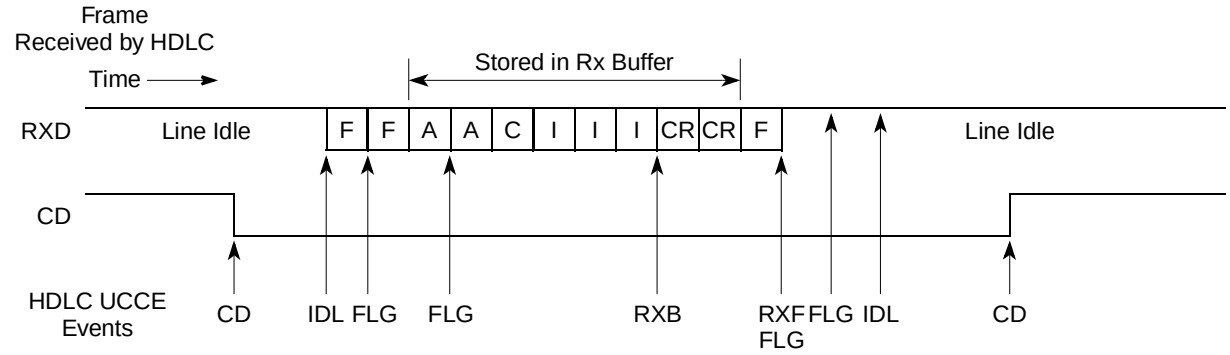
Table 29-6 describes UCCE/UCCM fields.

Table 29-6. UCCE/UCCM Field Descriptions

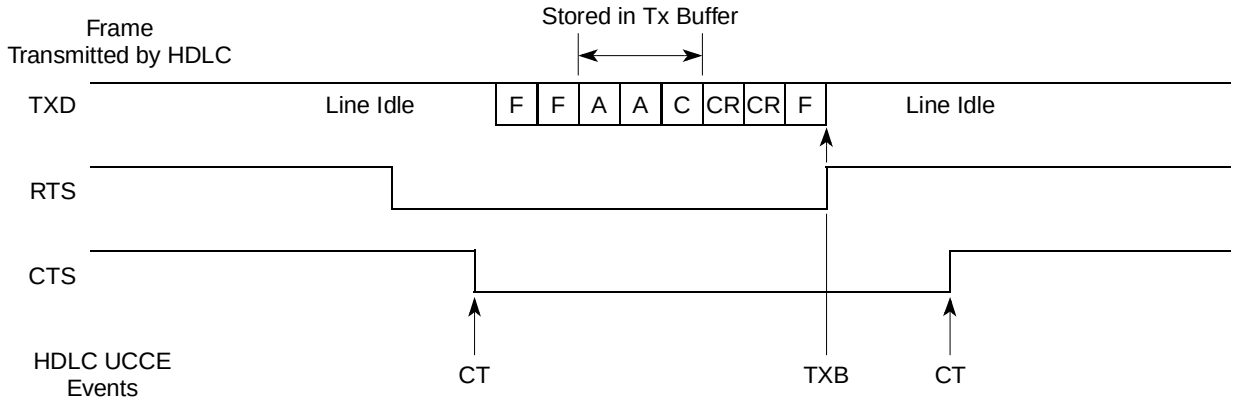
Bits	Name	Description
0–7	—	Reserved, should be cleared.
8	GRA	Graceful stop complete. A graceful stop, which was initiated by the GRACEFUL STOP TRANSMIT command, is now complete. GRA is set as soon as the transmitter finishes transmitting any frame that is in progress when the command was issued. It is set immediately if no frame is in progress when the command is issued.
9–10	—	Reserved, should be cleared.
11	TXE	Tx error. An error ($\overline{\text{CTS}}$ lost or underrun) occurs on the transmitter channel.
12	RXF	Rx frame. A complete frame is received on the HDLC channel. This bit is set no sooner than two clocks after receipt of the last bit of the closing flag.
13	BSY	Busy condition. A frame is received and discarded due to a lack of buffers.
14	TXB	Transmit buffer. Enabled by setting TxBD[I]. A buffer is sent on the HDLC channel. TXB is set no sooner than when the last bit of the closing flag begins its transmission if the buffer is the last one in the frame. Otherwise, TXB is set after the last byte of the buffer is written to the transmit FIFO buffer.
15	RXB	Receive buffer. Enabled by setting RxBD[I]. RXB is set when a buffer is filled, even if the buffer is the last in a frame (unlike RXB in the UCCE/UCCM).
16–21	—	Reserved, should be cleared.
22	FLG	Flag status changed. The HDLC controller stops or starts receiving HDLC flags. The real-time status can be obtained in UCCS; see Section 29.2.2.6, “UCC Status Register (UCCS).”
23	IDL	Idle sequence status changed. A change in the status of the serial line is detected on the HDLC line. The real-time status can be read in UCCS; see Section 29.2.2.6, “UCC Status Register (UCCS).”
24–31	—	Reserved, should be cleared.

Figure 29-9 shows interrupts that can be generated in the HDLC protocol.



Notes:

1. RXB event assumes receive buffers are 6 bytes each.
2. The second IDL event occurs after 15 ones are received in a row.
3. The FLG interrupts show the beginning and end of flag reception.
4. The FLG interrupt at the end of the frame may precede the RXF interrupt due to receive FIFO latency.
5. The CD event must be programmed in the parallel I/O port, not in the UCC itself.
6. F = flag, A = address byte, C = control byte, I = information byte, and CR = CRC byte



Notes:

1. TXB event shown assumes all three bytes were put into a single buffer.
2. Example shows one additional opening flag. This is programmable.
3. The CT event must be programmed in the parallel I/O port, not in the UCC itself.

Figure 29-9. HDLC Interrupt Event Example

29.2.2.6 UCC Status Register (UCCS)

The UCCS register, shown in Figure 29-10, allows the user to monitor real-time status conditions on the RXD line. The real-time status of the $\overline{\text{CTS}}$ and $\overline{\text{CD}}$ signals are part of the parallel I/O port.

Address: UCC_base + 0x18 Access: Read Only

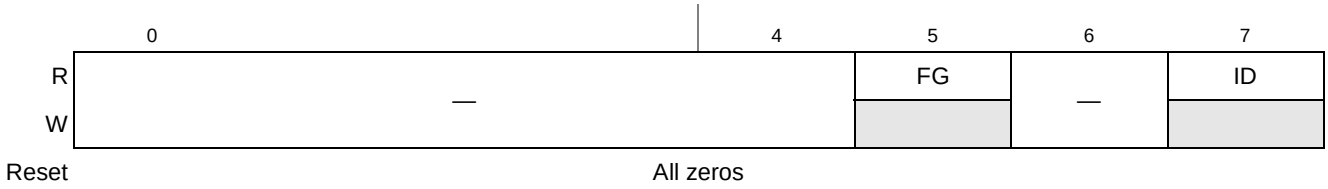


Figure 29-10. HDLC Status Register (UCCS)

Figure 29-11. HDLC Status Register (UCCS)

Table 29-7. HDLC Status Register Field Descriptions

Bits	Name	Description
0–4	—	Reserved, should be cleared.
5	FG	Flags. While FG is cleared, each time a new bit is received the most recently received 8 bits are examined to see if a flag is present. FG is set as soon as an HDLC flag (0x7E) is received on the line. Once FG is set, it remains set at least 8 bit times while the next 8 bits of input data are examined. If another flag occurs, FG stays set for at least another eight bits. Otherwise, FG is cleared and the search begins again. • 0 HDLC flags are not currently being received. • 1 HDLC flags are currently being received.
6	—	Reserved, should be cleared.
7	ID	Idle status. ID is set when the RXD signal is a logic one for 15 or more consecutive bit times; it is cleared after a logic zero is received. • 0 The line is busy. • 1 The line is idle.

29.3 Functional Description

29.3.1 HDLC Channel Frame Transmission Processing

The HDLC transmitter is designed to work with almost no core intervention. When the core enables a transmitter, it starts sending flags or idles as programmed in the HDLC mode register (UPSMR). The HDLC controller polls the first BD in the transmit channel BD table. When there is a frame to transmit, the HDLC controller fetches the data (address, control, and information) from the first buffer and begins sending the frame after first inserting the user-specified minimum number of flags between frames. When the end of the current buffer is reached and TxBD[L] (last buffer in frame) is set, the UCC appends the CRC (if selected) and closing flag. In HDLC, the lsb of each octet and the msb of the CRC are sent first. Figure 29-12 shows a typical HDLC frame.

Opening Flag	Address	Control	Information (Optional)	CRC	Closing Flag
8 Bits	16 Bits	8 Bits	8*n* Bits	16 Bits	8 Bits

Figure 29-12. HDLC Framing Structure

After the closing flag is sent, the HDLC controller writes the frame status bits into the BD and clears the R bit. When the end of the current BD is reached and the L (last) bit is not set (working in multi buffer mode), only the R bit is cleared. In either mode, an interrupt can be issued if the I bit in the TxBD is set. The HDLC controller then proceeds to the next TxBD in the table. In this way, the core can be interrupted after each buffer, after a specific buffer, after each frame, or after a number of frames.

To rearrange the transmit queue before the RISC has sent all buffers, issue the STOP TRANSMIT command. This can be useful for sending expedited data before previously linked buffers or for error situations. When receiving the STOP TRANSMIT command, the HDLC controller aborts the current frame transmission and starts transmitting idles or flags. When the HDLC controller is given the RESTART TRANSMIT command, it resumes transmission. To insert a high-priority frame without aborting the current frame, the GRACEFUL STOP TRANSMIT command can be issued. A special interrupt (GRA) can be generated in the event register when the current frame is complete.

29.3.2 HDLC Channel Frame Reception Processing

The HDLC receiver is designed to work with almost no core intervention and can perform address recognition, CRC checking, and maximum frame length checking. The received frame is available for any HDLC-based protocol. When the core enables a receiver, the receiver waits for an opening flag character. When it detects the first byte of the frame, the HDLC controller compares the frame address against the user-programmable addresses. The user has four 16-bit address registers and an address mask available for address matching. The HDLC controller compares the received address field to the user-defined values after masking with the address mask. The HDLC controller can also detect broadcast (all ones) address frames if one address register is written with all ones.

If a match is detected, the HDLC controller checks the prefetched BD, and if empty, begins transferring the incoming frame to the BD's associated buffer. When the buffer is full, the HDLC controller clears BD[E] and generates an interrupt if BD[I] = 1. If the incoming frame is larger than the buffer, the HDLC controller fetches the next BD in the table and, if it is empty, continues transferring the frame to the associated buffer.

During this process, the HDLC controller checks for frames that are too long. When the frame ends, the CRC field is checked against the recalculated value and written to the buffer. The data length written to the last BD in the HDLC frame is the length of the entire frame. This enables HDLC protocols that lose frames to correctly recognize a frame-too-long condition.

The HDLC controller then sets the last-buffer-in-frame bit, writes the frame status bits into the BD, clears the E bit, and fetches the next BD. The HDLC controller then generates a maskable interrupt, indicating that a frame was received and is in memory. The HDLC controller then waits for a new frame. Back-to-back frames can be received, separated only by a single shared flag.

The user can configure the HDLC controller not to interrupt the core until a specified number of frames have been received. This is configured in the received frames threshold (RFTHR) location of the parameter RAM. This function can be combined with a timer to implement a time-out if fewer than the threshold number of frames are received.

29.3.3 HDLC Bus Mode with Collision Detection

The HDLC controller includes an option for hardware collision detection and retransmission on an open-drain connected HDLC bus, referred to as HDLC bus mode. Most HDLC-based controllers provide only point-to-point communications; however, the HDLC bus enhancement allows implementation of an HDLC-based LAN and other point-to-multipoint configurations. The HDLC bus is based on techniques used in the CCITT ISDN I.430 and ANSI T1.605 standards for D-channel point-to-multipoint operation over the S/T interface. However, the HDLC bus does not fully comply with I.430 or T1.605 and cannot replace devices that implement these protocols. Instead, it is more suited to non-ISDN LAN and point-to-multipoint configurations.

Review the basic features of the I.430 and T1.605 before learning about the HDLC bus. The I.430 and T1.605 define a way to connect eight terminals over the D-channel of the S/T ISDN bus. The layer 2 protocol is a variant of HDLC, called LAPD. However, at layer 1, a method is provided to allow the eight terminals to send frames to the switch through the physical S/T bus.

To determine whether a channel is clear, the S/T interface device looks at an echo bit on the line designed to echo the last bit sent on the D channel. Depending on the class of terminal and the context, an S/T interface device waits for 7–10 ones on the echo bit before letting the LAPD frame begin transmission, after which the S/T interface monitors transmitted data. As long as the echo bit matches the sent data, transmission continues. If the echo bit is ever 0 when the transmit bit is 1, a collision occurs between terminals; the station(s) that sent a one stops transmitting. The station that sent a zero continues as normal.

The I.430 and T1.605 standards provide a physical layer protocol that allows multiple terminals to share one physical connection. These protocols handle collisions efficiently because one station can always complete its transmission, at which point, it lowers its own priority to give other devices fair access to the physical connection.

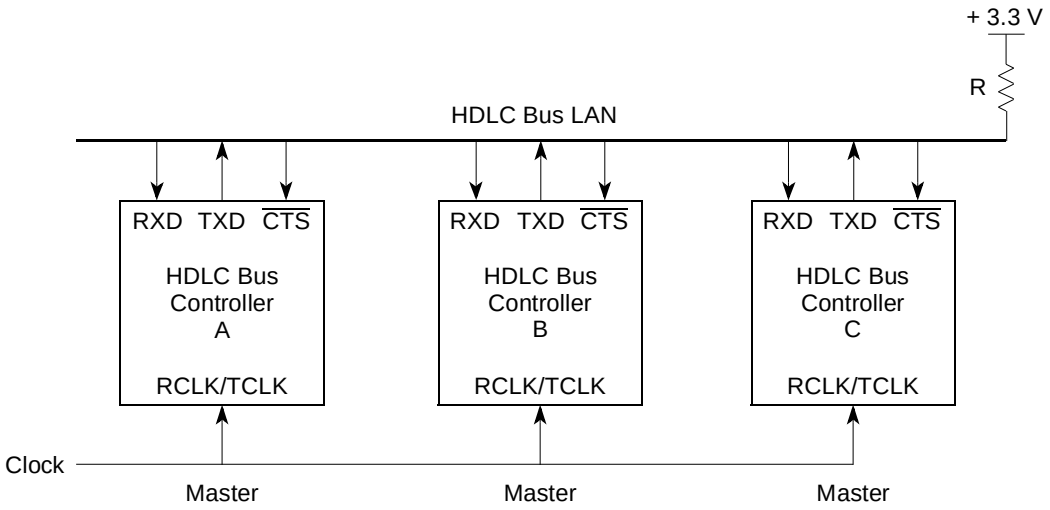
The HDLC bus differs from the I.430 and T1.605 standards as follows:

- The HDLC bus uses a separate input signal rather than the echo bit to monitor data; the transmitted data is simply connected to the $\overline{\text{CTS}}$ input.
- The HDLC bus is a synchronous, digital open-drain connection for short-distance configurations, rather than the more complex S/T interface.
- Any HDLC-based frame protocol can be used at layer 2, not just LAPD.
- HDLC bus devices wait 8–10 rather than 7–10 bit times before transmitting. (HDLC bus has only one class.)

The collision-detection mechanism supports only:

- NRZ-encoded data
- A common synchronous clock for all receivers and transmitters
- Open-drain connection via port pin configuration or via external transceivers

Figure 29-13 shows the most common HDLC bus LAN configuration, a multi master configuration. A station can transfer data to or from any other LAN station. Transmissions are half-duplex, which is typical in LANs.

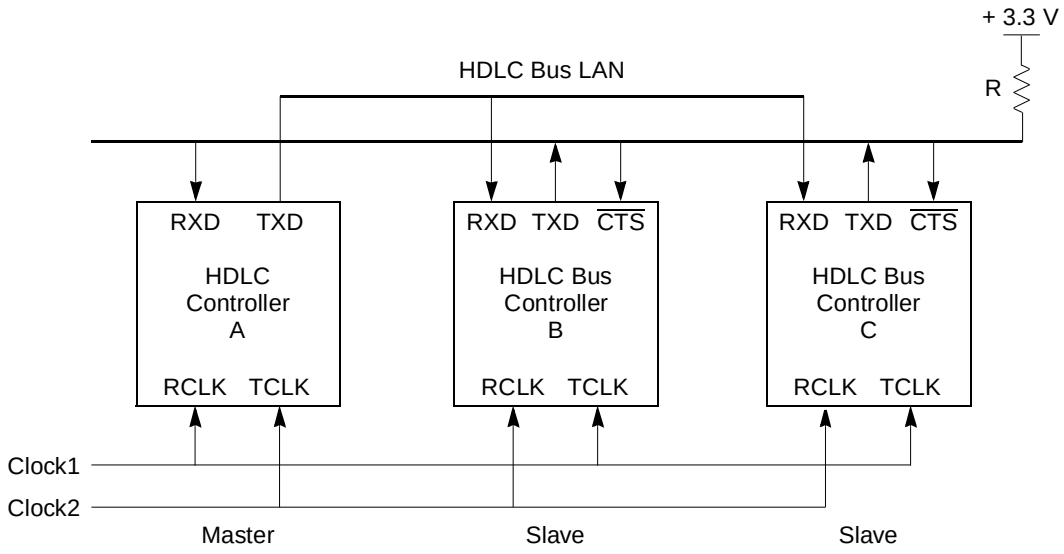


NOTES:

1. Transceivers can be used to extend the LAN size.
2. The TXD pins of slave devices should be configured to open-drain in the port C parallel I/O port.
3. Clock is a common RCLK/TCLK for all stations.

Figure 29-13. Typical HDLC Bus Multi master Configuration

In single-master configuration, a master station transmits to any slave station without collisions. Slaves communicate only with the master, but can experience collisions in their access over the bus. In this configuration, a slave that communicates with another slave must first transmit its data to the master, where the data is buffered in RAM and then resent to the other slave. The benefit of this configuration, however, is that full-duplex operation can be obtained. In a point-to-multipoint environment, this is the preferred configuration. Figure 29-14 shows the single-master configuration.



NOTES:
1. Transceivers may be used to extend the LAN size.
2. The TXD pins of slave devices should be configured to open-drain in the port C parallel I/O port.
3. Clock1 is the master RCLK and the slave TCLK.
4. Clock2 is the master TCLK and the slave RCLK.

Figure 29-14. Typical HDLC Bus Single-Master Configuration

29.3.3.1 HDLC Bus Features

The main features of the HDLC bus are as follows:

- Superset of the HDLC controller features
- Automatic HDLC bus access
- Automatic retransmission in case of collision
- May be used with the NMSI or a TDM bus
- Delayed $\overline{\text{RTS}}$ mode

29.3.3.2 Accessing the HDLC Bus

The HDLC bus protocol ensures orderly bus control when multiple transmitters attempt simultaneous access. The transmitter sending a zero bit at the time of collision completes the transmission. If a station sends out an opening flag (0x7E) while another station is already sending, the collision is always detected within the first byte, because the transmission in progress is using zero bit insertion to prevent flag imitation.

While in the active condition (ready to transmit), the HDLC bus controller monitors the bus using $\overline{\text{CTS}}$. It counts the one bits on $\overline{\text{CTS}}$. When eight consecutive ones are counted, the HDLC bus controller starts transmitting on the line; if a zero is detected, the internal counter is cleared. During transmission, data is continuously compared with the external bus using $\overline{\text{CTS}}$. $\overline{\text{CTS}}$ is sampled halfway through the bit time using the rising edge of the Tx clock. If the transmitted bit matches the received $\overline{\text{CTS}}$ bus sample, transmission continues. However, if the received $\overline{\text{CTS}}$ sample is 0 and the transmitted bit is 1, transmission

stops after that bit and waits for an idle line before attempting retransmission. Since the HDLC bus uses a wired-OR scheme, a transmitted zero has priority over a transmitted 1. Figure 29-15 shows how $\overline{\text{CTS}}$ is used to detect collisions.

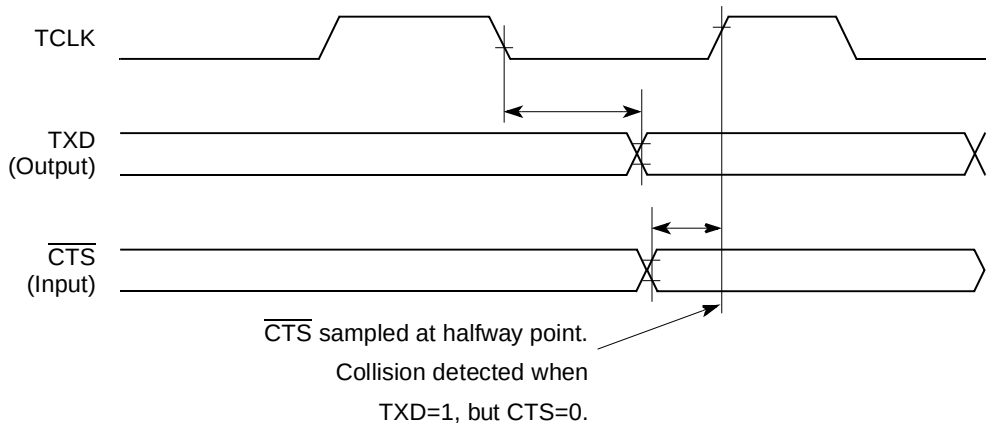


Figure 29-15. Detecting an HDLC Bus Collision

If both the destination address and source address are included in the HDLC frame, then a predefined priority of stations results; if two stations begin to transmit simultaneously, they necessarily detect a collision no later than the end of the source address.

The HDLC bus priority mechanism ensures that stations share the bus equally. To minimize idle time between messages, a station normally waits for eight one bits on the line before attempting transmission. After successfully sending a frame, a station waits for 10 rather than eight consecutive one bits before attempting another transmission. This mechanism ensures that another station waiting to transmit acquires the bus before a station can transmit twice. When a low priority station detects 10 consecutive ones, it tries to transmit; if it fails, it reinstates the high priority of waiting for only eight ones.

29.3.3.3 Increasing Performance

Because it uses a wired-OR configuration, HDLC bus performance is limited by the rise time of the one bit. To increase performance, give the one bit more rise time by using a clock that is low longer than it is high, as shown in Figure 29-16.

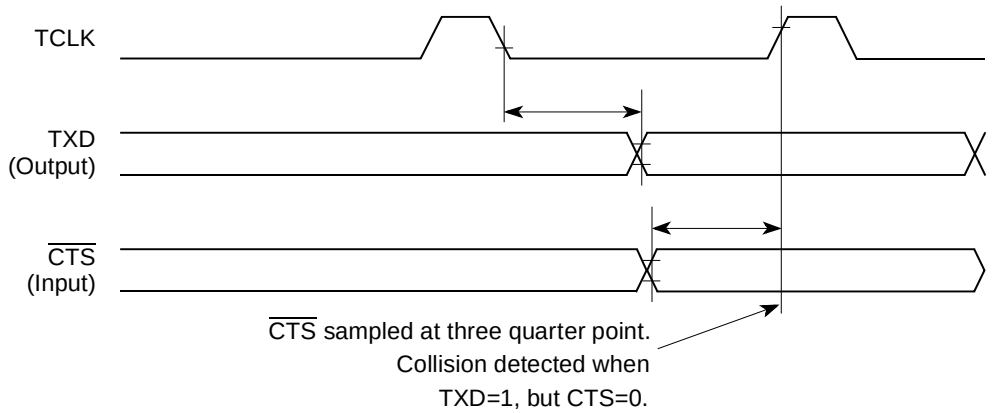

Figure 29-16. Non symmetrical Tx Clock Duty Cycle for Increased Performance

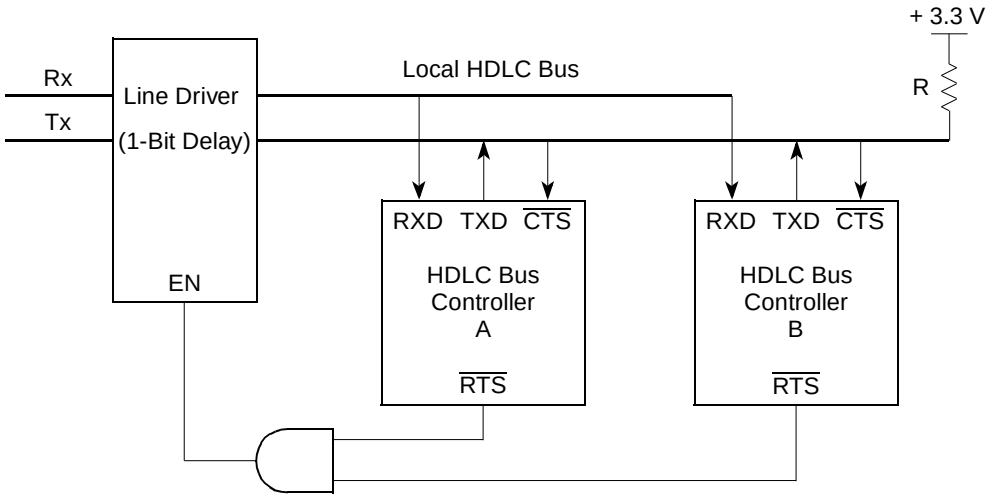
29.3.3.4 Delayed $\overline{\text{RTS}}$ Mode

Figure 29-17 shows local HDLC bus controllers using a standard transmission line and a local bus. The controllers do not communicate with each other but with a station on the transmission line; yet the HDLC bus protocol controls access to the transmission line.



NOTES:
1. The TXD pins of slave devices should be configured to open-drain in the port C parallel I/O port.
2. The RTS pins of each HDLC bus controller are configured to delayed RTS mode.

Figure 29-17. HDLC Bus Transmission Line Configuration

Normally, $\overline{\text{RTS}}$ goes active at the beginning of the opening flag's first bit. Setting UPSMR[BRM] delays $\overline{\text{RTS}}$ by one bit, which is useful when the HDLC bus connects multiple local stations to a transmission line. If the transmission line driver has a one-bit delay, the delayed $\overline{\text{RTS}}$ can be used to enable the output of the line driver. As a result, the electrical effects of collisions are isolated locally. Figure 29-18 shows $\overline{\text{RTS}}$ timing.

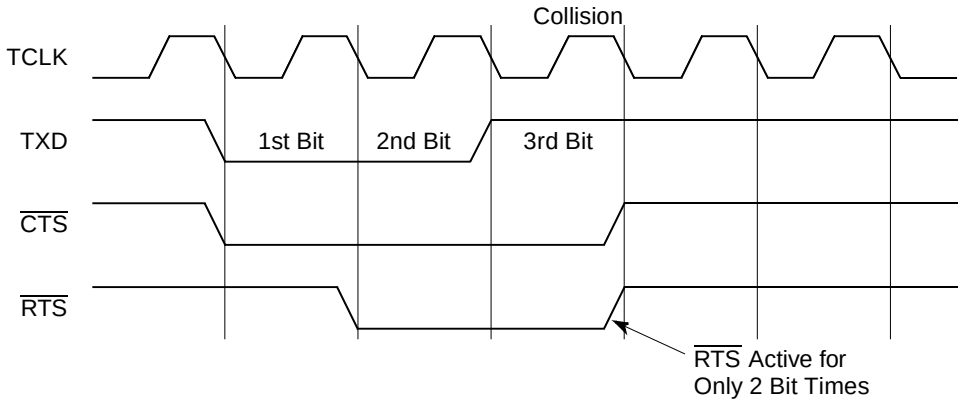


Figure 29-18. Delayed $\overline{\text{RTS}}$ Mode

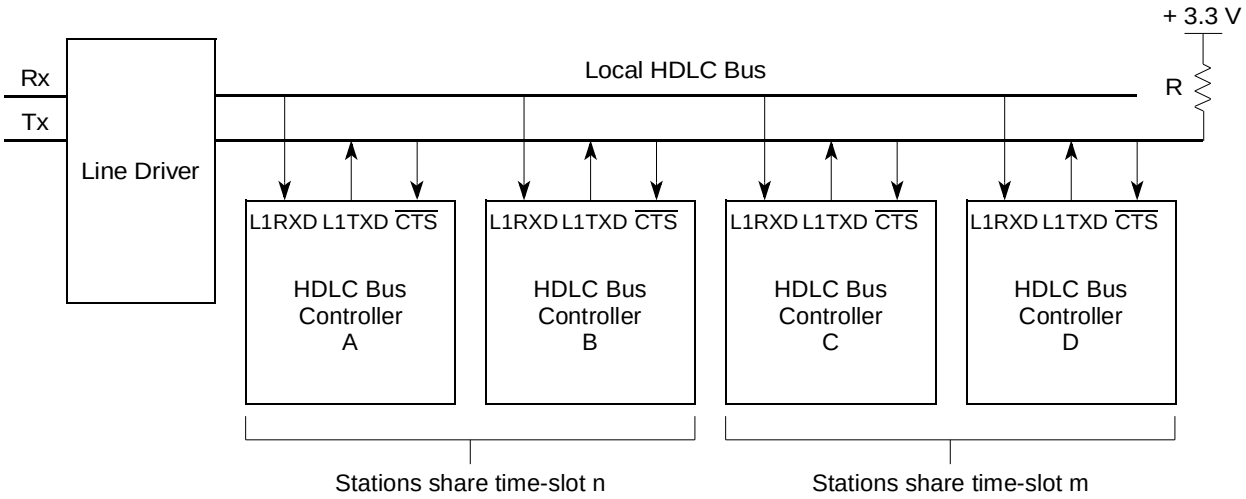
29.3.3.5 Using the Time Slot Assigner (TSA)

HDLC bus controllers can be used with a time-division multiplexed transmission line and a local bus, as shown in Figure 29-19. Local stations use time slots to communicate over the TDM transmission line; stations that share a time slot use the HDLC bus protocol to control access to the local bus.



NOTES:
1. All TXD pins of slave devices should be configured to open-drain in the port C parallel I/O port.
2. The TSA in the SI of each station is used to configure the preferred time slot.
3. The choice of the number of stations to share a time slot is user-defined. It is two in this example.

Figure 29-19. HDLC Bus TDM Transmission Line Configuration

The local UCCs in HDLC bus mode communicate only with the transmission line and not with each other. The UCCs use the TSA of the serial interface, receiving and sending data over L1TXD*x* and L1RXD*x*. Because collisions are still detected from the individual UCC $\overline{\text{CTS}}$ pin, it must be configured to connect to the chosen UCC. Because the UCC only receives clocks during its time slot, $\overline{\text{CTS}}$ is sampled only during the Tx clock edges of the particular UCC time slot.

29.3.3.6 HDLC Command Set

The transmit and receive commands are issued to the CECR; see Section 20.3.1, “QUICC Engine Command Register (CECR).”

Table 29-8 describes the transmit commands that apply to the HDLC controller.

Table 29-8. Transmit Commands

Command	Description
STOP TRANSMIT	After the hardware or software is reset and the channel is enabled in the UCC mode register, the channel is in transmit enable mode and starts polling the first BD in the table every 256 transmit clocks (immediately if FTODR[TOD] = 1). The STOP TRANSMIT command disables the transmission of frames on the transmit channel. If this command is received by the HDLC controller during frame transmission, transmission is aborted after a maximum of 64 additional bits are sent and the transmit FIFO buffer is flushed. The TBPTR is not advanced, no new BD is accessed, and no new frames are sent for this channel. The transmitter sends an abort sequence consisting of 0x7F (if the command was given during frame transmission) and begins sending flags or idles, as indicated by the HDLC mode register. Note that if UPSMR[MFF] = 1, one or more small frames can be flushed from the transmit FIFO buffer. The GRACEFUL STOP TRANSMIT command can be used to avoid this.
GRACEFUL STOP TRANSMIT	Used to stop transmission smoothly rather than abruptly, as performed by the regular STOP TRANSMIT command. It stops transmission after the current frame finishes sending or immediately if no frame is being sent. UCCE[GRA] is set once transmission has stopped. Then the HDLC transmit parameters (including BDs) can be modified. The TBPTR points to the next TxBD in the table. Transmission begins once the R bit of the next BD is set and the RESTART TRANSMIT command is issued.
RESTART TRANSMIT	Enables character transmission on the transmit channel. This command is expected by the HDLC controller after a STOP TRANSMIT command is issued and the channel in its UCC mode register is disabled, after a GRACEFUL STOP TRANSMIT command, or after a transmitter error (underrun or $\overline{\text{CTS}}$ lost with no automatic frame retransmission). The HDLC controller resumes sending from the current TBPTR in the channel TxBD table.
INIT TX PARAMETERS	Initializes all transmit parameters in this serial channel parameter RAM to their reset state. This command should only be issued when the transmitter is disabled. Notice that the INIT TX AND RX PARAMETERS command can also be used to reset the transmit and receive parameters.

Table 29-9 describes the receive commands that apply to the HDLC controller.

Table 29-9. Receive Commands

Command	Description
ENTER HUNT MODE	After the hardware or software is reset and the channel is enabled in the UCC mode register, the channel is in receive enable mode and uses the first BD in the table. The ENTER HUNT MODE command is generally used to force the HDLC receiver to abort reception of the current frame and enter the hunt mode. In hunt mode, the HDLC controller continually scans the input data stream for the flag sequence. After receiving the command, the current receive buffer is closed, the error status flags and length field are cleared, RxBD[E] (the empty bit) is set, and the CRC calculation is reset. Further frame reception uses the current RxBD.
INIT RX PARAMETERS	Initializes all the receive parameters in this serial channel parameter RAM to their reset state and should be issued only when the receiver is disabled. Notice that the INIT TX AND RX PARAMETERS command resets both receive and transmit parameters.

29.3.3.7 HDLC Error Handling

The HDLC controller reports frame reception and transmission error conditions using the channel BDs, error counters, and HDLC event register (UCCE). Table 29-10 describes HDLC transmission errors, which are reported through the TxBD.

Table 29-10. HDLC Transmission Errors

Error	Description
Transmitter Underrun	When this error occurs, the channel terminates buffer transmission, closes the buffer, sets the underrun (U) bit in the BD, and generates the TXE interrupt if it is enabled. The channel resumes transmission after receiving the RESTART TRANSMIT command.
$\overline{\text{CTS}}$ Lost during Frame Transmission	When this error occurs, the channel terminates buffer transmission, closes the buffer, sets TxBD[CT], and generates a TXE interrupt (if it is enabled). The channel resumes transmission after receiving the RESTART TRANSMIT command.

Table 29-11 describes HDLC reception errors, which are reported through the RxBD.

Table 29-11. HDLC Reception Errors

Error	Description
Overrun Error	The HDLC controller maintains an internal FIFO buffer for receiving data. The RISC begins programming the SDMA channel and updating the CRC whenever data is received in the FIFO buffer. When a receive FIFO overrun occurs, the channel writes the received data byte to the internal FIFO buffer over the previously received byte. The previous byte and the frame status are lost. The channel closes the buffer with RxBD[OV] set and generates the RXF interrupt, if it is enabled. The receiver then enters hunt mode. Even if the overrun occurs during a frame whose address is not matched in the address recognition logic, an RxBD with data length two is opened to report the overrun and the RXF interrupt is generated if it is enabled.
$\overline{\text{CD}}$ Lost During Frame Reception	When this error occurs, the channel terminates frame reception, closes the buffer, sets RxBD[CD], and generates the RXF interrupt if it is enabled. This error has highest priority. The rest of the frame is lost and other errors are not checked in that frame. At this point, the receiver enters hunt mode. When $\overline{\text{CD}}$ is lost during flags or during the first data byte, data does not transfer to the Rx FIFO.
$\overline{\text{CD}}$ Lost after frame reception	For GUMR[CDS]=1, if $\overline{\text{CD}}$ is deasserted 1 to 7 bit time after the closing flag, the channel report this as a new frame $\overline{\text{CD}}$ lost error. It close the RxBD, sets RxBD[CD], RxBD[Length]=1 and generates the RXF interrupt if it is enabled. At this point, the receiver enters hunt mode. In this mode, if CD do not envelope the frame, the line should go idle for 8 bit time or more before $\overline{\text{CD}}$ is deasserted to prevent this error. For GUMR[CDS]=0; if $\overline{\text{CD}}$ is deasserted 0 to 7 bit time after the closing flag the channel report this as a new frame $\overline{\text{CD}}$ lost error. In this mode, the line should go idle for 8 bit time or more before $\overline{\text{CD}}$ is deasserted to prevent this error
Abort Sequence	The HDLC controller detects an abort sequence when seven or more consecutive ones are received. When this error occurs and the HDLC controller receives a frame, the channel closes the buffer by setting RxBD[AB] and generates the RXF interrupt, if enabled. The channel also increments the abort sequence counter. The CRC and nonoctet error status conditions are not checked on aborted frames. The receiver then enters hunt mode. When an abort sequence is received, the user is given no indication that an HDLC controller is not currently receiving a frame.

Table 29-11. HDLC Reception Errors (continued)

<table>
<tr><th>Error</th><th>Description</th></tr>
<tr><td>Nonoctet Aligned Frame</td><td>When this error occurs, the channel writes the received data to the data buffer, closes the buffer, sets the Rx nonoctet aligned frame bit RxBD[NO], and generates the RXF interrupt, if it is enabled. The CRC error status should be disregarded on nonoctet frames. After a nonoctet aligned frame is received, the receiver enters hunt mode. An immediate back-to-back frame is still received. The nonoctet data portion may be derived from the last byte in the buffer by finding the least-significant set bit, which marks the end of valid data as follows:
<table>
<tr><td>msb</td><td></td><td></td><td></td><td></td><td></td><td></td><td>lsb</td></tr>
<tr><td colspan="4">Valid data</td><td>1</td><td>0</td><td>0</td><td>0</td></tr>
</table></td></tr>
<tr><td>CRC Error</td><td>When this error occurs, the channel writes the received CRC to the data buffer, closes the buffer, sets RxBD[CR], and generates the RXF interrupt, if it is enabled. The channel also increments the CRC error counter. After receiving a frame with a CRC error, the receiver enters hunt mode. An immediate back-to-back frame is still received. CRC checking cannot be disabled, but the CRC error can be ignored if checking is not required.</td></tr>
</table>

29.4 Initialization Information

29.4.1 HDLC Bus Protocol Programming

The HDLC bus on the QUICC Engine module is implemented using the UCC in HDLC mode with bus-specific options selected in the UPSMR and GUMR, as outlined below.

29.4.1.1 Programming GUMR and UPSMR for the HDLC Bus Protocol

To program the protocol-specific mode register (UPSMR), set the bits as described below:

- Configure NOF as preferred
- Set RTE and BUS to 1
- Set BRM to 1 if delayed $\overline{\text{RTS}}$ is desired
- Configure CRC to 16-bit CRC CCITT (0b00).
- Configure other bits to zero or default.

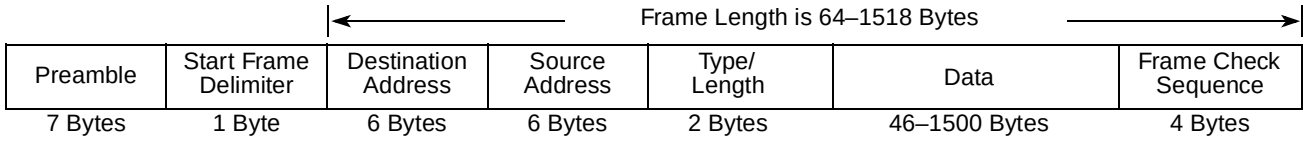
To program the general UCC mode register (GUMR), set the bits as described below:

- Set MODE to HDLC mode (0b0000).
- Configure CTSS to 1 and all other bits to zero or default.
- Configure the DIAG bits for normal operation (0b00).
- Configure TENC and RENC for NRZ (0b000).
- Clear RTSM to send idles between frames.
- Set GUMR _L[ENT, ENR] as the last step to begin operation.

Chapter 30
UCC Ethernet Controller (UEC)

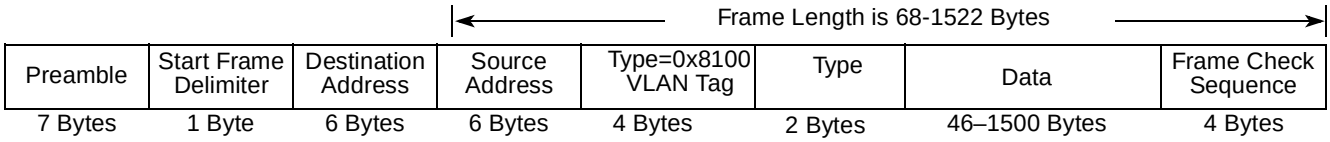
30.1 Introduction

The Ethernet IEEE Std 802.3 protocol is a widely-used LAN, based on the carrier-sense multiple access/collision detect (CSMA/CD) approach. Because Ethernet and IEEE Std. 802.3 protocols are similar and can coexist on the same LAN, both are referred to as Ethernet in this manual, unless otherwise noted. Ethernet/IEEE Std. 802.3 frames are based on the frame structure shown in Figure 30-1.



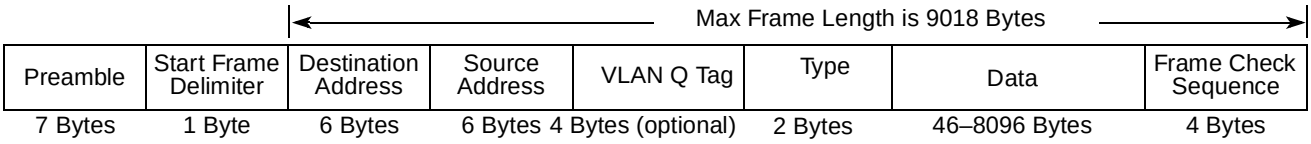
Note: The lsb of each octet is transmitted first.

Figure 30-1. Untagged Ethernet Frame Structure



Note: The lsb of each octet is transmitted first.

Figure 30-2. VLAN Tagged Ethernet Frame Structure



Note: The lsb of each octet is transmitted first.

Figure 30-3. VLAN Tagged Jumbo Ethernet Frame Structure

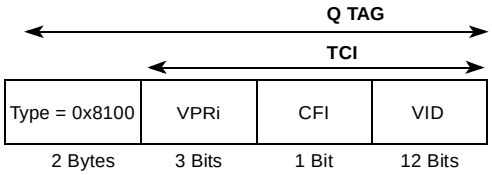


Figure 30-4. VLAN Q TAG

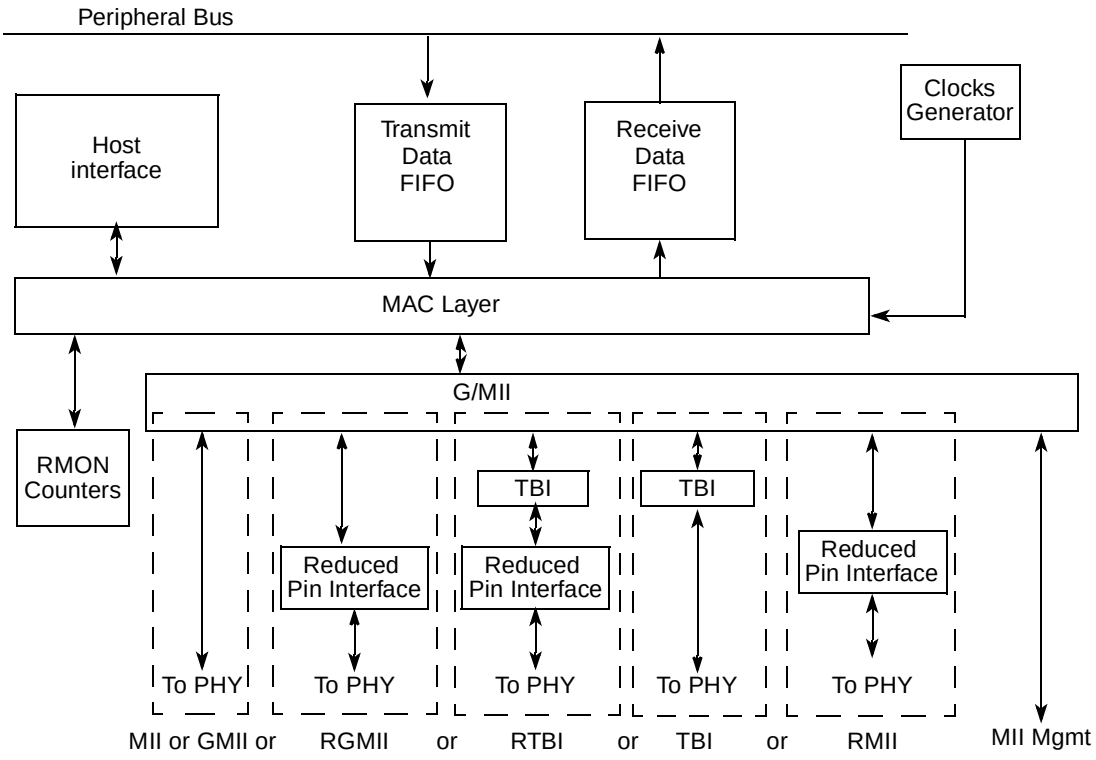
Note that the maximum frame length is user programmable. The figures depict a few examples.

The elements of an Ethernet frame are as follows:

- 7-byte preamble of alternating ones and zeros
- Start frame delimiter (SFD)—Signifies the beginning of the frame
- 48-bit destination address
- 48-bit source address—Original versions of the IEEE Std. 802.3 specification allowed 16-bit addressing, which has never been widely used.
- Ethernet type field/IEEE Std. 802.3 length field. The UEC considers the two bytes immediately following the MAC source address as the frame length if its numerical value is less or equal to 0x600. Otherwise the field is considered as a type field. Specifically, if a value of 0x8100 is detected, the UEC assumes a VLAN tag is present.
- Data
- 4-byte frame-check sequence (FCS), which is the standard 32-bit CCITT-CRC polynomial used in many protocols.

Figure 30-5 describes the block diagram of the UCC Ethernet controller.



Note: The TBI and RTBI are not available on all UCCs

Figure 30-5. UCC Ethernet Controller Block Diagram

30.2 Overview

The UCC Ethernet Controller is a 10/100/Gigabit Ethernet Controller. The UEC, supports several standard MAC-PHY interfaces to connect to an external Ethernet transceiver.

- 10/100 Mbps MII interface (IEEE 802.3-2002 standard)

- RMII interface
- 1000 Mbps GMII interface (IEEE 802.3 -2002standard)
- 1000 Mbps TBI interface (IEEE 802.302002 standard)
- 1000 Mbps RGMII/RTBI reduced interface

The RMII interface (low pin count Reduced Media Independent Interface as specified by the RMII Consortium™ standard), is a reduced MII interface. The purpose of this interface is to provide a low cost alternative to the MII, with an 8-pin interface instead of 16 (MDC and MDIO pins not included).

The GMII/MII provides a standard interface between the MAC layer and the physical layer for 10/100/1000 Mbps operations. It isolates the MAC layer and the physical layer, enabling the MAC layer to be used with various implementations of the physical layer.

The TBI provides connectivity between a 1000 Mbps MAC and 1000BASE-X SERDES.

30.3 Features

The UCC Ethernet Controller includes the following features:

- Support for different Ethernet physical interfaces:
  - 10/100 Mbps IEEE Std. 802.3 MII
  - 10/100 Mbps RMII (Consortium standard)
  - 1000 Mbps IEEE Std. 802.3-2002 GMII
  - 1000 Mbps IEEE Std. 802.3-2002 TBI
  - 1000 Mbps only supports full-duplex RTBI
  - 10/100/1000 Mbps RGMII reduced interface
- Supports all RMII specification features:
  - Capable of supporting 10 and 100 Mbps data rates
  - Supporting half- and full-duplex 10/100Mbps
  - Provides independent 2-bit wide (di-bit) transmit and receive data paths
- Support half-duplex back-pressure (10/100 Mbps only)
  - Backpressure Control via Host Command
  - Automatic backpressure according to programmable Receive Thresholds (LossLess Flow Control)
- Supports PAUSE Flow Control for full duplex operation
  - Transmit Flow Control via a Host command
  - Automatic Transmit Automatic Flow Control according to programmable Receive FIFO Thresholds
  - Programmable MAC Parameter in Flow Control frame
  - Automatic resend of Flow Control frame if MAC parameter has expired and FIFO is still full
- Full collision support:
  - Enforce collision (jamming and TX_ER assertion)

  - Truncated binary exponential backoff algorithm for random wait
  - Automatic frame retransmission (until retry limit is reached)
  - Retransmission from transmit FIFO following a collision
  - Automatic discard of incoming collided frames
  - Delay transmission of new frames for specified interframe gap
    - Programmable IFG duration for back-to-back frames
    - Supports Defer
- Performs framing functions
  - Preamble generation and stripping
    - Programmable preamble size on transmit side
    - Optional Recognition of user defined preamble, and placement of preamble as part of data
    - Optional Transmission of user defined preamble
  - CRC generation and checking
  - Framing error handling
- Automatic padding of short frames on transmit to 64 bytes
  - Global Mode
  - Frame Based
- Detection of all erroneous frames as defined by IEEE Std. 802.3-2002
  - Filtering of erroneous frames
  - Statistics gathering
- Multi-buffer data structure
- Diagnostic mode:
  - Internal and external loopback mode
  - Echo mode (MII and RMII modes)
- Serial management interface MDC/MDIO
- Transmitter network management and diagnostics
  - Lost carrier sense
  - Underrun
  - Number of collisions exceeded the maximum allowed
  - Number of retries per frame
  - Deferred frame indication
  - Late collision
  - Excessive deferred frame indication
  - Error reporting modes
    - Per frame reporting in 10/100 (compatible with PowerQUICC II)
    - Interrupt based reporting for Gigabit rates
- Receiver network management and diagnostics

  - CRC error indication
  - Nonoctet alignment error
  - Frame too short/long
  - Overrun
  - Busy (out of buffers)
- Frame Filtering and Address recognition
  - MPC82xx backward compatible filtering mode
    - Five 48-bit addresses recognized or 64-bin hash table for physical address
    - 64-bin Group Address Hash Table
    - Optional Broadcast address filtering
    - Promiscuous Mode. Receives all frames regardless of address
    -
  - Programmable Parse Command Descriptor (PCD) mode
    - Programmable field Extraction: MAC src, MAC dst, VLAN Tag
    - Internal/External Lookup Tables with programmable size
    - Internal CAM Emulation or four way Hash based Lookup Modes
    - Programmable Match Actions: Receive, Reject
- Programmable maximum frame length
- Enhanced MIB statistics
  - Supports IEEE Std. 802.3-2002 Layer management for DTE
    - IEEE 1GE Management Enhancements
    - MAC Entity managed Objects
    - MAC Control entity managed object
    - PAUSE entity managed objects
  - Supports IEEE Std. 802.3-2002 Layer Management for Base Band repeaters
  - Supports IETF RFC 2819 / STD0059- RMON MIB
  - Supports IETF RFC 3635 Managed Object for Ethernet like Interface
  - Extensions to the standard statistics is added in order to adapt it to an environment with non-standard length (Jumbo frames, Tagged frames)
  - Enhanced transmitter statistics for non-CPU operation
- VLAN Support
  - Optional VLAN Tag extraction and insertion on Received Frames
  - Optional VLAN Tag insertion on Transmitted frames
  - Optional Enqueueing by VLAN priority field
  - Optional Filtering by VLAN Tag in Extended Parsing mode
- Supports IEEE Std. 802.1p/Q QoS with up to 8 Tx/Rx priority queues
  - Up to eight Tx/Rx BD rings to satisfy QoS requirements.

  - Receive queueing based on VLAN priority, IPv4 TOS field or IPv6 TC
  - Transmit Scheduler with SPQ/WFQ and Rate Limiter
- Optional L3 header checksum calculation
- Supports two Interrupt Modes
  - PQ2 compatible interrupts enabled on a per frame basis
  - Interrupt coalescing on Received frames.
  - Programmable threshold per receive queue
  - Programmable coalescing timeout
- Optional Shift of Data buffer by two bytes for L3 header alignments
- Extended Features
  - Queuing decision based on VLAN Priority or L3 IPv4 TOS field
  - IP header checksum verification and calculation
- Magic Packet Detection for Low Power Systems
- Support for Loss Less Flow Control
- Support for IEEE Std. 1588

30.4 Functional Description

30.4.1 Ethernet Frame Transmission

30.4.1.1 Ethernet Tx Flow

The Ethernet transmitter requires little core intervention. After the software driver initializes the system, the UCC Ethernet Controller (UEC) activates its transmit scheduler. As a result the UEC begins to poll the first Transmit Buffer Descriptor (TxBD) in one of the (up to) eight transmit queues as chosen by the scheduler. The TxBD ring is polled by the QUICCEngine. The user may program the polling time in UPTP register in the UCC. The deafult polling time is 256 transmit clocks. If TxBD[R] is set, the UCC Ethernet Controller begins moving transmit buffer from memory to the Tx Virtual FIFO. The Ethernet MAC transmitter takes data from Tx Virtual FIFO and transmits the data through the appropriate interface (TBI/RTBI/GMII/RGMII/MII/RMII) to the physical media. The transmitter, once initialized, runs until the end-of-frame (EOF) condition is detected, unless a collision within the collision window occurs (in half-duplex mode) or an abort condition is encountered.

The UEC transmit scheduler is designed to schedule up to eight queues for transmission. The scheduler combines both strict priority queues (SPQ) and weighted fair queues (WFQ). This allows the user to map latency-sensitive data transmissions to the strict priority queues, while bandwidth dependent data transmissions are mapped to the weighted fair queues. In addition, the scheduler maintains a rate limiter. The rate limiter allows limiting the average bit rate transmitted by the Gigabit Ethernet Port.

If the user has a frame ready to transmit, setting Transmit on Demand bit (UCC[TODR]) eliminates waiting for the next poll; the MAC immediately fetches the next Buffer Descriptor. The actual transmission on the line begins once all data for the frame is loaded into Tx Virtual FIFO or sufficient

transmit data (determined by the Tx FIFO threshold register) is in Tx Virtual FIFO. The MAC asserts TX_EN and sends the preamble sequence, start frame delimiter, and frame information in that order.

In half duplex mode, the transmitter waits for the carrier sense signal, CRS, to remain inactive for 60 bit times and transmission begins after an additional 36-bit times (96-bit times after CRS became active); refer to Table 30-1. When a station starts transmitting, it continually checks for collisions on the LAN. If a collision is detected, the station forces a jam of all ones on its frame and stops transmitting. Collisions usually occur close to the beginning of a frame. The station then waits a random period of time (backoff) before attempting to transmit again. Once the backoff completes, the station waits for silence on the LAN and then begins retransmission. This process is called a retry. If the frame is not successfully transmitted within 15 retries, an error is indicated.

Table 30-1. Ethernet Parameters Periods

	10 Mbps	100 Mbps	1000 Mbps
Transmit rate per byte	0. 8 us	0.08 uµs	0.008 uµs
Preamble plus SFD	6.4 us	0.64 µus	0.064 uµs
Interframe gap	9.6 µus	0.96 µus	0.096 uµs
Slot time	51.2 µus	5.12 uµs	4.096 uµs

In full-duplex mode, because collisions are ignored, frame transmission maintains only the interframe gap (96-bit times) regardless of CRS. If CRS continues to be asserted, MAC follows a specified back-off procedure and tries to retransmit the frame until the retry limit is reached. Data stored in Tx FIFO is retransmitted in case of a collision. This improves bus usage and latency.

The transmitter also monitors for an abort condition and terminates the current frame if an abort condition is encountered. In full-duplex mode, the protocol is independent of network activity, and only the transmit inter-frame gap must be enforced.

The UCC Ethernet Controller (UEC) implements automatic full-duplex flow control. If a flow control frame is received, the MAC does not send data until the pause duration is over. If MAC is currently sending data when a pause frame is received, it finishes sending the current frame, then suspends subsequent frames (except a pause frame) until the pause duration is over. For the latter, the MAC starts the timer while transmission is still in progress. According to 802.3, Annex 31B the pause period should start after completing the current transmit frame. This effectively shortens the desired PAUSE time, and it should not really be a problem from the user’s perspective unless the pause period is very short. In such cases it is advised to increase the pause time.

In addition, the UEC supports transmission of flow control frames (pause frames). Two mechanisms are provided: Automatic Flow control and CPU controlled flow control

The user may program the UEC to automatically appends FCS (32-bit CRC) at the end of the frame. The following bits in the programming model (if set) enable CRC generation:

- TxBD[PAD/CRC] is set in the last Tx BD
- TxBD[TC] is set in the last Tx BD
- MACCFG2[PAD/CRC] is set
- MACCFG2[CRE] is set

The following table specifies the behavior of the UEC depending on the bit programming:

Table 30-2. Tx CRC and PAD Mode

TxBD[PAD/CRC]	TxBD[TC]	MACCFG2[PAD/CRC]	MACCFG2[CRE]	CRC	PAD (frames of size under 64 bytes)
ignored	ignored	1	ignored	All frames	All relevant frames
0	ignored	0	1	All frames.	No
1	ignored	0	1	All frames	Padding of frames which have TxBD[PAD/CRC] set.
0	0	0	0	No	No padding
0	1	0	0	User programmable per BD	No padding
1	ignored	0	0	Padding of frames which have TxBD[PAD/CRC] set.	

Following the transmission of FCS, the Ethernet Controller writes the frame status bits into the BD and clears TxBD[R]. If the end of the frame if reached (TxBD[L]=1) the Ethernet controller updates the status bits in the Tx BD.

If TxBD[PAD/CRC] is set, the Ethernet Controller pads any frame shorter than 64 bytes. Note that transmitter padding is done to 64 bytes regardless of the presence of a VLAN tag in the frame.

A graceful transmit stop is used to pause transmission. The Ethernet controller stops immediately if no transmission is in progress or continues transmission until the current frame either finishes or terminates with an error. The UCCE[GRA] interrupt occurs once the graceful transmit stop operation is completed.

The UEC optionally inserts a VLAN Tag to the frame immediately after the MAC source address. The user may program the UEC to choose one of eight possible VLAN Tag values on a per frame basis. Note that some restrictions apply on the TxBD and data buffer when this mode is enabled. These restrictions are specified in the TxBD programming model.

The UEC supports Tx enhanced performance mode to improve packet processing rate performance. The performance enhancement mode is programmable and can be set in the UCC parameter RAM. When this mode is activated there is a restriction on the TxBD ring size: The size of the TxBD ring must be greater than the maximum number of BDs associated per frame

While the UEC is in 10/100 Mbps mode it sends the least significant nibble of each byte first. While it is in 1000 Mbps mode it sends the least significant bit of each byte first.

30.4.2 Ethernet Frame Reception

The UCC Ethernet Controller receiver is designed to work with little core intervention and can perform pattern matching, data extraction, address recognition, Ethernet type recognition, CRC checking, VLAN detection, short frame checking, and maximum frame-length checking.

After a hardware reset, the software driver initializes the Parameter RAM and the configuration register, issues an INIT Rx Tx Host Command, and then sets MACCFG1[RX_EN]. The Ethernet receiver is enabled and immediately starts processing receive frames.

The MAC hardware checks when RX_DV is asserted, it looks for the start of a frame by searching for a valid preamble/SFD (start of frame delimiter) header, which is stripped and the frame begins to be processed. If a valid header is not found, the frame is ignored. Part of the preamble is (optionally) user configurable.

If the receiver detects the first bytes of a frame, the UCC Ethernet Controller begins to perform the frame recognition function (i.e. Filtering). Two modes are supported: MPC82xx backward compatible frame filtering, and Extended Frame Filtering mode. The Extended Parsing supports large memory based lookup tables. As a result of the frame recognition function the UEC either receives or discards the frame. On received frames larger than 64bytes the user may enable header manipulation (insert/replace/remove of VLAN TCI field).

In MPC82xx mode the receiver can also filter frames based on physical (individual), group (multicast), and broadcast addresses.

If a frame is accepted, the UEC fetches Receive Buffer Descriptor (RxBD) from FIFO. If RxBD is not being used by the software (RxBD[E] is set), UEC starts transferring the incoming frame. RxBD[F] is set for the first RxBD used for any particular receive frame.

When the buffer is filled, the UEC clears RxBD[E] and, if enabled the UEC, generates an interrupt. If the incoming frame is larger than the buffer, the Ethernet controller fetches the next RxBD in the table. If it is empty, the controller continues receiving the rest of the frame. In half-duplex mode, if a collision is detected during the frame, no RxBD's are used; thus, no collision frames are presented to the user except late collisions, which indicates LAN problems.

The length of the data buffer associated with the RxBD, is determined by the MRBLR field in the UCC Parameter Ram. The smallest valid value is 128 bytes. During reception, the Ethernet controller checks for frames that are too short or too long.

After the frame ends (CRS is negated), the receive CRC and (optionally) the checksum fields are checked and written to the data buffer. If header manipulation is enabled, the value of the CRC written by the UEC at the end of the data buffer is not valid, and needs to be recalculated in case the frame is transmitted on an other port.

The data length written to the last RxBD in the Ethernet frame is the length of the entire frame, which enables the software to recognize a frame-too-long condition.

After the receive frame is complete, the UCC Ethernet Controller (UEC) sets RxBD[L], updates the frame status bits in the RxBD, and clears RxBD[E]. If RxBD[I] is set, the Ethernet controller generates a maskable interrupt indicating that a buffer was received and is in memory. If Receive frame interrupt is unmasked, and the interrupt coalescing counter has expired, the UEC issues an interrupt at the end of the frame.

The UEC receives serial data least-significant nibble first. While it is in 1000Mbps mode it receives the least-significant bit of a byte first.

30.4.3 Interframe Gap Time

If a station must transmit, it waits until the LAN becomes silent for a specified period (inter-frame gap). After a station begins sending, it continually checks for collisions on the LAN. If a collision is detected,

the station forces a jam signal (all ones) on its frame and stops transmitting. Collisions usually occur close to the beginning of a frame. The station then waits a random time period (back-off) before attempting to send again. After the back-off completes, the station waits for silence on the LAN and then begins retransmission on the LAN. This process is called a retry. If the frame is not successfully sent within a specified number of retries, an error is indicated.

The minimum inter-frame gap time for back-to-back transmission is 96 serial clocks. The receiver receives back-to-back frames with this minimum spacing. In addition, after waiting a required number of clocks (based on the backoff algorithm), the transmitter waits for carrier sense to be negated before retransmitting the frame. Retransmission begins 36 serial clocks after carrier sense is negated for at least 60 serial clocks.

If a collision occurs during frame transmission, the Ethernet controller continues transmission for at least 32-bit times, transmitting a jam pattern of 32 ones. If the collision occurs during the preamble sequence, the jam pattern is sent after the sequence ends.

If a collision occurs within 64-byte times, the process is retried. The transmitter waits a random number of slot times (A slot time is 512-bit times for 10/100) If a collision occurs after 64-byte times, no retransmission is performed, UCCE[TXE] is set, and the buffer is closed with a late-collision error indication in TxBD[LC]. If a collision occurs during frame reception, reception is stopped. This error is reported only in the RxBD if the frame is at least as long as the MINFLR or if UPSMR[RSH] = 1.

NOTE

The inter-frame gap between back-to-back frames may be programmable (in the IPGIFG register)

The rate limiter in the scheduler increases the actual Inter Frame Gap, from the minimum allowed in the standard, thus limiting the average bit rate on the line.

30.4.4 Multithreading

The UEC processes frames at wirespeed at rate of up to 1Gbps rates. In order to support this rate, the UEC receiver and the UEC transmitter are able to process a programmable number of frames at one time. This is implemented with the multithreading mechanism. Each thread processes a different frame. The suggested number of threads for Gigabit Ethernet is four threads. The INITETHERNET command programs the data structures needed for multithreading. See Section 30.8, “Ethernet Command Set,” for more details.

The QUICC Engine has multiple RISC Engines. The architecture supports real-time dynamic task assignment to the RISCs. This is achieved by programming the RISC Allocation Entry in the INIT RX AND TX Host Command to 0x3. It is possible for the user to assign each task to a specific RISC in a static way. This may be done by modifying the RISC Allocation Entry in the INIT RX AND TX Host Command.

30.4.5 Virtual FIFO

The UEC Receive and Transmit Virtual FIFOs are divided into blocks of 128 bytes each. With this FIFO configuration the UEC handles frames of up to 128 bytes in an optimal manner. The size of the Virtual FIFO is software configurable by programming the URFS and UTFS registers. See Section 27.5, “Fast Protocol FIFO Configuration Registers,” for suggested value of Virtual FIFO size. The size of Virtual

FIFO allocated for the UEC Transmitter and for the UEC receive depends on the bit rate, frame size, and overall load of the system bus and the QE.

NOTE

For the Rx Virtual FIFO, the user MUST allocate a memory block of size URFS+8 bytes in the multiuser RAM.

NOTE

For the Tx Virtual FIFO, if more than one thread is used, the minimum size of virtual FIFO is 816 bytes.

30.4.5.1 Virtual FIFO Overun Smoother

Overrun on the receive Virtual FIFO occurs when the QE is not able to remove data from the Virtual FIFO at the rate that the data is placed into the FIFO from the line. This condition causes the Virtual FIFO to fill up beyond its capacity, so incoming frames are discarded. With the Virtual FIFO Overrun smoother, the QE removes a programmable number of frames (OV_SkipFrame) from the Virtual FIFO, when an OV condition is detected. This feature is needed for performance enhancement in the case that the QE is heavily loaded.

In order to determine the correct value for the OV_SkipFrame parameter, the user should take the following steps:

Determine the maximum sustained Rx bit rate that can be supported by the QE without Virtual FIFO overrun (OV) condition. This variable is called ‘Sustained_Rx’ (Mbps).

Determine the maximum Rx bit under burst condition (probably 1Gbps). This variable is called ‘Burst_Rx’ Mbps.

Determine the average packet size in bytes. This variable is called ‘Ave_Pkt_Size’.

The value of OV_SkipFrame is:

*OV_SkipFrame > (Burst_Rx / Sustained_Rx) * (UCC Rx Virtual FIFO size in bytes / Ave_Pkt_Size)*

As an example:

Sustained_Rx = 333Mbps

Burst_Rx = 1Gbps

Ave_Pkt_Size = 256 bytes

UCC Rx Virtual FIFO size = 2Kbytes

*OV_SkipFrame = 1Gbps/333Mbps * 2048/256 = 24*

30.4.6 Termination and Interworking Modes of Operation

The receiver of the UCC Ethernet Controller is able to perform the following functions:

- Terminate frames to a CPU queue and issue a maskable interrupt

- Forward frames to an Etherent transmit queue (in the same port, or in an other port)
- Forward frames to an AAL5 or AAL2 Tx queue
- Forward frames to an ML/MC PPP or plain PPP Tx queue
- Terminate frame to a the CPU queue after forwarding and issue a maskable interrupt

30.4.7 IP Header Checksum

The UEC may programmed to check IP header checksum on the receiver, and generate IP header checksum on the transmitter.

On the receive side, if this feature is enabled in REMODER, the receive automatically checks the IP frame checksum, and reports an error in the RxBD. The UEC parses Ethernet frames (Etype > 0x600 programmable value) or 802.3 frames with a SNAP header. There are a number of restrictions on the types of frames the chcksum is calculated on the receive side.

In termination mode (REMODER[IWEn]=0) (MPC82xx legacy mode or Extended parsing and filtering mode): IPchecksum check is operational only on incomig frames without a VLAN Tag or on incoming frames which have one VLAN Tag.

On the transmit side, If enabled (in TEMODER) the user indicates to the UEC the offset from the beginning of the frame where the IP header starts. On a per frame basis (in the TxBD) it is possible to choose one out of eight user programmable offsets (programmed in the Tx Parameter RAM). Note that if the offset is programmed to 0xFF, checksum is not calculated. Also note that the value of the IP checksum in the IP header places by the CPU in memory must be zero. The IP header must reside in the first 128 bytes of the frame, and in the first data buffer (first TxBD).

The IPv4 header checksum is calculated by breaking up the header (including any options) into a sequence of 16-bit words, summing the words as a one s compliment sum, and performing a one s compliment (bit wise inversion) of the result. The header checksum field is initialized to zero in forming the original sum. One s complement summation is implemented most easily as a normal binary summation, but with the any carries out of the MSB being counted and summed back into the result until no more carries occur.

30.4.8 Flow Control

Flow Control is a mechanism for limiting the bit rate of the received frames when congestion is detected in the system. This is achieved by transmitting the Flow Control frame from the congested port. Flow-control instructions are transferred by special frames of minimum frame size. The length/type fields of these frames have a special value. Table 30-3 shows the flow-control frame structure.

Table 30-3. Flow Control Frame Structure

Size [Octets]	Description	Value	Comment
7	Preamble		
1	SFD		Start frame delimiter
6	Destination address	01-80C2-00-00-01	Multicast address reserved for use in MAC frames
6	Source address		
2	Length/type	88-08	Control frame type

Table 30-3. Flow Control Frame Structure (continued)

Size [Octets]	Description	Value	Comment
2	MAC opcode	00-01	Pause command
2	MAC parameter		Pause period measured in quanta of 512 bits time most-significant octet first.
2	Extension Field		As programmed in UEMPR register. See Section 30.5.1.17, "UCC Ethernet Mac Parameter Register (UEMPR)."
40	Reserved	—	
4	FCS		Frame check sequence (CRC)

30.4.8.1 Transmitting Flow Control Frames

The UEC has two mechanism for transmitting flow control frames:

- Hardware initiated Flow Control frames
- Host CPU initiated Flow Control frames

The hardware initiated Flow Control frames occur when the when the UCC Receive FIFO has reached a programmable threshold (UCC receive virtual FIFO emergency Threshold Register - URFET, see Section 27.5.3, "Receive Virtual FIFO Emergency Threshold (URFET)." The MAC Parameter is user programmable. The hardware automatically transmits additional Flow Control frames when the MAC parameter has expired unless the UCC receive FIFO is below the threshold. Also, if the Virtual FIFO has reached its low threshold, the UEC automatically transmits a Flow Control Frame with its MAC parameter set to zero, thus enabling the other side to resume transmission. The Automatic flow control mode is be enabled by setting UPSMR[AUFC] bit to one. It is possible to send an other pause frame while the pause timer has not expired. Therefore when the Receive FIFO is below the threshold, the UEC sends a Pause Control Frame with MAC parameter set to zero.

For CPU controlled flow control, the CPU issues a START FLOW CONTROL command to the QE via the CECR command register. The CPU specifies the value of the MAC Parameter in the UEMPR[PT] register. In order to send a Flow Control frame with MAC Parameter set to zero, the CPU issues a STOP FLOW CONTROL command.

Note that if the UEC detects nested Control frames (i.e. CPU control frame nested in the automatic control frame mechanism), it does not automatically transmit the Flow Control frame with zero MAC parameter. In this event, when the receive FIFO is below the threshold, a zero MAC parameter Flow Control frame is automatically sent by the UEC, only after the CPU has initiated a zero parameter Control Frame. In other words; the UEC actually transmits a FC frame with MAC Parameter = 0 if two conditions are met:

- The CPU has issues a STOP FLOW CONTROL command
- The Rx FIFO is filled below the URFET threshold

30.4.8.1.1 Loss Less Flow Control

The LossLess flow control feature is enabled by setting REMODER[LossLessFCEn] = 1. If enabled, the UEC transmits a Flow Control frame if the corresponding Rx BD Ring has reached a threshold. BDx LossLess FC Threshold contains the threshold for each one of the RxBDs in terms of the number of empty

RxBDs. If the UEC detects a condition in which there are fewer empty RxBDs than programmed in the threshold, a flow control frame is automatically transmitted.

Every time the CPU handles an RxBD, it must update the pointer to the next RxBD in the entry corresponding to the RxBD ring in the LossLess Flow Control Table. The CPU must update the BDx CPU BD Pointer with the pointer to the Buffer descriptor of the first RxBD that was not handled. Note that if the RxBD has the 'W' bit set, the CPU then must place the pointer to the first RxBD in the RxBD ring. It is strongly advised to write the value of the pointer without any read transaction for the CPU (for minimal performance impact).

The CPU must set the 'BDx LossLess FC Threshold' to a value that ensures that there are always some empty RxBDs in the RxBD ring. The number of empty RxBDs are MTU/MRBLR + 5 + N. MTU is the Maximum Transfer Unit (max frame size). If MTU > MAXD1 or MAXD2 then the number of empty RxBDs is MTU/MAXD1 + 5 + N.

N is determined as follows: All the frames temporarily located in the Virtual FIFO must have an empty RxBD available. In the worst case condition the Virtual FIFO is filled with the minimum size frame (i.e. 64 byte frames). Therefore N = Virtual FIFO size / (64+8) bytes.

30.4.8.2 Receiving a Flow Control Frame

When flow-control mode is enabled (MACCFG1[RFCE] is set) and the receiver identifies a pause-flow control frame sent to individual or broadcast addresses, transmission stops for the time specified in the control frame. During this pause, only the pause frame can be sent. Normal transmission resumes after the pause timer stops counting. If another pause-control frame is received during the pause, the period changes to the new value received.

All received FC Frames are mapped to the default receive queue as programmed in TCI field in the Global Rx Parameter RAM.

30.4.8.3 Back Pressure

Full-duplex flow control is provided for in IEEE Std. 802.3x. Currently the standard does not address flow control in half-duplex environments. Common in the industry, however, is the concept of back pressure. The UEC implements the optional back pressure mechanism using the raise carrier method. If the system receive logic wishes to stop the reception of packets in a network-friendly way, transmit half-duplex flow control (THDF) is set. If the medium is idle, the UEC raises the carrier by transmitting preamble. Other stations on the half-duplex network then defer to the carrier.

In the event the preamble transmission happens to cause a collision, UEC ensures the minimum 96-bit presence on the wire, then drops preamble and waits a back-off time depending on the value of the configuration bit, back pressure no back-off (half-duplex). These transmitting-preamble-for-back-pressure collisions are not counted. If HAFDUP[BPNB] is set, the UEC waits an inter-packet gap before resuming the transmission of preamble following the collision and does not defer. If cleared, the UEC adheres to the truncated BEB algorithm that allows the possibility of packets being received. This also can be detrimental in that packets can now experience excessive collisions, causing them to be dropped in the stations from which they originate. To reduce the likelihood of lost packets and packets leaking through the back pressure mechanism, BPNB must be set.

The UEC drops the carrier (ceases transmitting preamble) periodically to avoid excessive defer conditions in other stations on the shared network. If, while applying back pressure, the UEC is requested to send a packet, it stops sending preamble, and waits one IPG before sending the packet. HAFDUP[BPNB] applies for any collision that occurs during the sending of this packet. Collisions for packets while THBP is asserted are counted. UEC does not defer while attempting to send packets while in backpressure.

30.4.9 Frame Filtering and Address Recognition

The UEC supports two address recognition modes:

- MPC82xx backward compatible filtering mode
- Programmable Parse Command Descriptor (PCD) mode

30.4.9.1 MPC82xx Compatible Address Filtering Mode

In the MPC82xx backward-compatible filtering mode (REMODER[EXP]=0) the UCC Ethernet Controller (UEC) implements MPC82xx compatible filtering mode based on Destination MAC Address. In this mode the UEC filters the received frames based on different addressing types—physical (individual), group (multicast), broadcast (all-ones group address), and promiscuous. The difference between an individual address and a group address is determined by the I/G bit in the destination address field. Figure 30-6 is a flowchart for address recognition on received frames. In the physical type of address recognition, the UCC Ethernet Controller (UEC) first compares the MAC destination address field of the received frame with the physical address that the user programed in MACSTNADDR1,2 registers. If the comparison fails, and if REMODER[EXF]=1 (extended features are enabled) the UEC compares the MAC destination address field to the PADDR_H1..4]and PADDR_L1..4 entries programmed by the user in the Rx global parameter RAM. It is possible to change the values of PADDR1..4 on the fly. The UEC Rx filtering behavior is unpredictable during the time that these values are changed.

If it fails, the controller performs address recognition on multiple individual addresses using the IADDR_H/L hash table.

In the group type of address recognition, the Ethernet Controller determines whether the group address is a broadcast address. If it is a broadcast and broadcast addresses are enabled, the frame is accepted. If the group address is not a broadcast address, the user can perform address recognition on multiple group addresses using the GADDR_H/L hash table. In promiscuous mode, the Ethernet Controller receives all of the incoming frames regardless of their address..

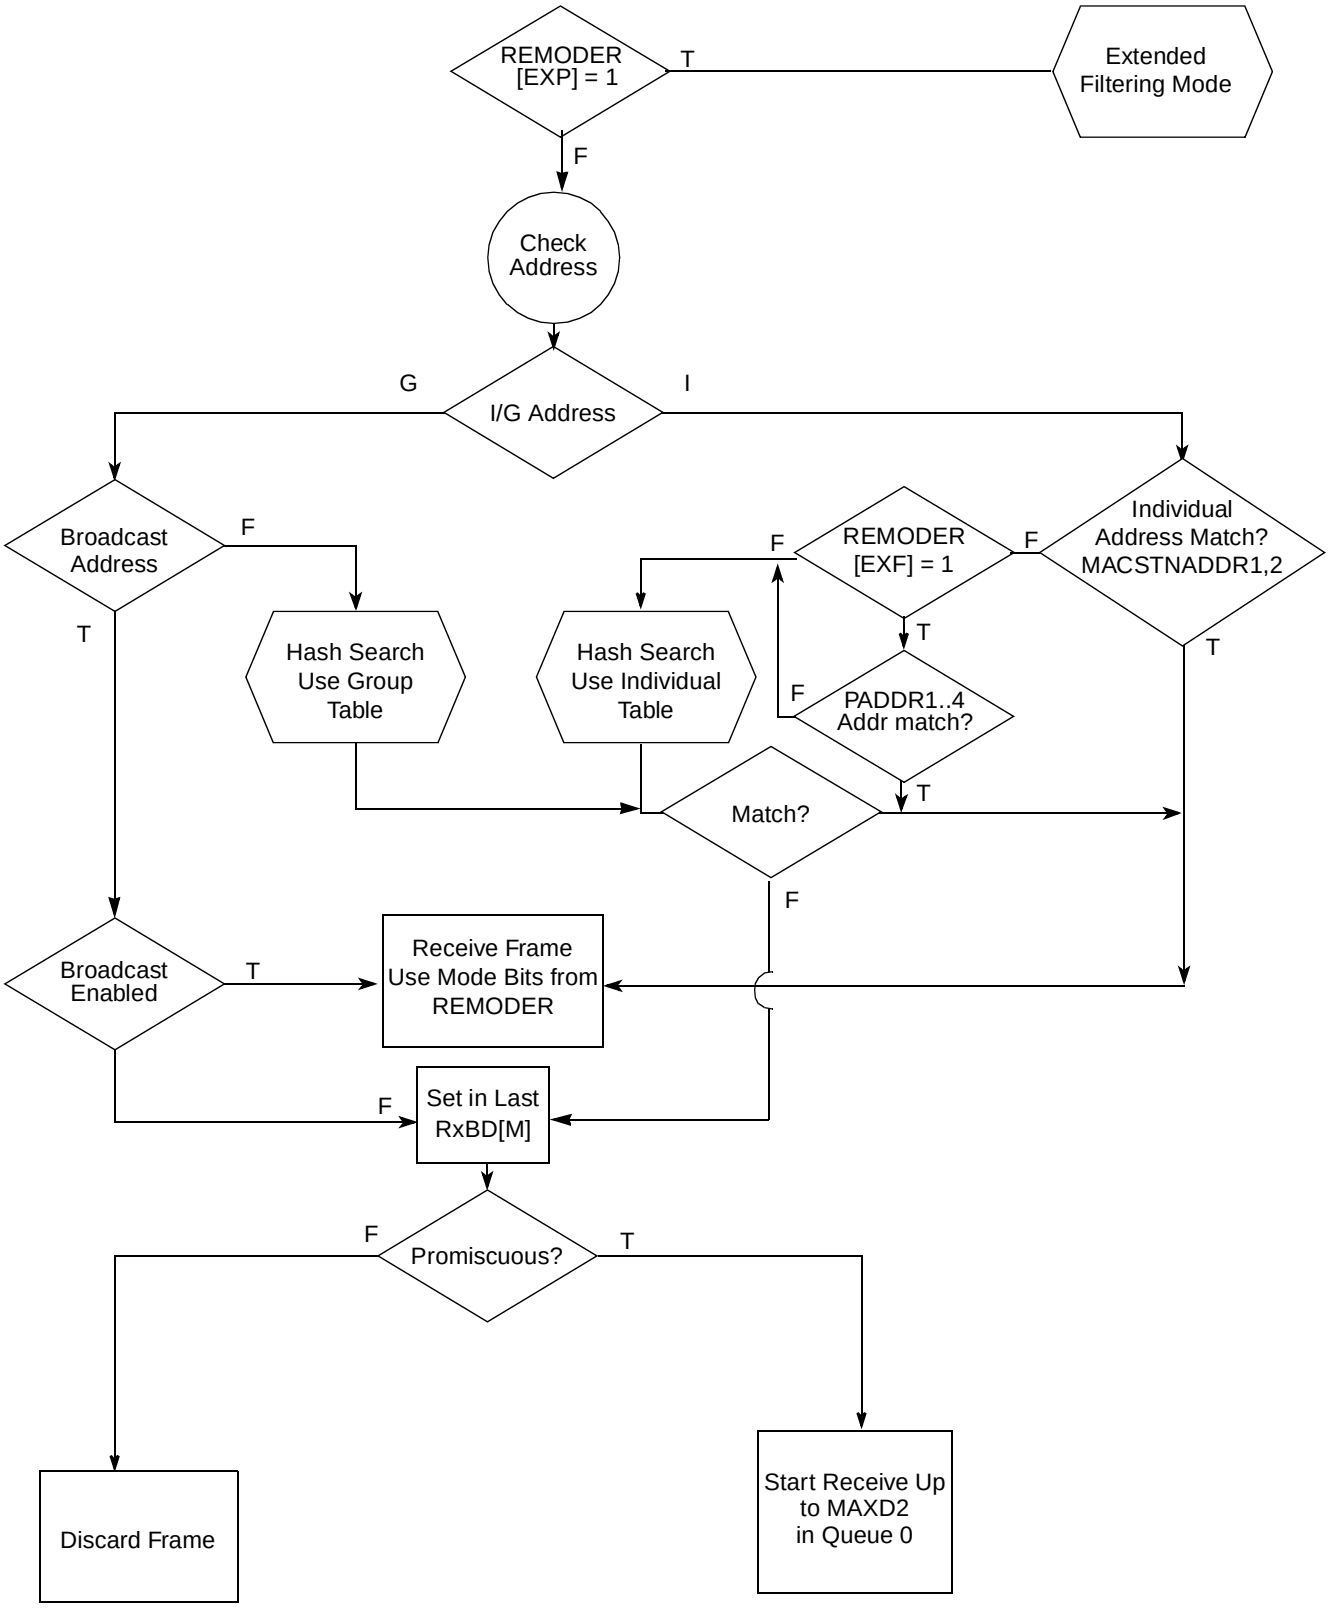


Figure 30-6. Address Filtering Flow REMODER[EXP]=0

30.4.9.1.1 Valid Bit Hash Table Algorithm

The hash table process used in the individual and group hash filtering operates as follows. The Ethernet controller maps any 48-bit address into one of 64 bins, which are represented by the 64 bits in GADDR_H/L or IADDR_H/L.

In order to program the GADDR field the user executes a QE command named SET GROUP ADDRESS. As a result the UCC Ethernet Controller maps the selected 48-bit address in TADDR into one of the 64 bits. This is performed by passing the 48-bit address through the on-chip 32-bit CRC generator and using 6 bits of the CRC-encoded result to generate a number between 1 and 64. Bit 26 of the CRC result selects between the two GADDRs or IADDRs; bits 27–31 of the CRC result select which bit is set.The same process is used when the Ethernet Controller receives a frame. If the CRC generator selects a bit that is set in the group/individual hash table, the frame is accepted; otherwise, it is rejected. The result is that if 8 group addresses are stored in the hash table and random group addresses are received, the hash table prevents roughly 56/64 (87.5%) of the group address frames from reaching memory. The core must further filter those that reach memory to determine if they contain one of the eight preferred addresses.

Better performance is achieved by using the group and individual hash tables in combination. For instance, if 8 group and 8 physical addresses are stored in their respective hash tables, 87.5% of all frames (not just group address frames) are prevented from reaching memory.

The effectiveness of the hash table declines as the number of addresses increases. For instance, with 128 addresses stored in a 64-bin hash table, the vast majority of the hash table bits are set, preventing only a small fraction of frames from reaching memory. In such instances, extended filtering mode is advised.

NOTE

The hash tables cannot be used to reject frames that match a set of selected addresses because unintended addresses can map to the same bit in the hash table.

30.4.9.2 Extended Parsing Mode

Extended parsing mode allows for enhanced frame filtering based on fields extracted from the L2 of the frame. The choice of the fields is user programmable. The user selects this mode by programming REMODER[EXP] = 1.

The CPU initializes eight byte data structures called Parse Command Descriptors (PCDs). In the PCDs the CPU selects which header fields are to be extracted from the frame headers to generate a LookupKey, and the type of LookupTable to be used for the lookup. The PCDs are programmed by the CPU at initialization.

Upon arrival of a frame, the UEC uses the PCDs as directives to parse the frame headers, generate a LookupKey (one or more) and perform table lookups. The LookupKey is generated by concatenating header fields. Note that frames of size under 64 bytes that are received by the UEC (as programmed in UPSMR[RSH] and MINFLR), are enqueued in queue 0 without parsing al all.

30.4.9.2.1 High Level Description of Parse Command Descriptors (PCDs)

There are different types of PCDs which are distinguished by their opcode field. The following sections describe the types of PCDs available. The first PCD are used to generate or modify the LookupKey:

- The GenerateL2LookupKey PCD is used to parse the frame and extract L2 header fields. The user may select the header fields to be extracted by setting an enable bit for each header field. The selected header fields are concatenated into a LookupKey which is used to perform a table lookup. The following header fields may be selected for extraction: MAC destination address, MAC source address, VLAN TAG. Up to 16 bytes from the frame headers may be extracted.
- The change mask PCD is used to mask fields from a LookupKey. For example, part of the TCI fields may be masked. The original LookupKey is saved in temporary storage.
- The restore mask PCD is used to restore the original LookupKey, to allow a new lookup based on other fields.

The Lookup PCD description follows:

- Four/Eight Way Hash Lookup PCD is used for long LookupKeys (up to 16) bytes and/or for large lookup tables. In this mode the LookupKey is hashed and the result is used to index a LookupTable in internal or external memory. The table is organized in four way sets. If all four ways are filled the user may add an other Lookup Table containing an other four ways set (applicable to Eight Way Lookup PCD). A mismatch in the compare of all four (or eight) tags, yields to a table lookup miss. Figure 30-7 is a description of the lookup flow using this mode:

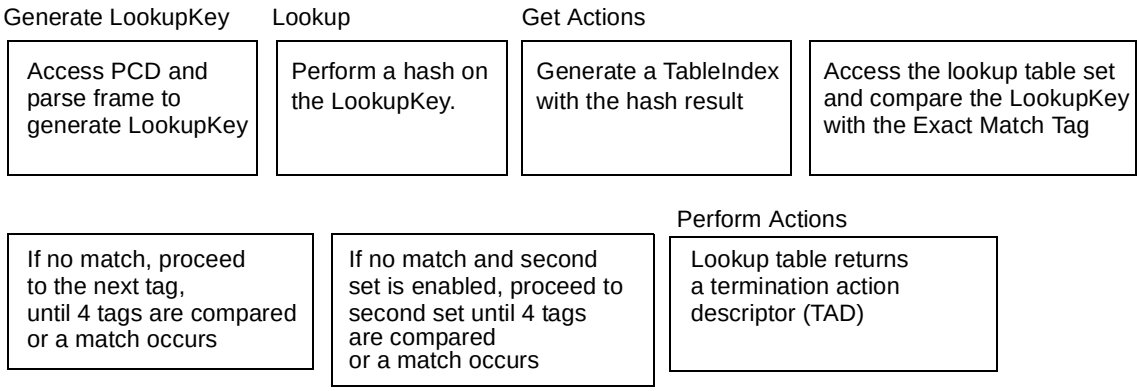

Figure 30-7. Flow for Hash mode

30.4.9.2.2 Address Filtering Flow

Figure 30-8 depicts the flow executed by the UEC in Extended Parsing mode.

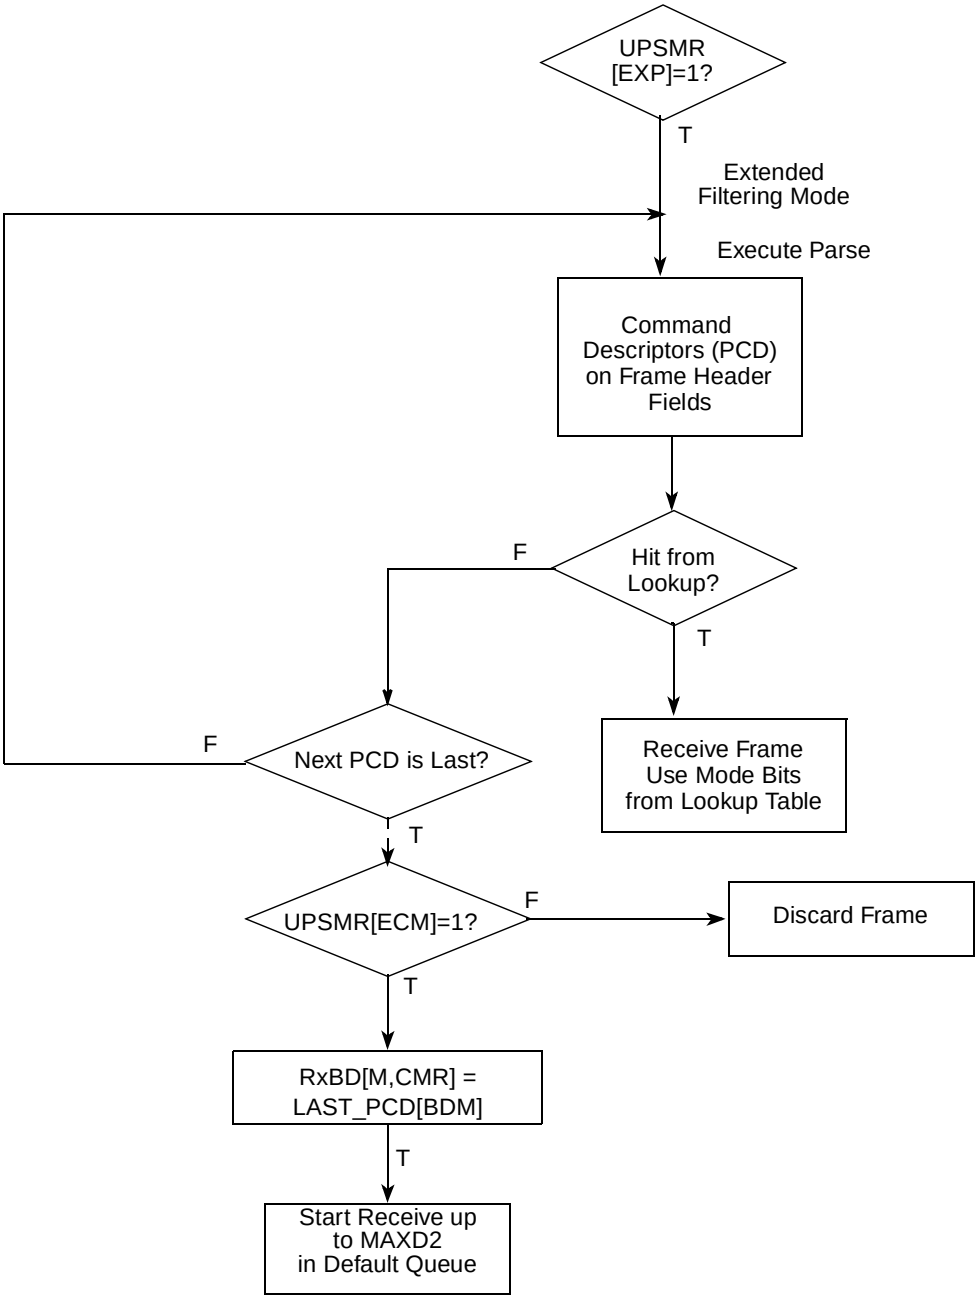

Figure 30-8. Address Filtering Flow REMODER[EXP] = 1

30.4.10 Header Manipulation

The UCC Ethernet Controller (UEC) supports user programmable insertion, replacement and deletion of a 2 byte Ethernet Type of 0x8100 and two bytes of VLAN Tag and priority on the Receive direction. On the transmit direction only the insertion operation is supported.

In the receive direction, if in Header Modify mode enabled by programming REMODER[VTagOP,VNoTagOP] bit not equal to zero (or if in Extended Parsing mode the corresponding bits in the result from the lookup table are non equal to zero) and if the frame does not contain a VLAN tag already, the UEC inserts a user defined VLAN Tag to the frame immediately after the MAC source address. The value of the VLAN Tag is taken from a user programmable default (if REMODER[EXP]=0) or it is programmed by the user in the lookup table, to allow different VLAN tags depending on the type of frame. This scheme allows for allocation of a different VLAN Tag for different Ethernet type fields.

If Header modify mode is enabled the last four bytes in the received frame do NOT contain the valid CRC of the modified frame.

In the Transmit direction, the user enables VLAN Tag insertion by programming the VLAN ID in the Buffer Descriptor. One of eight possible programmable VLANs is chosen. VLAN Tag ID=0, means no VLAN Tag insertion.

Note that header manipulation is not performed on received frames that are shorter than 16 bytes.

30.4.11 Receive and Transmit Buffer Descriptors (BDs)

The ethernet controller maintains multiple Tx/Rx Buffer Descriptor (BD) rings to satisfy QoS requirements.Up to eight Receive and eight Transmit BD rings are supported.

30.4.12 Quality of Service (QoS)

30.4.12.1 Receiver Queueing Decision

The queueing decision is based on the value of the QoS fields in the frame headers as they are received from the line (i.e. before any header manipulation peformed by the UEC), or the result of the lookup. The QoS fields that affect the queueing decision is taken from a global user programmable setting, or from the lookup table, or from the VLAN priority field in the VLAN header, or the TOS field in the IPv4 header or the TC field in IPv6 frame. The following table specifies how the queue priority is chosen by the UCC Ethernet Controller.

Table 30-4. Priority Selection Mode

User Programmble Mode if REMODER[EXP]=0 REMODER[RQoS] is used if REMODER[EXP]=1 TAD[RQoS] is used	Incoming Frame type			
	VLAN Tagged not IP	VLAN Tagged and IPv4 or IPv6	not VLAN Tagged not IPv4 or IPv6	not VLAN Tagged and IP
Use default queue REMODER[RQoS]=00 or TAD[RQoS]=00	User Programmable Queue as programmed in VPriority field in TCI or in TAD.			
Use L2 Priority REMODER[RQoS]=01or TAD[RQoS]=01	VLAN priority	VLAN priority	Default Queue	Default Queue
Use L3 Priority REMODER[RQoS]=10 or TAD[RQoS]=10	VLAN priority	IP TOS or Traffic class	Default Queue	IP TOS or Traffic class

1 Note: In MPC82xx Filtering mode (REMODER[EXP]=0): RQoS field is taken from the REMODER register. In Extended Parsing mode (REMODER[EXP]=1): RQoS field is taken from the Lookup Table (LUT) Entry.

2 Default queue is user programmable Rx Global Parameter RAM TCI[VPri].

3 Frames shorter than 64 bytes are enqueued in queue 0.

In Extended Parsing mode (REMODER[EXP]=1) there is also the option of explicitly determining the queue number in the lookup table, overriding the value of the VPri to TOS fields in the frame headers. The following figure depicts the queuing decision in term of a flow:

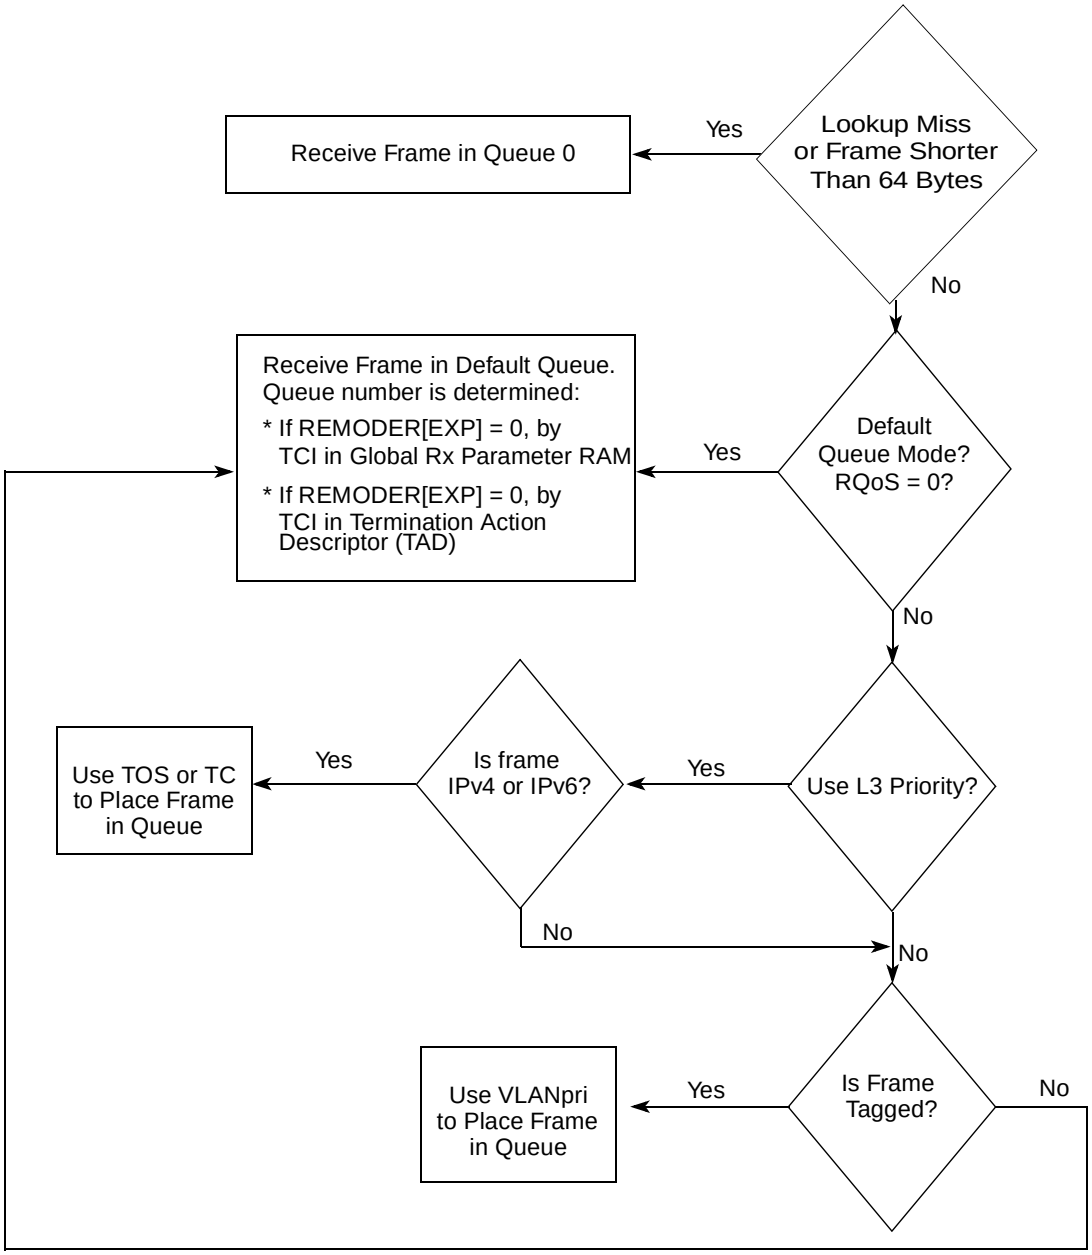

Figure 30-9. Receive Queueing Decision

30.4.13 Receive Interrupt Coalescing

Interrupt coalescing feature applies to interrupts issued on received frames. The user can program the UEC to issue a receive frame interrupt every programmable number of frames (programmed in Interrupt Timeout entry in the Global Rx Parameter RAM).

The ethernet controller may also generate interrupts after every Buffer Descriptor is received or transmitted, if enabled in the Buffer Descriptor and unmasked in the Interrupt Event Register. There is no interrupt coalescing for Buffer Descriptor interrupts.

30.4.14 Align IP address

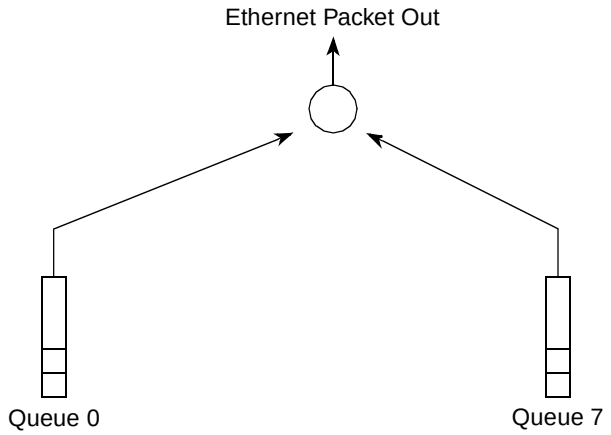
The UCC Ethernet Controller (UEC) supports IP address alignment to four bytes on received frames. If enabled, the UEC places the first byte of the frame two bytes from the address pointed by the pointer in the RxBD. The first two bytes in the data buffer contain undefined data.

30.4.15 Statistics Gathering

The UCC Ethernet Controller (UEC) implements a set of statistical counters. These counters allow the implementation of MIBs to support IEEE Std. 802.3-2002,1Giga Ethernet Enhancements RFC2819 and RFC3635. Some of the counters are implemented in Hardware, and they have a maskable event bit that interrupts the CPU when they overflow. Other counters have their value stored in the Parameter RAM. The receive statistics counters and the transmit statistics counters my be disabled separately in order to improve overall performance of the UEC.

30.4.16 Ethernet Scheduler Theory of Operation

The scheduling scheme of the Ethernet controller transmitter role is to select the next packet to be transmitted on the line. A single transmitter resource (UCC Ethernet port) is shared by 8 queues, as depicted in the figure below. Each of the queues contains a random number of packets with a random length, from 64 bytes to Jumbo frame (up to 9600 Bytes). The scheduling system is invoked whenever a new packet has to be transmitted, and updated after packet transmission completion.



Ethernet scheduler determines the next packet to be transmitted on the shared transmitter.

Figure 30-10. Ethernet Scheduler Role

30.4.16.1 Scheduling System Features

- Up to 8 Output Queues
- Strict priority (SP) scheduling
- Weighted Fair queuing (WFQ) scheduling
- Combined mode of both SP and WFQ in the same queue Structure
- Token bucket type shaping

- Rate limiting
- Various Traffic Shaper bypass modes, global and per queue for high QoS
- Transmit ASAP mode
- Extra bandwidth mode
- Supports both Work conserving and Non work conserving operation
- Maximum packet length of Jumbo size (9.6KB)
- BW Resolution in WFQ of 4Mbps
- Minimum rate of 4Mbps (Excluding rate of 0 - Queue disabled)
- Maximum rate of 1Gbps continuously

Minimum rate limiting 32kbps with TSRUnit=1us, and can be even lower with higher value of RTSR pre scalar please see formulas below.

Note that is the scheduler uses timer stamp register number 2 See description of CETSCR2. See Section 20.3.9, “QUICC Engine Time-Stamp Control Register (CETSCR).”

30.4.16.1.1 Scheduler Description

The Ethernet scheduling system is composed of two main functional modules: A work conserving scheduler, and a data shaper. This is shown in the next figure:

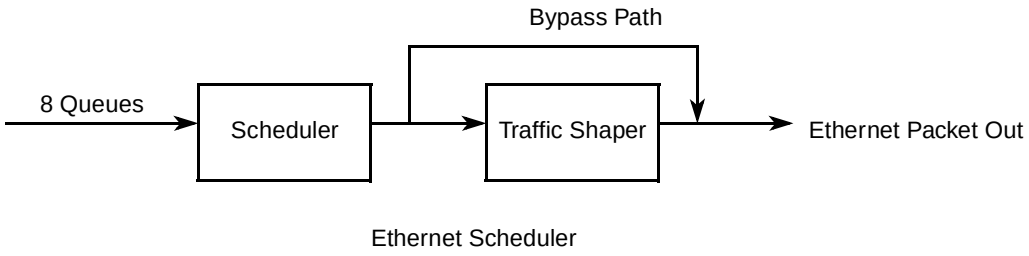


Figure 30-11. Ethernet Scheduling System

The scheduler module selects the next queue to be handled by an Ethernet UCC. The Traffic Shaper controls the data rate on the line using a real time scale, enabling the user either to limit data rate to a certain value, or to limit the maximum burst length, or both.

30.4.16.1.2 Scheduler Module

The scheduler module supports two scheduling hierarchies. The upper hierarchy imposes a scheduling policy of Strict priority. The lower hierarchy implies a scheduling policy of Weighted Fair Queuing (WFQ). The scheduler module handles up to 8 queues, each of them may be associated either with a different QoS or pre allocated BW. A sample configuration is shown in the figure below:

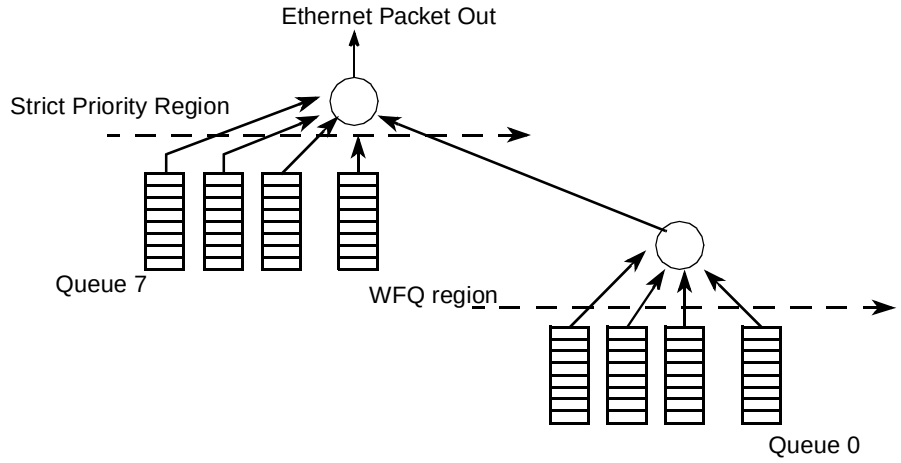

Figure 30-12. Sample Scheduler Configuration

In the example, queues 7-4 are transmitted first, if they are back logged. 3-0 that are configured in WFQ mode, are selected for transmission only if the strict priority queues are not back-logged. In this case, they are sharing the remaining bandwidth according to pre-defined relations.

Any queue may be configured either as SP queue (Strict priority) or as a WFQ queue. The SP queues are always with higher priority than the WFQ queues. Queues configuration can be varied on-line without any packet loss.

30.4.16.1.3 Traffic Shaper Module

The Traffic Shaper controls the absolute data rate on the bus. It can work in a mode of rate-limiting, Token bucket shaping, Bypass, or per queue by pass.

30.4.16.1.4 Toke Bucket Shaping

In this mode, the traffic shaper shapes output traffic according to the constraints of average data rate, and max burst length. Note that in Ethernet one must burst always in peak data rate until the end of the packet. Thus, the minimal value of maximum burst length is the longest packet, that may be a Jumbo packet in certain cases.

However, if the receiver side can tolerate longer bursts, the Traffic Shaper may allow a concatenation of packets (with minimum IPG as required by IEEE Std. 802.3-2202 between them) in order to increase line efficiency.

Thus, the Traffic Shaper supports Token Bucket shaping with peak rate of 1Gbps, and programmable max burst length and programmable average rate.

30.4.16.1.5 Rate Limiting

In this mode, the traffic shaper adjust the IPG after any packet transmission so that the average data rate will be as programmed. For instance, if the required rate is 0.5Gbps, after a packet of length of 64 bytes

there will be an IPG with size of 64 bytes. This allows minimal FIFO size in the communication peer receive side.

30.4.16.1.6 Traffic Shaper Bypass

Traffic shaper can be canceled. In this mode, the scheduling is work conserving, based on the scheduler module only. The user should expect 1Gbps bursts in any length, except from 12 bytes IPG, as defined by IEEE Std. 802.3.

30.4.16.1.7 Traffic Shaper per queue Bypass

For any of the queues, two orthogonal Bypass modes are supported: Transmit ASAP and Extra BW. Any queue may be configured in each of them in orthogonal manner.

In “Transmit ASAP” bypass mode, the queue transmission condition is not depending on the Traffic Shaper state, i.e. transmission occurs instantly. This mode is suitable for highest priority, lowest absolute delay queue.

In “Extra BW” mode (Extra bandwidth mode), the BW a queue has is added to the nominal BW. For instance, assume that queues 5-0 are configured in WFQ, queues 7-6 in SP. Queue 7 is for high priority control packets, with small delay and small BW. Queue 7 is configured in Transmit ASAP bypass mode, and Extra BW bypass mode. Queue 6 is configured in Transmit ASAP bypass mode. Queues 5-0 are with no bypass mode.

System behavior will be as follows: If the Traffic Shaper is programmed to 0.5Gbps, and the traffic is queue 7 is 0.1Gbps, the total BW of the line will be 0.5Gbps+ Queue 7 rate that is 0.6Gbps. However, the traffic in Queue 6 + queues 5-0 will be limited to 0.5Gbps by the Traffic Shaper.

Queue 6 will transmit instantly, since its in the Transmit ASAP mode; However, its BW will be deduce from the total BW of 0.5Gbps.

Note, however, that if the total BW of the “Transmit ASAP” queues is higher than the total BW budget, than “Transmit ASAP” has a priority (BW is not kept).

See Section 30.15, “Traffic Shaper Programming Considerations,” for example of scheduler programming.

30.4.16.1.8 Dynamic Changes

The Queue configuration may changed by the user on-line without ceasing data transmission. In order to transfer a queue from the SP group to the WFQ group the user can change the value of the bit associated with this specific queue in the StrictPriorityQ parameter.

If a queue is transferred from the SP group to the WFQ group, the parameter WeightFactor should be initialized as well.

If the data rate of a certain queue in the WFQ group has top be changed, the user may access directly the WeightFactor associated with this queue and change it. There is no need to stop transmission, neither stop substitution of packets in any of the queues.

30.4.16.1.9 Prioritized Queues

A Queue may be prioritized in two ways: Either by configure it to Strict Priority, or by giving it a very low WeightFactor in the WFQ system. In the first case, the queue will always gets its priority if it is not empty. The second case, however, will prevent the case of starvation if there is a chance that the SP Q will be busy most of the time. It is recommended that if a Queue that has to be in high priority is empty most of the time, it will be configured as SP queue.

If a Queue that has to get high priority is not empty most of the time, it is recommended to configure it as WFQ queue with low WeightFactor in order to prevent starvation. In this case, the TxASAP and ExBW bits should be configured as required by the application. TxASAP set means that whenever this queue is selected by the WFQ mechanism it will be transmitted, regardless of the state of the rate limiter. However, configuring it as WFQ will allow also other queues to be active.

See Section 30.5.3.3.3, “Scheduler Programming Model and Data Structures” for the scheduler programming model.

30.4.17 IEEE Standard 1588 Support

The UEC provides the hooks for the support of IEEE Std. 1588.

The 1588 HW assistance is supported on the following interfaces:

- MII 10/100Mbps (full and half duplex)
- RMII 10/100Mbps (full and half duplex)
- GMII/RGMII 1000Mbps (full duplex)
- RGMII 10/100Mbps (half and full duplex)

The following describes the main actions performed for each operation mode when a PTP frame was received. Frame Reception

30.4.17.1 In_band Mode

This mode is determined in the TSMR (see 1588 spec) register. The receiver’s timestamps are transferred as part of the data payload. The user sets the PTP bit in the Tx BD while sending a PTP frame, and gets a PTP indication in the Rx BD when a PTP frame has received.

The receive TSU (time stamp unit) is monitoring the received Ethernet frame on the physical line. When SFD is detected the 1588 Rx TSU locks the Real Time Value of the 1588 clock and then notifies the Ethernet MAC that SFD is detected and the timestamp associated with it is ready.

The Ethernet MAC stores the 64bit timestamp in the Memory as part of the frame at the first eight bytes of each Ethernet frame regardless of PTP indication.

When the Rx TSU parse unit is detecting a PTP frame it will notify the Ethernet MAC that a PTP frame has detected and the Ethernet controller will set RxBD[RPTP]

When the Software detects that a PTP frame has arrived by getting an interrupt or by polling the RxBD[RPTP] it will search for the PTP frame type and read the timestamp located in the first eight bytes of each frame in the memory if needed.

In case the PTP frame is marked with CRC, Overrun or Non-octet receive errors the interrupt in the TMR_PEVNT will not be set and the software should drop this frame regardless of the indication in the RxBD[RPTP]

Note that in order to work in in_band mode the following bits should be set:

UPSMR[PTPE] - 1588 enable

TSMR[opmode] - inband mode

MACCFG2[SRP] - soft receive preamble

When working in 1588 inband mode the customize preamble mode is not supported

30.4.17.2 Out_band Mode

The receive TSU (time stamp unit) is monitoring the received Ethernet frame on the physical line. When SFD is detected the 1588 Rx TSU locks the Real Time Value of the 1588 clock.

If the Rx TSU parse unit is detected a PTP frame it will notify the Ethernet MAC that a PTP frame has detected and the Ethernet controller will set RxBD[RPTP]. In addition, the Rx TSU will set the corresponding bit in the event register and generate an interrupt to the CPU.

When the Software detects that a PTP frame has arrived by getting an interrupt or by polling the RxBD[RPTP] it will read the dedicated timestamp register(TMR_UCx_RXTS_H/L) through the host interface.

In case the PTP frame is marked with CRC, Overrun or Non-octet receive errors the interrupt in the TMR_PEVNT will not be set and the software should drop this frame regardless of the indication in the RxBD[RPTP]

30.4.17.3 PTP frame transmission

The following describes the main actions performed for each operation mode when a PTP frame is transmitted:

30.4.17.3.1 In_band Mode

If the Software transmits a PTP frame, it should set the appropriate bit in the buffer descriptor TxBD[TPTP]. The Ethernet MAC is responsible to indicate the Tx TSU that a PTP frame is transmitted.

The transmit TSU (time stamp unit) is monitoring the transmitted Ethernet frame on the physical line. When SFD is detected the 1588 Tx TSU locks the Real Time Value of the 1588 clock. If the Tx TSU gets a PTP frame indication it sets the corresponding bit in the event register and generates interrupt to the CPU.

The SW should access the dedicated timestamp register (TMR_UCx_TXTS_H/L) through the host interface after an interrupt generation or when the last bit in the TxBD is set (TxBD[last])

30.4.17.3.2 Out_band Mode

Same as inband mode

30.4.18 Magic Packet Detection

The UEC supports automatic detection of Magic packets. This feature is useful for Low Power systems. The Magic Packet feature is enabled by performing the SW sequence described below. Once the UEC enters magic packet mode no frames are received by the UEC until a magic packet frame is detected. When such a frame arrives the UEC automatically sets UCCE[MPD] and disables MACCFG2[MPE] bit. If unmasked an interrupt is issued to the CPU which wakes it up from low power mode.

The CPU must follow this sequence in order to enter Magic Packet Detection Mode:

1. The host performs a Graceful Receive Stop and Graceful Transmit Stop on the ethernet controllers.
2. The host determines that Transmission/Reception has stopped
3. The host disable UCC Tx and UCC Rx (disable ENT & ENR in the GUMR mode register).
4. The host sets a Magic Packet mode bit in the MAC (MACCFG2)
5. The host enable UCC Tx and UCC Rx (enable ENT & ENR in the GUMR mode register).

Now the UEC is in Magic Packet detect mode. Upon detection of a magic packet the UEC asserts an interrupt to the CPU.

1. The host determines that magic packet is detected by the Rx MAC (via interrupt)
2. The host performs a Resume Receive and Resume Transmit commands on the Ethernet controllers

30.4.19 UEC Physical Interfaces

The physical interface is user programmable by configuring the PSMR, MACCFG2 registers.

30.4.19.1 10 and 100 Mbps MII Interface Operations

The MII is the media independent interface defined by the 802.3 standard for 10/100 Mbps operation. The speed of operation is determined by the TX_CLK and RX_CLK pins which are driven by the transceiver. The actual bit rate of the transceiver is determined either by auto-negotiation or it is controlled by software via the serial management interface (MDC/MDIO pins) to the transceiver.

30.4.19.2 10 and 100 Mbps RMII Interface Operations

The Reduced Media Independent Interface (RMII) is defined by the RMII Consortium for 10/100 Mbps operations. In this mode, the UCC Ethernet Controller converts MII signals to/from RMII signals. In RMII mode, a single clock reference (ref_clk) is sourced from the MAC to PHY (or from an external source)

30.4.19.3 1000 Mbps GMII and TBI Interface Operations

The GMII is the gigabit media independent interface defined by the 802.3 standard for 1000 Mbps operation. Independently, the MAC-PHY interface can also operate in TBI mode. Note that either the TBI or GMII interface is chosen and not both at the same time. TBI is the ten-bit interface which contains PCS functions (10-bit encoding/decoding) as defined by the 802.3z standard. The UCC Ethernet Controller provides the GTX_CLK to the PHY in GMII or TBI mode of operation.

30.4.19.4 1000 Mbps RGMII and RTBI Interface Operations

The RGMII and RTBI are intended to be an alternative to the GMII and TBI interfaces respectively. The principle objective is to reduce the number of pins required to interconnect the MAC and PHY. In order to accomplish this objective, the data paths and all associated control signals are reduced and control signals are multiplexed together and both edges of the clock are used. For gigabit operation, the clocks operate at 125 MHz.

30.4.20 Diagnostic Modes

30.4.20.1 Internal Loopback Mode

The UCC Ethernet Controller operates in internal loopback mode by programming the GUMR[DIAG] bits. In this mode the Transmit output of the GMII,MII,RGMII is connected internally to the receiver input, and RXD is ignored.

In TBI mode internal loopback mode is selected by programming the LoopBack bit in CR register (See Section 30.11.7.4, “Control Register (CR)”). In RTBI mode loopback is not supported.

In RMII mode, loopback operation may be achieved in the same way as for MII, or by setting UPSMR[RLPB] bit. This bit allows for the loop to be closed in the RMII interface itself.

30.4.20.2 Echo Mode

In this mode, the channels automatically retransmit received data. The receiver operates normally. The UCC Ethernet Controller will operate in echo mode by setting GUMR[DIAG] = 10.

For echo and loopback at the same time set GUMR[DIAG]=01 and UPSMR[RLPB]=0.

Note that Echo mode is supported only in MII and RMII mode

30.4.20.3 Full- and Half-Duplex Operations

Full-duplex mode is intended for use on point-to-point links between switches or end node to switch. Half-duplex mode is used in connections between an end node and a repeater, or between repeaters. When configured in half-duplex mode (half-duplex mode is only for RGMII 10/100 Mbps and MII/RMII 10/100 Mbps operations), (MACCFG2[FDX] register, bit 31), the MAC complies with the IEEE CSMA/CD access method. When configured in full-duplex mode (10/100/1000 Mbps operation, (MACCFG2[FDX] = 1), the MAC supports flow control. When flow control is enabled, it allows the MAC to receive or send PAUSE frames. Note that the GMII, TBI and RTBI interfaces support only the full duplex mode.

30.5 Programming Model

The UCC Ethernet Controller device is programmed by a combination of mode registers and of parameter RAMs. All accesses to and from 32 bit registers must be via 32-bit accesses. There is no support for accesses other than 32-bit on these registers. The following sections describe the registers in details.

30.5.1 Register Descriptions

This section describes the MAC registers and provides a brief overview of the functionality that can be exercised through the use of these registers, particularly those that provide functionality not explicitly required by the IEEE 802.3 standard. All of the 32 bit MAC registers must be accessed as 32 bit entities.

30.5.1.1 UCC Protocol Specific Ethernet Mode Register (UPSMR)

In Ethernet mode, the UCC protocol-specific mode register, shown in Figure 30-13, functions as the Ethernet mode register.

NOTE

This register must be initialized after the GUEMR Register, see Section 23.3.2, "General UCC Extended Mode Register (GUEMR)."

Table 30-5. UPSMR Ethernet Field Descriptions

Bits	Name	Description
0	FTFE	Flush Tx FIFO when a Flow Control frame is received. This bit must be set when running the L2 switch. Otherwise it should be cleared. If this bit is set and a Flow Control frame is received, the UEC send the current frame till completion, and then flushes the frames in the transmit FIFO. No transmission occurs till the MAC Parameter time has elapsed.
1	PTPE	PTP Enable 0 - Disable IEEE Std. 1588 assist connection to MAC I/F 1 - Enable IEEE Std. 1588 assist connection to MAC I/F
2-4	Reserved	Set to zero
5	ECM	This bit is valid if REMODER[EXP]=1 0 - Discard frames that miss in the Extended Parsing Mode Lookup 1 - Receive Frames that miss in the Extended Parsing Mode. The Rx queue is queue number 0.
6	HSE	Hardware Statistics Enable 0 - Do no perform hardware statistics. See Section 30.7.5, "UCC Statistics (Hardware Counters)." 1 - Perform hardware statistics. This bit is equivalent to the RMON bit in MPC82xx.

Table 30-5. UPSMR Ethernet Field Descriptions (continued)

Bits	Name	Description
7	Res	Must be set to zero.
8	Res	Set to zero
9	PRO	Promiscuous valid if REMODER[EXP]=0. 0 Check the destination address of incoming frames 1 Receive the frame regardless of its address.
10	Res	Set to zero.
11	RSH	Receive short frames 0 Discard short frames (frames smaller than the value specified in MINFLR) 1 Receive short frames
12	RPM	GMII/TBI Reduced pin mode interfaces. See Table 30-6 for usage of this bit.
13	R10M	RGMII/RMII 10/100 mode. See Table 30-6 for usage of this bit.
14	RLPB	RMII Loopback mode 0 - RMII is not in loopback mode 1 - RMII is in internal loopback mode Note that GUMR[DIAG]=00 in this mode.
15	TBIM	Ten-bit interface mode. See Table 30-6 for usage of this bit.
16–17	AUFC	Automatic Flow Control Enable 00 - No Automatic Flow Control frames are sent by the UEC. CPU may initiate a transmit flow control frame issuing START FLOW CONTROL command. 01 - In full duplex mode, the UEC sends a pause frame when RxFIFO reaches its special emergency threshold (that is, URFSET is crossed upwards). When the RxFIFO empties out below the emergency threshold (that is, URFET is crossed downwards), the UEC automatically sends pause frame with MAC parameter duration of “zero pause quantas”. It is assumed the URFET < URFSET. In half-duplex mode, when URFSET is crossed, the MAC applies back pressure algorithm on the line by sending preambles on the line when no data is available for transmit; when URFET is crossed downwards, the UEC disables the back pressure algorithm. See Section 27.5.4, “Receive Virtual FIFO Special Emergency Threshold (URFSET). 10 - Reserved (not allowed) 11 - In addition to the behaviour described when AUFC = 01, the UEC sends a pause frame when the receive buffers are busy. The UEC fills its RxFIFO until it reaches its threshold, and then a flow control frame is sent automatically. This mode serves as an automatic flow control mechanism for external buffers. In half-duplex mode the MAC applies back pressure algorithm on the line by sending preambles on the line when no data is available for transmit.
18	Res (1)	Must be set to ONE.
19	RMM	RMII Mode. See Table 30-6 for usage of this bit.
20	MDCP	Management Data Clock Prescale This field allows to MDC source clock to be divided by 8 0 - The source clock for MDC division is (CE/16 clock) 1 - The source clock for MDC division is (CE/2 clock) Note: If MDCP = 1, MIIMCFG[29:31] values should not be set to 000, 001, or 010. This bit is cleared by default. MDC divider - see MIIMCFG[28:31] Table 30-14

Table 30-5. UPSMR Ethernet Field Descriptions (continued)

Bits	Name	Description
21	Reserved	Set to zero
22	BRO	Broadcast address 0 Receive all frames containing the broadcast address 1 Reject all frames containing the broadcast address unless UPSMR[PRO] = 1
23–31	Reserved	Set to zero

The following Table summarizes the register programming needed to configure the UEC in the desired mode. Only the combinations in this table are allowed:

Table 30-6. Interface Mode Configuration 10/100

Mode	MACCFG2[IFM]	UPSMR[RPM]	UPSMR[TBIM]	UPSMR[R10M]	UPSMR[RMM]	MACCFG2[FDX]
MII	01	0	0	0	0	1 or 0
RMII(100)	01	0	0	0	1	1 or 0
RMII(10)	01	0	0	1	1	1 or 0

Table 30-7. Interface Mode Configuration GEnet

Mode	MACCFG2[IFM]	UPSMR[RPM]	UPSMR[TBIM]	UPSMR[R10M]	UPSMR[RMM]	MACCFG2[FDX]
GMII	10	0	0	0	0	1
TBI	10	0	1	0	0	1
RTBI	10	1	1	0	0	1
RGMII(1000)	10	1	0	0	0	1
RGMII (100)	01	1	0	0	0	1
RGMII(10)	01	1	0	1	0	1

The behavior of the UCC Ethernet Controller is not specified if programmed to other combinations of these bits.

30.5.1.2 Ethernet Event Register (UCCE)/Mask Register (UCCM)

The UCCE is used as the Ethernet event register when the UCC functions as an Ethernet Controller. It generates interrupts and reports events recognized by the Ethernet Channel. On recognition of an event, the Ethernet Controller sets the corresponding UCCE bit. Interrupts generated by this register can be masked in the Ethernet mask register (UCCM).

The UCCM has the same bit format as UCCE, refer to Figure 30-14. Setting an UCCM bit enables and clears a bit masking the corresponding interrupt in the UCCE.

The UCCE can be read at any time. Bits are cleared by writing ones; writing zeros does not affect bit values. Unmasked UCCE bits must be cleared before CP clears the internal interrupt request.

Offset	UCCx_base + 0x10 UCCE UCCx_base + 0x14 UCCM															
Bits	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Figure 30-14. Ethernet Event/Mask Register (UCCE/UCCM)

Table 30-8 describes the UCCE/UCCM fields.

Table 30-8. UCCE/UCCM Mode Register Descriptions

Bits	Name	Description
0	MPD	Magic Packet Detection 0 - No Magic packet has been detected 1 - Magic Packet has been detected.
1	SCAR	Hardware Statistics Carry overflow Event. 0 - No overflow 1- A bit in the SCAR is set, and the respective bit in the SCAM register is set (unmasked).
2	GRA	Graceful stop complete. A graceful stop, initiated by the GRACEFUL STOP TRANSMIT command, is complete. When the command is issued, GRA is set as soon the transmitter finishes sending a frame in progress. If no frame is in progress, GRA is set immediately.
3	CBPR	In half duplex mode Change Back Pressure 0 - No change in backpressure state 1 - The UEC Transmitter is in backpressure state. The UEC is forcing preambles on the line, or is transmitting valid frames on the line. 1 - The UEC transmitter has entered the backpressure state (i.e.the receiver has signalled to the transmitter to enter backpressure. See Section 27.5.4, “Receive Virtual FIFO Special Emergency Threshold (URFSET)” for FIFO thresholds that triggers this event); OR the UEC has exited the backpressure state (i.e. the RxFIFO is filled below the threshold programmed in the URFET register, see Section 27.5.3, “Receive Virtual FIFO Emergency Threshold (URFET).”The status on the UEC transmitter is reflected in the UCCS Register. In full duplex mode Change Pause0 - No change in PAUSE state. 1 - The UEC transmitter has entered the PAUSE state (i.e. it has received a PAUSE frame and its transmitter is currently not transmitting on the line); OR the UEC has exited a PAUSE state (i.e. either the MAC parameter time has expired, or a PAUSE frame with MAC parameter zero has been received). The status on the UEC transmitter is reflected in the UCCS Register.
4	BSY	Busy condition. Set when a frame is received and discarded due to a lack of free Rx Buffer Descriptors

Table 30-8. UCCE/UCCM Mode Register Descriptions (continued)

Bits	Name	Description
5	RXC	RX Flow control. A control frame has been received (FSMR[FCE] must be set). As soon as the transmitter finishes sending the current frame, a pause operation is performed.
6	TXC	TX Flow control. An out-of-sequence frame was sent.
7	TXE	Tx error. An error occurred on the transmitter channel. In full duplex mode this is an underrun condition.
8:15	TXB0-7	Tx buffer. Set when a buffer has been sent on the Ethernet channel, from queue number 0-7 respectively. Note that interrupts for TxBDs are asserted to the CPU after the Last TxBD of the frame has been transmitted.
16:23	RXB0-7	Rx buffer. Set when a complete buffer is received on the Ethernet channel on queues number 0-7 respectively and the respictive RxBD[I] bit is set. If REMODER[IWEn]=1 these bits are used as follows:
24:31	RXF0-7	Rx frame. Set when a complete frame is received on the Ethernet channel on queue number 0-7 respectively.

30.5.1.3 Ethernet Status Register (UCCS)

The UCCS contains the real time status of Ethernet Transmitter.

Offset	UCCx_base + 0x17 UCCS							
Bits	0	1	2	3	4	5	6	7
Field	0						BPR	MPD
R/W	R							

Figure 30-15. Ethernet Status Register (UCCS)

Table 30-9 describes the UCCS fields.

Table 30-9. UCCS Register Descriptions

Bits	Name	Description
0-5		Read zero
6	BPR	Back Pressure (in half duplex mode) 0 - UEC is not in backpressure state 1 - The UEC Transmitter is in backpressure state OR Pause State (in full duplex mode) 0 - The UEC is not in PAUSE state. 1 - The UEC transmitter is in PAUSE state and is not transmitting on the line.
7	MPD	Magic Packet Detected 0 - No Magic Packet was detected 1 - Magic Packet was detected

30.5.1.4 MAC Configuration 1 Register (MACCFG1)

MAC configuration registers (MACCFG1 and 2) provide the means of configuring the MAC in multiple ways:

- Adjusting the preamble length—The length of the preamble can be adjusted from the nominal 7 bytes to some other (non-zero) value.
- Varying pad/CRC combinations—Three different pad/CRC combinations are provided to handle a variety of system requirements. Most simple are frames that already have a valid FCS field. In this case, CRC is checked and reported via the transmit statistics vector (TSV[51:0]). The other two options include appending a valid CRC, or padding and then appending a valid CRC, resulting in a minimum frame of 64 octets. In addition to the programmable register set, the pad/CRC behavior can be dynamically adjusted on a per-frame basis.

The MACCFG1 register is written by the user. Figure 30-16 describes the definition for the MACCFG1 register.

Offset	UCC EMAC1:UCCx_base + 0x100; UCC EMAC2:UCCx_base + 0x200

Reset	0000_0000_0000_0000															

Figure 30-16. MACCFG1 Register Definition

Table 30-10 describes the MACCFG1 fields.

Table 30-10. MACCFG1 Field Descriptions

Bits	Name	Description
0–25	—	Set to zero
26	Rx_Flow	Receive flow control. This bit is cleared by default. 0 The receive MAC control ignores PAUSE flow control frames. 1 The receive MAC control detects and acts on PAUSE flow control frames.
27	Tx_Flow	Transmit flow control. This bit is cleared by default. 0 The transmit MAC control may not send PAUSE flow control frames if requested by the system. 1 The transmit MAC control may send PAUSE flow control frames if requested by the system.
28	Sync'd Rx EN	Receive enable synchronized to the receive stream. (Read-only) 0 Frame reception is not enabled. 1 Frame reception is enabled.

Table 30-10. MACCFG1 Field Descriptions (continued)

Bits	Name	Description
29	Rx_EN	Receive enable. This bit is cleared by default. 0 The MAC may not receive frames from the PHY 1 The MAC may receive frames from the PHY. This bit must be set before GUMR[ENR] is set.
30	Sync'd Tx EN	Transmit enable synchronized to the transmit stream. (Read-only) 0 Frame transmission is not enabled. 1 Frame transmission is enabled.
31	Tx_EN	Transmit enable. This bit is cleared by default. 0 The MAC may not transmit frames from the system. 1 The MAC may transmit frames from the system. This bit must be set before GUMR[ENT] is set.

30.5.1.5 MAC Configuration 2 Register (MACCFG2)

The MACCFG2 register is written by the user. Figure 30-17 describes the definition for the MACCFG2 register.

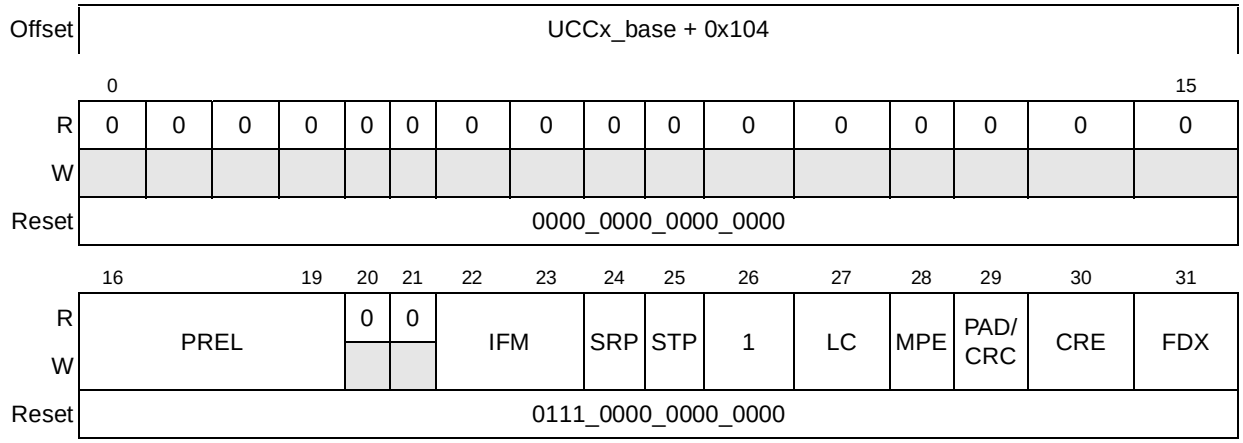

Figure 30-17. MACCFG2 Register Definition

Table 30-11 describes the MACCFG2 fields.

Table 30-11. MACCFG2 Field Descriptions

Bits	Name	Description
0–15	Reserved	Set to zero
16–19	PREL	Preamble Length This field determines the length in bytes of the preamble field of the frame. Its default is 0x7. A preamble length of 0 is not supported. The Tx MAC supports only MACCFG2[PREL] = 3..7.
20–21	Reserved	Set to zero

Table 30-11. MACCFG2 Field Descriptions (continued)

Bits	Name	Description
22–23	IFM	Interface Mode. This field determines the type of interface to which the MAC is connected. Its default is 00. See Table 30-6 for usage of this bit. 00 Reserved 01 Nibble mode (MII/RMII/RGMII 10/100bps) 10 Byte mode (GMII/TBI/RTBI/RGMII 1000bps) 11 Reserved
24	SRP	Soft Receive Preamble 0 - Do not place the Receive Preamble before the Data 1 - Place eight bytes of the received Preamble and SFD before the data in the Data Buffer pointed by the first buffer descriptor of the frame. **Note**: In TBI or RMII this bit should be cleared
25	STP	Soft Transmit Preamble 0 - Transmit normal preamble of length MACCFG2[PREL], and use the data in the data buffer as regular frame payload. 1 - If TxBD[PP]=1, use the first 8 bytes of the data buffer as 7 bytes of preamble and one byte of place holder.The Ethernet Controller transmits the SFD automatically. All eight bytes must reside in one data buffer pointed by one Buffer Descriptor. If this bit is set and TxBD[PP]=0 the UEC transmits 7 bytes of preamble (compliant to 802.3). MACCFG2[PREL] must be programmed to 0x7 and the preamble length is 7 bytes. Other values of MACCFG2[PREL] result in undefined behavior of the UEC. **Note**: In TBI or RMII this bit should be cleared **Note:** MACCFG2[STP] must be set if TxBD[PP] is set.
26	Reserved	Must be set to ONE.
27	LC	Length check. This bit is cleared by default. 0 No length field checking is performed. 1 The MAC checks the frame's length field to ensure it matches the actual data field length. If the actual received frame length does not match the value in the length field the value of InRangLenRxER statistics counter is incremented.
28	MPE	Magic Packet Enable 0 - The Magic Packet Detection Feature is disabled 1 - Magic Packet Detection is enabled. No frames are received by the UEC after the current frame has been received. The UEC automatically detects a Magic packet and as result asserts UCCE[MPD] and resets this bit. If unmasked an interrupt is issued to the CPU which wakes it up from low power mode.
29	PAD/CRC	Pad to 64 bytes and append CRC. This bit is cleared by default. 0 Frames presented to the MAC have a valid length and contain a CRC. 1 The MAC pads all transmitted short frames and appends a CRC to every frame regardless of padding requirement.

Table 30-11. MACCFG2 Field Descriptions (continued)

Bits	Name	Description
30	CRE	CRC Enable. If the configuration bit PAD/CRC ENABLE or the per-frame PAD/CRC ENABLE is set, CRC ENABLE is ignored. This bit is cleared by default. 0 Frames presented to the MAC have a valid length and contain a valid CRC. 1 The MAC appends a CRC on all frames. Clear this bit if frames presented to the MAC have a valid length and contain a valid CRC.
31	FDX	Full-duplex configure. This bit is cleared by default. 0 The MAC operates in half-duplex mode. 1 The MAC operates in full-duplex mode.

30.5.1.6 Inter-frame Gap/Inter-Frame Gap Register (IPGIFG)

The IPGIFG register is written by the user.

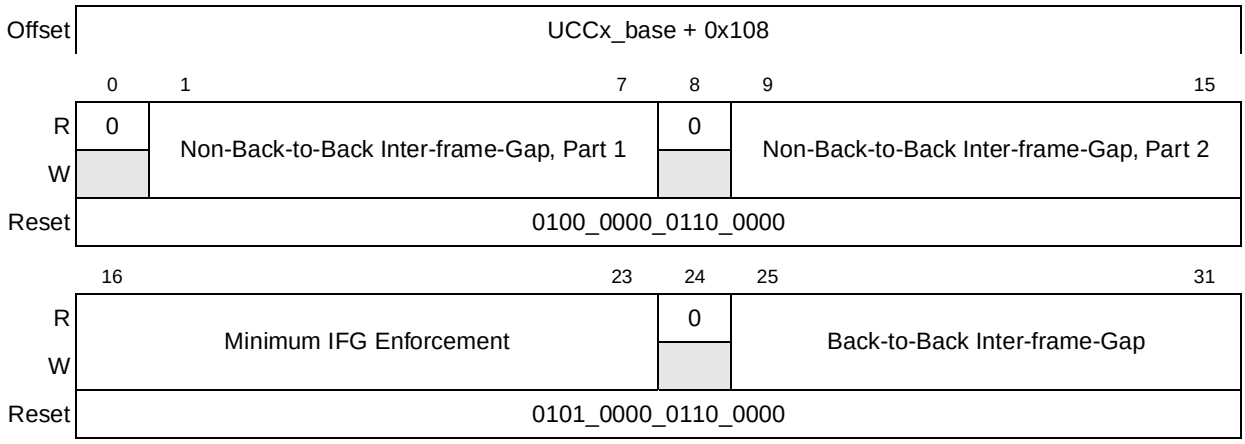

Figure 30-18. IPGIFG Register Definition

Table 30-12 describes the IPGIFG fields.

Table 30-12. IPGIFG Field Descriptions

Bits	Name	Description
0	—	Reserved
1–7	Non-Back-to-Back Inter-frame-Gap, Part 1	This is a programmable field representing the optional carrier Sense window referenced in IEEE Std. 802.3/4.2.3.2.1 ‘carrier deference.’ If carrier is detected during the timing of IPGR1, the MAC defers to carrier. If, however, carrier becomes active after IPGR1, MAC continues timing IPGR2 and transmits, knowingly causing a collision; thus, ensuring fair access to medium. Its range of values is 0x00 to IPGR2. Its default is 0x40 (64d) which follows the two-thirds/one-third guideline.
8	—	Reserved
9–15	Non-Back-to-Back Inter-frame-Gap, Part 2	This is a programmable field representing the non-back-to-back inter-frame-gap in bits. Its default is 0x60 (96d), which represents the minimum IPG of 96 bits.
16–23	Minimum IFG Enforcement[1]	This is a programmable field representing the minimum number of bits of IFG to enforce between frames. A frame is dropped whose IFG is less than that programmed. The default setting of 0x50 (80d) represents half of the nominal minimum IFG which is 160 bits. Zero is not a legal value.
24	—	Reserved
25–31	Back-to-Back Inter-frame-Gap	This is a programmable field representing the IPG between back-to-back frames. This is the IPG parameter used exclusively in full-duplex mode and in half-duplex mode if two transmit frames are sent back-to-back. Set this field to the number of bits of IPG desired. The default setting of 0x60 (96d) represents the minimum IPG of 96 bits.

[1] Value zero is restricted from use.

30.5.1.7 Half-Duplex Register (HAFDUP)

The HAFDUP register is written by the user. Figure 30-19 describes the definition for the HAFDUP register.

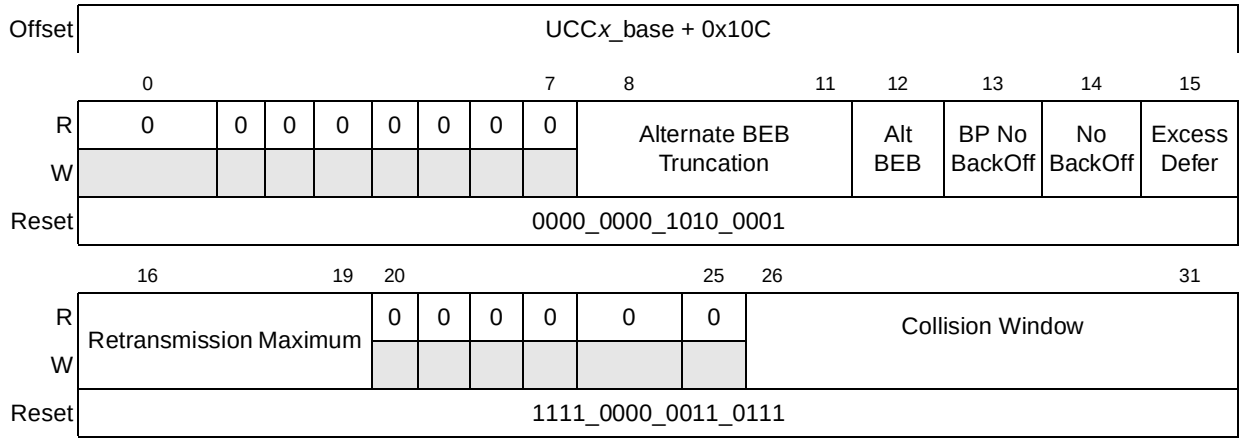

Figure 30-19. Half-Duplex Register Definition

Table 30-13 describes the HAFDUP fields.

Table 30-13. HAFDUP Field Descriptions

Bits	Name	Description
0–7	—	Reserved
8–11	Alternate BEB Truncation	This field is used while ALTERNATE BINARY EXPONENTIAL BACKOFF ENABLE is set. The value programmed is substituted for the Ethernet standard value of ten. Its default is 0xA.
12	Alt BEB	Alternate binary exponential backoff. This bit is cleared by default. 0 The Tx MAC follows the standard binary exponential backoff rule. 1 The Tx MAC uses the ALTERNATE BINARY EXPONENTIAL BACKOFF TRUNCATION setting instead of the 802.3 standard tenth collision. The standard specifies that any collision after the tenth, uses one less than 210 as the maximum backoff time.
13	BP No BackOff	Back pressure no backoff. This bit is cleared by default. 0 The Tx MAC follows the binary exponential backoff rule. 1 The Tx MAC immediately re-transmits, following a collision, during backpressure operation.
14	No BackOff	No backoff. This bit is cleared by default. 0 The Tx MAC follows the binary exponential back off rule. 1 The Tx MAC immediately re-transmits following a collision.
15	Excess Defer	Setting this bit configures the Tx MAC to allow the transmission of a frame that is excessively deferred. An excess defer condition occurs when the Ethernet Controller waits for more than 3036-byte time while attempting to send a frame. Clearing this bit causes the Tx MAC to abort the transmission of a frame that is excessively deferred. It is set by default.
16–19	Retransmission Maximum	This is a programmable field specifying the number of retransmission attempts following a collision before aborting the frame due to excessive collisions. The standard specifies the attempt limit to be 0xF (15d). Its default value is 0xF

Table 30-13. HAFDUP Field Descriptions (continued)

Bits	Name	Description
20–25	—	Reserved
26–31	Collision Window	This is a programmable field representing the slot time or collision window during which collisions occur in properly configured networks. Because the collision window starts at the beginning of transmission, the preamble and SFD are included. Its default of 0x37 (55d) corresponds to the count of frame bytes at the end of the window.

30.5.1.8 MII Management Configuration Register (MIIMCFG)

The MIIMCFG register is written by the user. Figure 30-20 describes the definition for the MIIMCFG register.

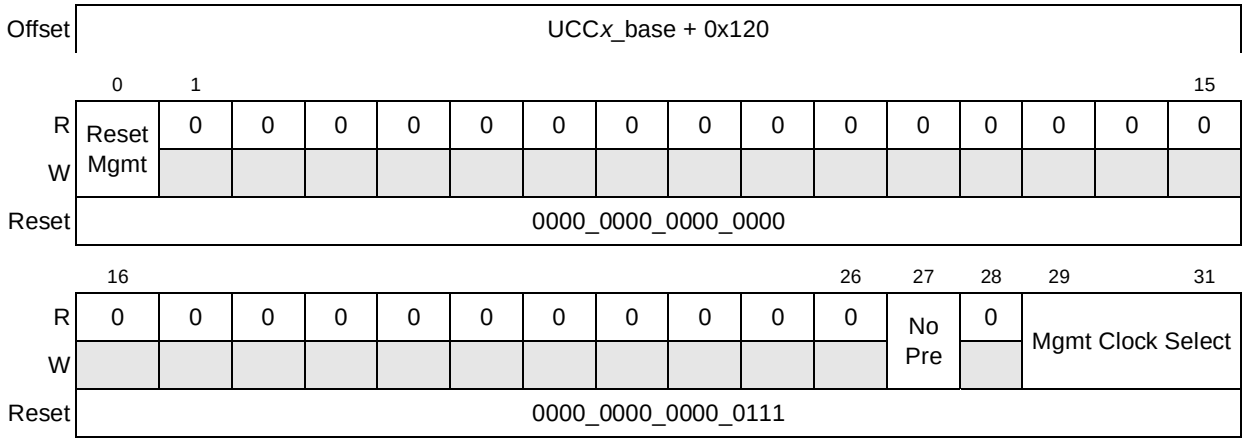

Figure 30-20. MII Management Configuration Register Definition

Table 30-14 describes the MIIMCFG fields.

Table 30-14. MIIMCFG Field Descriptions

Bits	Name	Description
0	Reset Mgmt	Reset management. This bit is cleared by default. 0 Allow the MII MGMT to perform mgmt read/write cycles if requested. 1 Reset the MII MGMT.
1–26	—	Reserved
27	No Pre	Preamble suppress. This bit is cleared by default. 0 The MII MGMT performs Mgmt read/write cycles with 32 clocks of preamble. 1 The MII MGMT suppresses preamble generation and reduces the Mgmt cycle from 64 clocks to 32 clocks. This is in accordance with IEEE Std. 802.3/22.2.4.4.2.

Table 30-14. MIIMCFG Field Descriptions (continued)

Bits	Name	Description
28	—	Reserved
29–31	Mgmt Clock Select	This field determines the clock frequency of the Mgmt Clock (CE_MDC). Its default value is 111. The source clock frequency is equal to the QUICC Engine clock divided by 16. 000 Source clock divided by 4 001 Source clock divided by 4 010 Source clock divided by 6 011 Source clock divided by 8 100 Source clock divided by 10 101 Source clock divided by 14 110 Source clock divided by 20 111 Source clock divided by 28

30.5.1.9 MII Management Command (MIIMCOM)

The MIIMCOM register is written by the user. Figure 30-21 describes the definition for the MIIMCOM register.

Offset: UCC*x*_base + 0x124

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Figure 30-21. MIIMCOM Register Definition

Table 30-15 describes the MIIMCOM register.

Table 30-15. MIIMCOM Descriptions

Bits	Name	Description
0–29	—	Reserved

Table 30-15. MIIMCOM Descriptions (continued)

Bits	Name	Description
30	Scan Cycle	Scan cycle. This bit is cleared by default. 0 Normal operation. 1 The MII management continuously performs read cycles. This is useful for polling a PHY register, for example, monitoring link fails. Data is returned in register MIIMSTAT[PHY Status].
31	Read Cycle	Read cycle. This bit is cleared by default but is not self-clearing once set. 0 Normal operation. 1 The MII management performs a single read cycle upon the transition of this bit from 0 to 1 using the PHY address (at MIIMADD[PHY Address]) and the register address (at MIIMADD[Register Address]). The 0 to 1 transition of this bit also causes the MIIMIND[BUSY] bit to be set. The read is complete when the MIIMIND[BUSY] bit clears. Data is returned in register MIIMSTAT[PHY Status].

30.5.1.10 MII Management Address Register (MIIMADD)

The MIIMADD register is written by the user. Figure 30-22 describes the definition for the MIIMADD register.

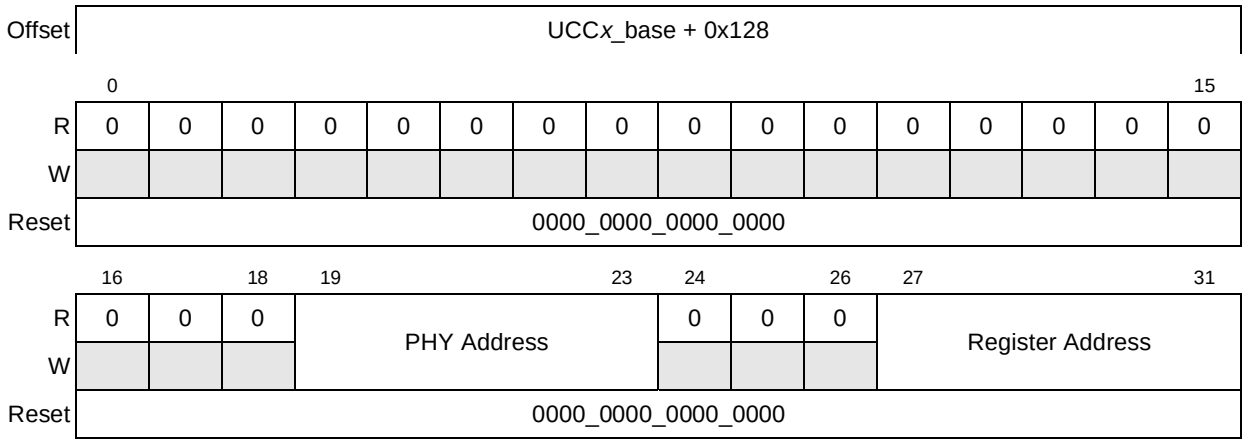

Figure 30-22. MIIMADD Register Definition

Table 30-16 describes the MIIMADD fields.

Table 30-16. MIIMADD Field Descriptions

Bits	Name	Description
0–18	—	Reserved
19–23	PHY Address	This field represents the 5-bit PHY address field of Mgmt cycles. Up to 31 PHYs can be addressed, with one address reserved for internal TBI registers (corresponding to the value of TBIPA[TBIPA] whose default value is 0x00). Reprogramming of TBIPA[TBIPA] to a non-zero value allows PHY address to then be set to 0.
24–26	—	Reserved
27–31	Register Address	This field represents the 5-bit register address field of Mgmt cycles. Up to 32 registers can be accessed. Its default value is 0x00.

30.5.1.11 MII Management Control Register (MIIMCON)

The MIIMCON register is written by the user. Figure 30-23 describes the definition for the MIIMCON register.

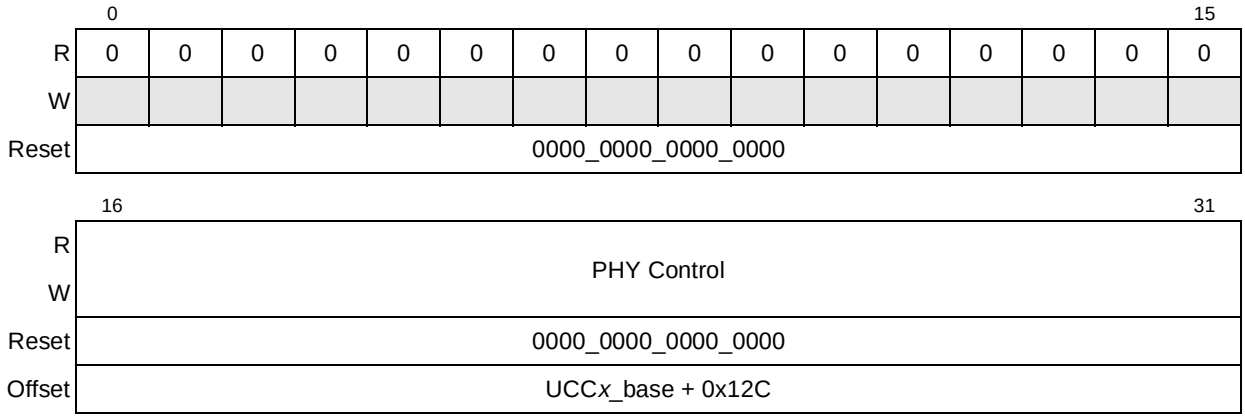

Figure 30-23. MII Mgmt Control Register Definition

Table 30-17 describes the MIICON fields.

Table 30-17. MIIMCON Field Descriptions

Bits	Name	Description
0–15	—	Reserved
16–31	PHY Control	If written, an MII Mgmt write cycle is performed using this 16-bit data, the pre-configured PHY address (at MIIMADD[PHY Address]) and the register address (at MIIMADD[Register Address]). Its default value is 0x0000.

30.5.1.12 MII Management Status Register (MIIMSTAT)

The MIIMSTAT register is read-only by the user. Figure 30-24 describes the definition for the MIIMSTAT register.

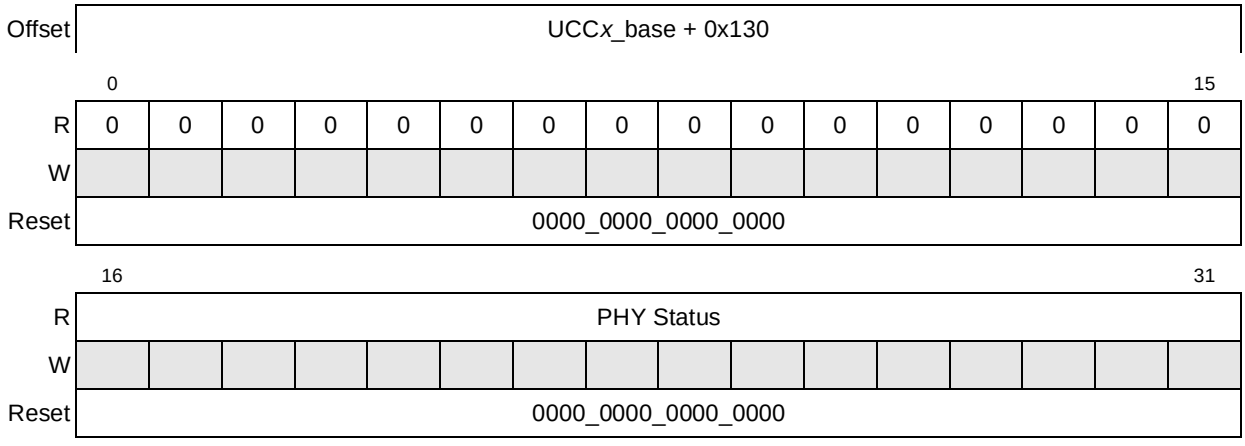

Figure 30-24. MIIMSTAT Register Definition

Table 30-18 describes the MIIMSTAT fields.

Table 30-18. MIIMSTAT Field Descriptions

Bits	Name	Description
0–15	—	Reserved
16–31	PHY Status	Following an MII Mgmt read cycle, the 16-bit data can be read from this location. Its default value is 0x0000.

30.5.1.13 MII Management Indicator Register (MIIMIND)

The MIIMIND register is read-only by the user. Figure 30-25 describes the definition for the MIIMIND register.

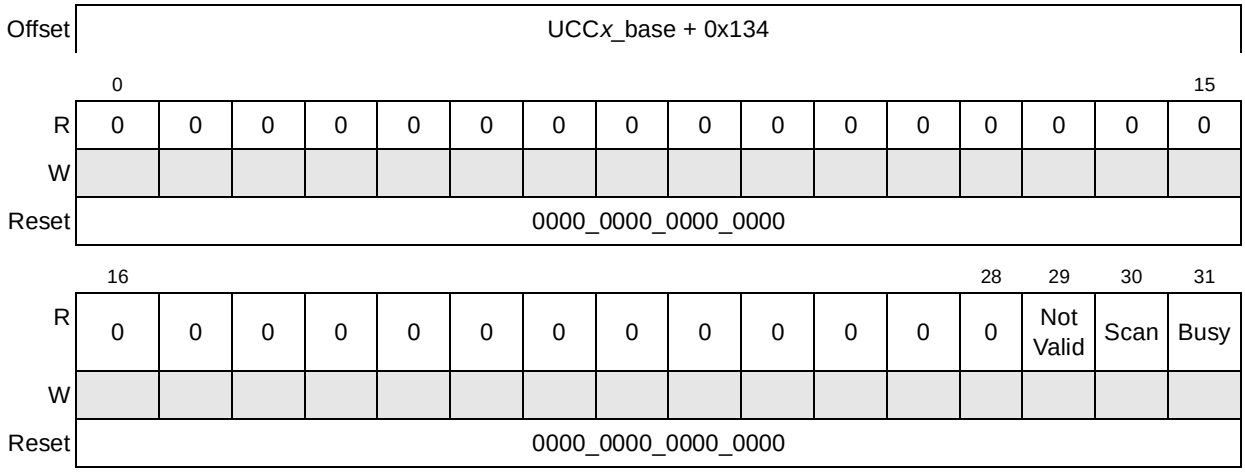

Figure 30-25. MII Mgmt Indicator Register Definition

Table 30-19 describes the MIIMIND fields.

Table 30-19. MIIMIND Field Descriptions

Bits	Name	Description
0–28	—	Reserved
29	Not Valid	Not valid. 0 MII Mgmt read cycle has completed and the Read Data is valid. 1 MII Mgmt read cycle has not completed and the Read Data is not yet valid.
30	Scan	Scan in progress. 0 A scan operation (continuous MII Mgmt read cycles) is not in progress. 1 A scan operation (continuous MII Mgmt read cycles) is in progress.
31	Busy	Busy. 0 MII Mgmt block is not currently performing an MII Mgmt read or write cycle. 1 MII Mgmt block is currently performing an MII Mgmt read or write cycle.

30.5.1.14 Interface Status Register (IFSTAT)

The IFSTAT register is read by the user. Figure 30-26 describes the definition for the IFSTAT register.

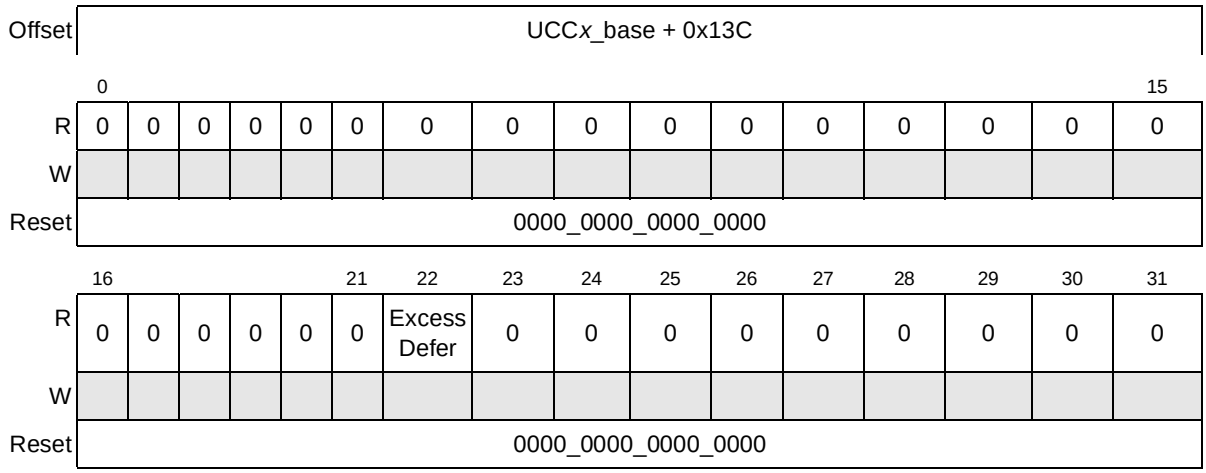

Figure 30-26. Interface Status Register Definition

Table 30-20 describes the IFSTAT fields.

Table 30-20. IFSTAT Field Descriptions

Bits	Name	Description
0–21	—	Reserved
22	Excess Defer	Excessive transmission defer. This bit latches high and is cleared when read. This bit is cleared by default. 0 Normal operation. 1 The MAC excessively defers a transmission.
23–31	—	Reserved

30.5.1.15 Station Address Part 1 Register (MACSTNADDR1)

MACSTNADDR1 register combined with MACSTNADDR2 are used for two purposes:

- Address filtering
- Source address for Flow Control frames

The MACSTNADDR1 register is written by the user. Figure 30-27 describes the definition for the MACSTNADDR1 register. The value of the station address written by the user into MACSTNADDR1 and MACSTNADDR2 is byte reversed from how it would appear in the DA field of a frame in memory. For example, for a station address of 0x12345678ABCD, perform a write to MACSTNADDR1 of 0xCDAB7856, and to MACSTNADDR2 of 0x34120000. When the user reads MACSTNADDR1, 0xCDAB7856 will be returned. A read of MACSTNADDR2 will return a value of 0x34120000. Note, the I/G and U/L bits of the frame's DA field is located at the LSBs of the 1st octet stored in MACSTNADDR2, where the I/G bit is bit 15, and the U/L bit is bit 14.

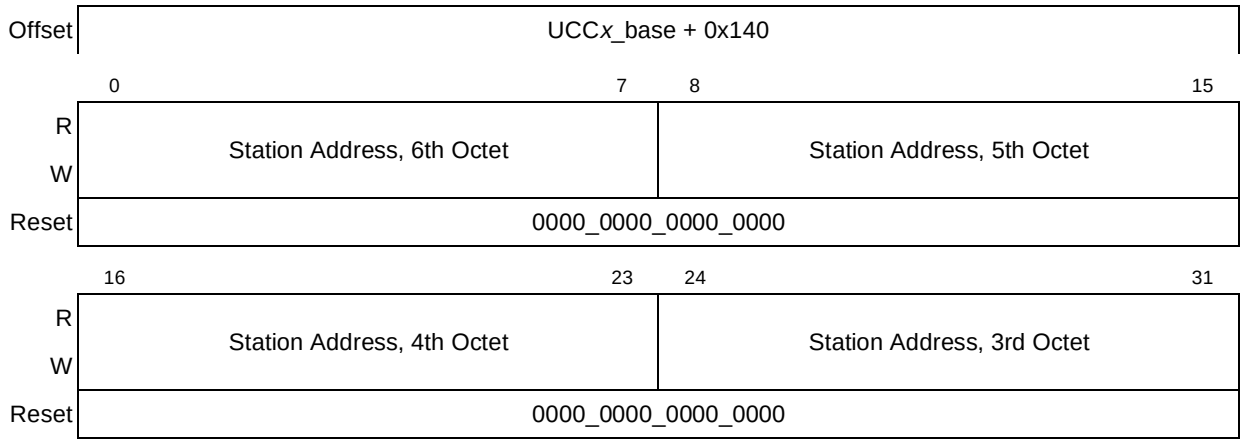

Figure 30-27. Station Address Part 1 Register Definition

Table 30-21 describes the MACSTNADR1 fields.

Table 30-21. MACSTNADR1 Field Descriptions

Bits	Name	Description
0–7	Station Address, 6th Octet	This field holds the sixth octet of the station address. The sixth octet is stored in 40–47and defaults to a value of 0x00.
8–15	Station Address, 5th Octet	This field holds the fifth octet of the station address. The fifth octet is stored in 32–39 and defaults to a value of 0x00.
16–23	Station Address, 4th Octet	This field holds the fourth octet of the station address. The fourth octet is stored in 24–31 and defaults to a value of 0x00.
24–31	Station Address, 3rd Octet	This field holds the third octet of the station address. The third octet is stored in 16–23 and defaults to a value of 0x00.

30.5.1.16 Station Address Part 2 Register (MACSTNADDR2)

The MACSTNADDR2 register is written by the user. Figure 30-28 describes the definition for the MACSTNADDR2 register. Note, the I/G and U/L bits of the frame's DA field is located at the LSBs of the 1st octet stored in MACSTNADDR2, where the I/G bit is bit 15, and the U/L bit is bit 14.

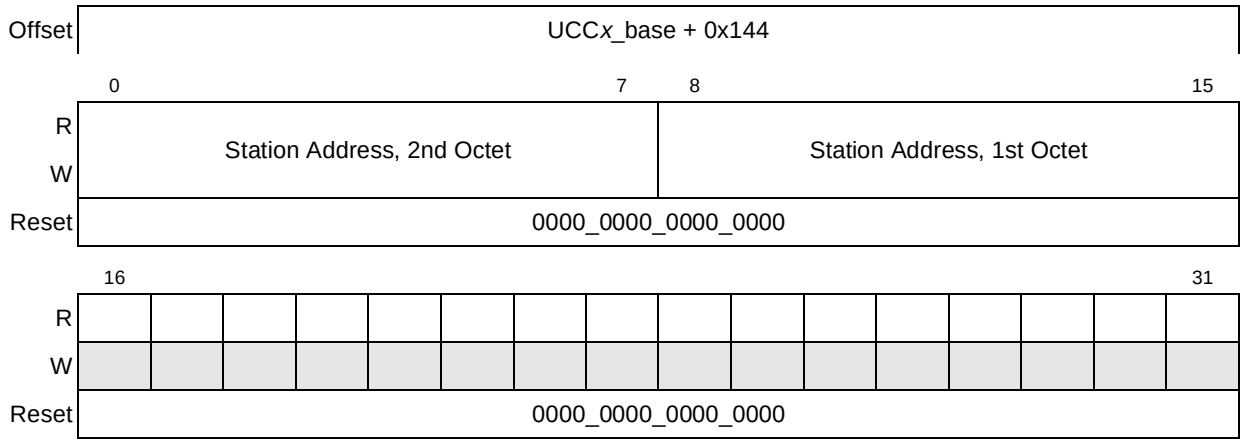

Figure 30-28. Station Address Part 2 Register Definition

Table 30-22 describes the MACSTNADDR2 fields.

Table 30-22. MACSTNADDR2 Field Descriptions

Bits	Name	Description
0–7	Station Address, 2nd Octet	This field holds the second octet of the station address. The second octet is stored in 8–15 and defaults to a value of 0x00.
8–15	Station Address, 1st Octet	This field holds the first octet of the station address. The first octet is stored in 0–7 and defaults to a value of 0x00.
16–31	—	Reserved

30.5.1.17 UCC Ethernet Mac Parameter Register (UEMPR)

offset	UCC*x*_base + 0x150															
Bits	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	Pause time value (MAC Parameter)

Bits	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
Field	Reserved											**TBIPA**				
R/W	R/W															
Reset	0000_0000_0000_000															

Figure 30-30. UCC Ten Bit Interface Physical Address Register (UTBIPAR)

Table 30-24. UTBIPA Field Descriptions

Bits	Name	Description
0–26	—	Reserved
27-31	TBIPA	This field is used to program the PHY address of the ten-bit interface s MII management bus. To access the TBI register the user must write the TBIPA value to the MIIMADD [PHY Address] register located in the MAC register, MII Management Address Register (MIIMADD).

30.5.1.19 UCC Ethernet Statistics Control Register (UESCR)

Offset	UCC*x*_base + 0x158															
Bits	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	AUTOZ	CLRCNT	MAXCOV						SCOV							
R/W	R/W															
Reset	0000_1000_0000_0100															

Figure 30-31. Ethernet Event/Mask Register (UESCR)

Table 30-25 describes the UESCR fields.

Table 30-25. UESCR Field Descriptions

Bits	Name	Description
0	AUTOZ	Automatically zero addressed statistical counter values, input to MSTAT module. 0 The user must write the addressed counter zero after a host read. 1 The addressed counter value is zeroed on a host read. This is a steady state signal and must be set prior to enabling the Ethernet controller and must not be changed without proper care.
1	CLRCNT	Clear all statistics counters 0 Allow MSTAT counters to continue to increment. 1 Reset all MSTAT counters. This bit is self-resetting.
2-7	MAXCOV	Maximum Coalescing Value. This field is used to limit the latency of the uCode in returning Tx buffers to the CPU. The maximum latency is SCOV * MAXCOV * “time to transmit 64 bytes” Default value after reset is 8. The user should not alter the value of this field.
8-15	SCOV	Status Coalescing Value. 0x1-0xFF - The default value after reset is 0x4. This field impacts the performance of the QUICC Engine. It does not affect the functional operation of the QE. The user should not alter the value of this field. 0x0 value is not legal.

30.5.2 Buffer Descriptors

A buffer descriptor is a fixed-size, aligned block of memory that points to a buffer of data for UEC to handle. The UCC Ethernet Controller attempts to prefetch the Buffer Descriptors in groups of four. Certain restriction apply to the BD ring as described in the following sections.

30.5.2.1 Transmit Data Buffer Descriptor (TxBD)

Data is presented to the UCC Ethernet Controller for transmission by arranging it in memory buffers referenced by the TxBDs. In the TxBD the user initializes the R, PAD, W, L, and TC bits and the length (in bytes) in the first word, and the buffer pointer in the second word.

The following restrictions apply to the transmit BD Ring:

- The minimum BD ring size (i.e. number of BDs in the transmit BD ring) must be at least two TxBDs.
- The BD ring must be aligned to 32byte boundary.
- The user must allocate memory size of multiple of 32 bytes for the BD ring. If the size of the BD ring is not a multiple of 32 bytes, the user must pad the remaining bytes with zeroes.
- In VLAN insertion mode other restriction apply. See Figure 30-32 TxBD[VID] field.
- The BD ring size in units of BDs must be greater than the maximum number of TxBDs that construct a frame (i.e., it is forbidden to occupy an entire TxBD ring for a single frame).
- At least one of the following restrictions must be met:
  - When multiple TxBDs are associated with a single frame, the user must set the Rbit of the first TxBD only when the entire frame and the other BDs have been placed in the external memory,

and all Rbits of all BDs are set (i.e. the Rbit of the first BD in a Tx frame must be set last by the CPU).

— The TxBD Ring size must be larger than (UESCR[SCOV] * M + 1) where M=Maximum number of BDs per frame plus one. UESCR[SCOV] default value is four.

The following suggestions yield to better performance

- Single BD per frame.
- The user should set the Rbit in the BDs in groups of four. The UEC prefetches four BDs at one time. The UEC fetches the BDs with Rbit cleared again and again until it finds the Rbit set.
- The prefetching mechanism for the TxBDs is not optimal if the size of the TxBD ring is smaller than four TxBDs.

The Ethernet Controller clears the R bit in the first word of the BD after it finishes using the data buffer. The transfer status bits are then updated. Additional transmit frame status can be found in statistic counters in the RMON block.

Figure 30-32. Transmit Buffer Descriptor

Offset + 2	DATA LENGTH															
Offset + 4	TX DATA BUFFER POINTER															
Offset + 6																

Table 30-26. Transmit Buffer Descriptor Field Description

Offset	Bits	Name	Description
Offset + 0	0	R	Ready, written by UCC Ethernet Controller and user. 0 The data buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated data buffer. The UCC Ethernet Controller clears this bit after the buffer is transmitted or after an error condition is encountered. 1 The data buffer, which is prepared for transmission by the user, was not transmitted or is currently being transmitted. No fields of this BD may be written by the user once this bit is set.
Offset + 0	1	PAD/CRC	PAD/CRC. Padding and CRC attachment for frames. 0 Do not add padding to short frames. No CRC is appended unless TxBD[TC] is set. 1 Add PAD/CRCs to frames. PAD bytes are inserted until the length of the transmitted frame equals 64 bytes. Unlike the MPC8260 which PADs up to MINFLR value, UCC Ethernet Controller PADs always up to the IEEE minimum frame length of 64 bytes. CRC is always appended to frames. Notes: 1. Valid only if MACCFG2[PAD/CRC enable] is cleared. If MACCFG2[PAD/CRC enable] is set, this bit is ignored. 2. This bit must be set in the last TxBD of the frame. It is ignored if set in other TxBDs of the frame.
Offset + 0	2	W	Wrap. Written by user. 0 The next buffer descriptor is found in the consecutive location. 1 The next buffer descriptor is found at the location defined in TBASE.
Offset + 0	3	I	Interrupt. Written by user. 0 No interrupt is generated after this buffer is serviced. 1 UCCE[TXB] or UCCE[TXE] are set after this buffer is serviced. These bits can cause an interrupt if they are enabled (That is, UCCM[TXBEN] or UCCM[TXFEN] are set).
Offset + 0	4	L	Last in frame. Written by user. 0 The buffer is not the last in the transmit frame. 1 The buffer is the last in the transmit frame.
Offset + 0	5	TC	Tx CRC. Written by user. 0 End transmission immediately after the last data byte with no hardware generated CRC appended. 1 Transmit the CRC sequence after the last data byte. Notes: 1. Valid only if MACCFG2[PAD/CRC enable] is cleared. If MACCFG2[PAD/CRC enable] is set, this bit is ignored. 2. This bit must be set in the last TxBD of the frame. It is ignored if set in other TxBDs of the frame.
Offset + 0	6	DEF	Hardware updates this bit when an excess defer condition occurs.DEF—Defer indication, written by hardware. 0 This frame was not deferred. 1 If HAFDUP[EXCESS_DEFER]=1, this frame did not have a collision before it was sent but it was sent late because of deferring. If HAFDUP[EXCESS_DEFER]=0, this frame was aborted and not sent.

Table 30-26. Transmit Buffer Descriptor Field Description (continued)

Offset	Bits	Name	Description
Offset + 0	7	PP/ExDef	Programmable Preamble (programmed by the CPU) 0 - Do not transmit a programmable preamble. 1 - Transmit Programmable preamble. The size of the preamble programmed in register MACCFG2[PREL] field must be 0x7; the preamble bytes are prepended to the data in the data buffer. Excessive Defer (written by the UEC) 0 - No defer 1 - Excessive Defer has occurred in this frame. **Note:** MACCFG2[STP] must be set if TxBD[PP] is set. Note: This bit must be set in the first TxBD of the frame. It is ignored if set in other TxBDs of the frame.
Offset + 0	8	LC	Late collision (written by UCC Ethernet Controller). 0 No late collision. 1 A collision occurred after 64 bytes are sent. The UCC Ethernet Controller terminates the transmission and updates LC. PTP (written by CPU) 0 No PTP action 1 This frame is a IEEE Std. 1588 PTP frame. This frame is timestamped by the UEC at the time it transmitted on the line, and if unmasked, an interrupt is issued to the CPU. This bit is set only on the first TxBD of a frame. See Chapter 31, "QUICC Engine IEEE1588 Assist."
Offset + 0	9	IPCH0/ RL	IPCHI0, IPCHI1 (bit 14), IPCHI2 (bit15). Written by the CPU. Number of entry in IPH_Offset in Section 30.5.3.3, "Tx Global Parameter RAM" used as an offset from the beginning of the frame from which IP checksum is calculated for the transmit frame. If the table contains a 0xFF the checksum is not calculated. These bits must be set in the first TxBD of the frame. 000 - Use entry number 0 001 - Use entry number 1 ..... 111 - Use entry number 7 Note that the IP header must reside in the first TxBD of the frame, and in the first 128 bytes of the frame. The IPCH[0..2] bits must be programmed to a valid value in the first BD of the frame. In other TxBDs of the frame this field is ignored. The value of the IP checksum field in the frame in memory must be zero. Retransmission Limit. Written by UCC Ethernet Controller. 0 Transmission before maximum retry limit is hit. 1 The transmitter failed (max. retry limit + 1) attempts to successfully send a message due to repeated collisions. The UCC Ethernet Controller terminates the transmission and updates RL.

Table 30-26. Transmit Buffer Descriptor Field Description (continued)

Offset	Bits	Name	Description
Offset + 0	10–13	RC / VID	Retry Count. Written by UCC Ethernet Controller. 0 The frame is sent correctly the first time or if RL is set then the retry limit has been reached 1 One or more attempts where needed to send the transmit frame. If this field is 15, then 15 or more retries were needed. The Ethernet controller updates RC after sending the buffer. VLAN Tag ID and Enable; Written by the Host CPU. ID of VLAN Tag to be transmitted. The VLAN Tag value resides in a Table located in the UCC Global multiport RAM at VTBL_BASE. 0xxx - Do not Insert a VLAN Tag on the Transmitted Frame 1nnn- Use VLAN Tag at index VTBL_BASE+0xnnn For VLAN Tag ID insertion, this field must be programmed to ‘1nnn’ only in the first BD of the frame. Other Tx BDs in the frame must have this field programmed to ‘0000’. The Data length of the first TxBD of the frame must be >= 12 bytes.
Offset + 0	14	IPCHI1/ UN	IPCHI1. See description for bit 9. Underrun. Written by UCC Ethernet Controller. 0 No underrun encountered (data was retrieved from external memory in time to send a complete frame). 1 The Ethernet Controller encountered a transmitter underrun condition while sending the associated buffer. The UCC Ethernet Controller terminates the transmission and updates UN.
Offset + 0	15	IPCHI2/ CSL	IPCHI2. See description for bit 9. Carrier sense lost. Carrier sense is lost during frame transmission. The Ethernet controller updates CSL after sending the buffer.
Offset + 2	0–15	Data Length	Data length is the number of octets the UCC Ethernet Controller should transmit from this BD’s data buffer. It is never modified by the UCC Ethernet Controller. This field must be greater than zero. This field must be greater than zero.
Offset + 4	0–31	TX Data Buffer Pointer	The transmit buffer pointer contains the address of the associated data buffer. There are no alignment requirements for this address.

30.5.2.2 Receive Buffer Descriptor (RxBD)

In the RxBD, the user initializes the E, I, and W bits in the first word and the pointer in the second word. The first word of the RxBD contains control and status bits. The UCC Ethernet Controller modifies the E, L, F, M, BC, MC, LG, NO, SH, CR, OV, and IPCH bits and writes the length of the used portion of the buffer in the first word. The M, BC, MC, LG, NO, SH, CR, OV, and IPCH bits in the first word of the buffer descriptor are valid if the L bit is set.

The following restrictions apply to the receive BD Ring:

- The BD ring size (i.e. number of BDs in the receive BD ring) must be modulo four.
- The smallest numbers of BDs in a BD ring is eight
- The BD ring must be initialized with empty BDs (E=1) before the Ethernet init command is executed. Otherwise a busy condition occurs on the first frame
- The BD ring must be aligned to 32byte boundary
- MRBLR must be a multiple of Virtual FIFO block size (i.e. a multiple of 128 bytes)

The following suggestions yield to better performance

- The user should set the E bit in the BDs in groups of four. The UEC prefetches four BDs at one time. The UEC fetches the BDs with E bit cleared again and again until it finds the E bit set.
- It is suggested to initialize a BD ring that can host multiple frames to avoid busy condition
- Single BD per frame

In the RxBD, the user initializes the E, I, and W bits in the first word and the pointer in the second word. If the data buffer is used, UCC Ethernet Controller modifies the E, L, F, M, BC, MC, LG, NO, SH, CR, OV, and TR bits and writes the length of the used portion of the buffer in the first word. The M, BC, MC, LG, NO, SH, CR, OV, and IPCH bits in the first word of the buffer descriptor are only modified by UCC Ethernet Controller if the L bit is set. The first word of the RxBD contains control and status bits. Its format is detailed below. Figure 30-33 describes the definition for the RxBD.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0	E	Res	W	I	L	F	PTP	M	BC	MC	LG	NO	SH	CR	OV	IPCH
Offset + 2	DATA LENGTH															
Offset + 4	RX DATA BUFFER POINTER															
Offset + 6																

Figure 30-33. Receive Buffer Descriptor

Table 30-27. Receive Buffer Descriptor Field Descriptions

Offset	Bits	Name	Description
Offset + 0	0	E	Empty, written by the UCC Ethernet Controller (when cleared) and by the user (when set). 0 The data buffer associated with this BD is filled with received data, or data reception is aborted due to an error condition. The status and length fields have been updated as required. 1 The data buffer associated with this BD is empty, or reception is currently in progress.
Offset + 0	1	—	Reserved. Set to zero.
Offset + 0	2	W	Wrap, written by user. 0 The next buffer descriptor is found in the consecutive location. 1 The next buffer descriptor is found at the location defined in RBASE.
Offset + 0	3	I	Interrupt, written by user. 0 No interrupt is generated after this buffer is serviced. 1 UCCE[RXB0..7] is set after this buffer is serviced. This bit can cause an interrupt if enabled (UCCM[RXBEN1..7]).

Table 30-27. Receive Buffer Descriptor Field Descriptions (continued)

Offset	Bits	Name	Description
Offset + 0	4	L	Last in frame, written by the UCC Ethernet Controller. 0 The buffer is not the last in a frame. 1 The buffer is the last in a frame.
Offset + 0	5	F	First in frame, written by the UCC Ethernet Controller. 0 The buffer is not the first in a frame. 1 The buffer is the first in a frame.
Offset + 0	6	PTP	If IEEE Std. 1588 mode is enabled in the UCC this bit is set by the UCE if this is a PTP frame. Refer to Chapter 31, "QUICC Engine IEEE1588 Assist." In this case LAST_PCD[BDM0] feature is not supported. If IEEE Std. 1588 Mode is disabled in the UCC this bit is set as follows. If REMODER[EXP]=1. Valid only when L bit is set in the RxBD This bit is set if LAST_PCD[BDM0] is set
Offset + 0	7	M	Miss, written by the UCC Ethernet Controller. (This bit is valid only if the L-bit is set and UCC Ethernet Controller is in promiscuous mode and if REMODER[EXP]=0) This bit is set by the UCC Ethernet Controller for frames that were accepted in promiscuous mode, but were flagged as a 'miss' by the internal address recognition; thus, while in promiscuous mode, the user can use the M-bit to quickly determine whether the frame was destined to this station. 0 The frame was received because of an address recognition hit. 1 The frame was received because of promiscuous mode. If REMODER[EXP]=1. Valid only when L bit is set in the RxBD This bit is set is LAST_PCD[BDM1] is set.
Offset + 0	8	BC	Broadcast. Written by UCC Ethernet Controller. (Only valid if L is set.) Is set if the DA is broadcast (FF-FF-FF-FF-FF-FF).
Offset + 0	9	MC	Multicast. Written by UCC Ethernet Controller (Only valid if L is set.) Note that if BC is set, this bit is also set.
Offset + 0	10	LG	Rx frame length violation, written by the UCC Ethernet Controller (only valid if L is set). A frame length greater than maximum frame length was recognized. This bit is valid only if the L-bit is set.
Offset + 0	11	NO	Rx non-octet aligned frame, written by the UCC Ethernet Controller (only valid if L is set). A frame that contained a number of bits not divisible by eight was received.
Offset + 0	12	SH	Short frame, written by the UCC Ethernet Controller (only valid if L is set). A frame length that was less than the minimum length defined for this channel (MINFLR) was recognized,.
Offset + 0	13	CR	Rx CRC error, written by the UCC Ethernet Controller (only valid if L is set). The CR bit in the BD is set in the following cases: a) The CRC value a the end of the frame does not match the CRC calculated on the frame received from the line before any header modification. b) If a receive code group error is detected, or c) The previous frame got rx_er (code symbol error) and in addition it has been dropped due to an IPG violation (IPG smaller then 96 bit time).
Offset + 0	14	OV	Overrun, written by the UCC Ethernet Controller (only valid if L is set). A receive FIFO overrun occurred during frame reception. If this bit is set, the other status bits, M, LG, NO, SH, CR lose their normal meaning and are zero and should be ignored.

Table 30-27. Receive Buffer Descriptor Field Descriptions (continued)

Offset	Bits	Name	Description
Offset + 0	15	IPCH	IP Checksum written by the UCC Ethernet Controller if REMODER[IPCHK]=1 0 - IP checksum check on IPv4 header passed 1 - IP checksum check on IPv4 header failed Note: This bit is NOT changed by the UCC Ethernet Controller if REMODER[IPCHK]=0.
Offset + 2	0–15	Data Length	Data length, written by the UCC Ethernet Controller. Data length is the number of octets written by the UCC Ethernet Controller into this BD's data buffer if L is cleared (the value is equal to MRBL), or the length of the frame including CRC, if L is set. Note that when IPAE is enabled (IP address alignment) the frame length does not include the two extra 'garbage' bytes inserted at the beginning for purpose of alignment.
Offset + 4	0–31	Rx Data Buffer Pointer	Receive buffer pointer, written by the user. The receive buffer pointer, which always points to the first location of the associated data buffer, must be 8-byte aligned. The buffer must reside in memory external to the UCC Ethernet Controller.

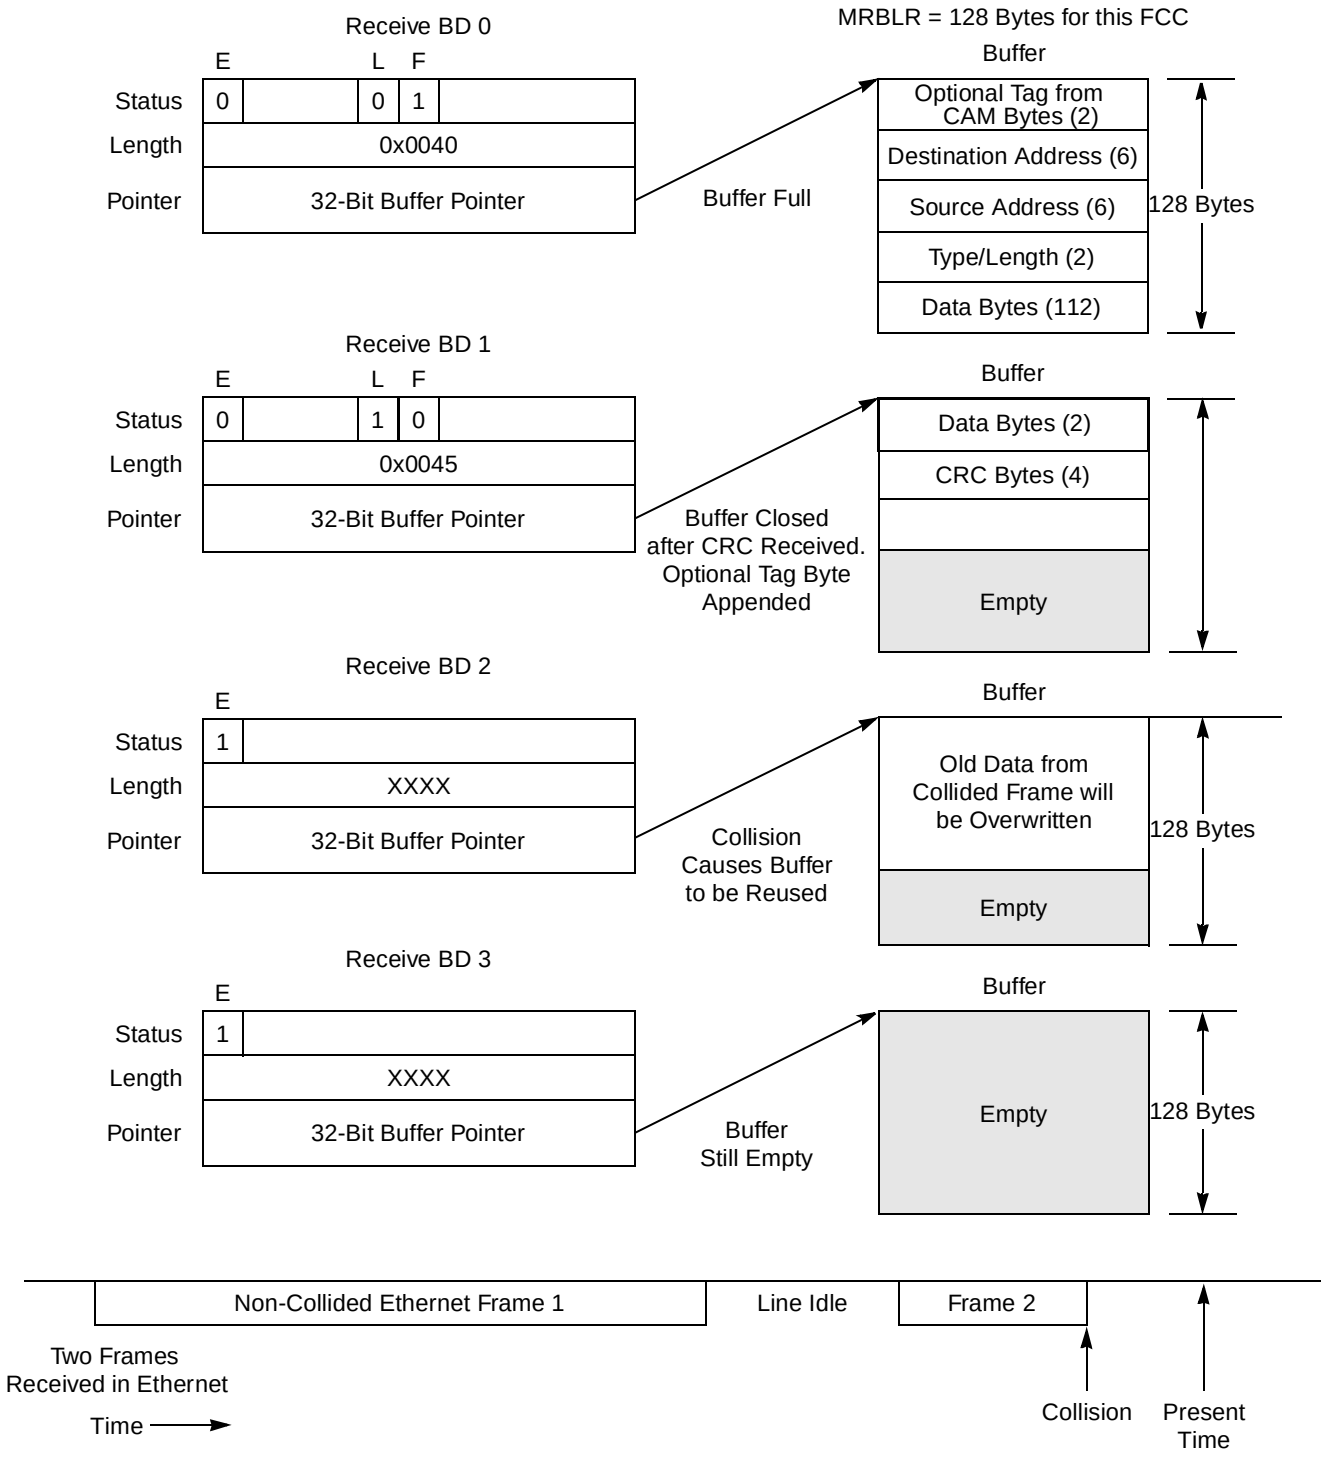

Figure 30-34. Example of Ethernet Receiving Using RxBD

30.5.3 Parameter RAM

The UCC Ethernet transmitter and receiver have their own individual Parameter RAM. Each Parameter RAM is split into two types: Global Parameter RAMs and Thread Parameter RAM.

The BASE Address for the UCC Parameter RAM and of Thread Parameter RAM is determined by the QE Commands “Section 30.8.1, Init Tx, Init Rx and InitTx and Rx Parameters Command” on page 115. The number of threads that each UCC runs is configured in the same command.

The Ethernet INIT command must be executed after the Rx and Tx Parameter RAM have been initialized by the user.

The following table specifies the multiuser RAM allocation for data structures necessary for the UEC as a function of the number of queues and the nominal bit rate on the interface. One data structure is associated with the nominal bit rate which is programmed in INIT RX PARAMETERS[RGF] and INIT TX PARAMETERS[TGF] fields. The other data structure is associated with the number of queues, which is programmed in REMODER[NumOfQueues] and TEMODER[NumOfQueues] fields.

Table 30-28. Rx Global Parameter RAM Allocation

	Extended Filtering	Bit Rate					Number of queues							
	REMODER [EXP]=1	1Gbps	10/100 Mbps	Other values for system optimizations			1		2		4		8	
Number of Threads		4	1	2	6	8								
Pointer Name	EXFGlobal Param	RQPTR	RQPTR	RQPTR	RQPTR	RQPTR	RBDQPTR	IntCoalescingPTR	RBDQPTR	IntCoalescingPTR	RBDQPTR	IntCoalescingPTR	RBDQPTR	IntCoalescingPTR
Global Parameter RAM size	16bytes	160 bytes	40 bytes	80 bytes	240 bytes	320 bytes	48 bytes	8 bytes	96 bytes	16 bytes	192 bytes	32 bytes	384bytes	64 bytes

The following table summarizes the memory size for the thread parameter RAM, depending on the features selected by the user. Each thread requires a separate parameter RAM of the size mentioned in this table.

Table 30-29. Rx Thread Parameter RAM allocation

Mode	Basic Thread Parameter RAM	REMODER[EXP]=1 Extended Parsing Mode			Total
	Always Needed	Lookup Type			
Termination	128[1]	No External[2] HashLookup		64	192
		ExternalHash Lookup[5]	8 byte LookupKey	128	256
			16 byte LookupKey	160	288

1 See Section 30.5.3.6, “Rx Thread Parameter RAM”

2 Optionally part of Rx Thread Parameter RAM.

The following table summarized the memory size needed for the Tx Parameter RAM.

Table 30-30. Tx Parameter RAM Allocation

	Bit Rate					Number of queues			
	1Gbps	10/100Mbps	Other values for system optimizations			1	2	4	8
Number of Threads	4	1	2	6	8				
Pointer Name	TQPTR	TQPTR	TQPTR	TQPTR	TQPTR	SQPTR	SQPTR	SQPTR	SQPTR
Multiuser RAM size	416 bytes	136 bytes	208 bytes	624 bytes	832 bytes	64 bytes	128 bytes	256 bytes	512 bytes

30.5.3.1 Transmitter Parameter RAM Overview

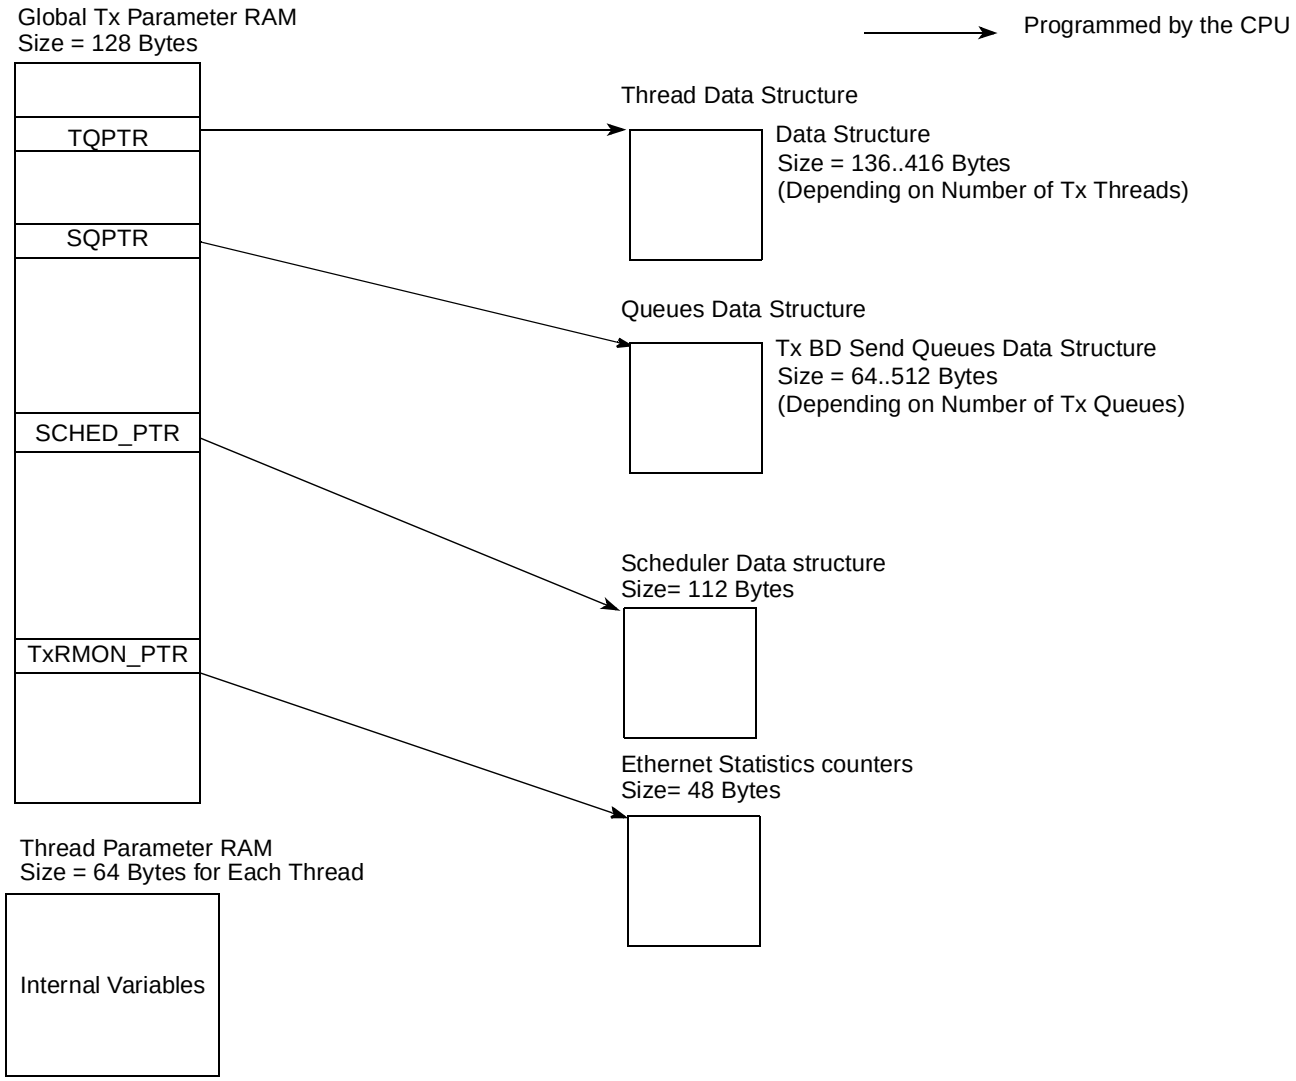

Figure 30-35. Transmitter Parameter RAM Data Structures

30.5.3.2 Receiver Parameter RAM Overview

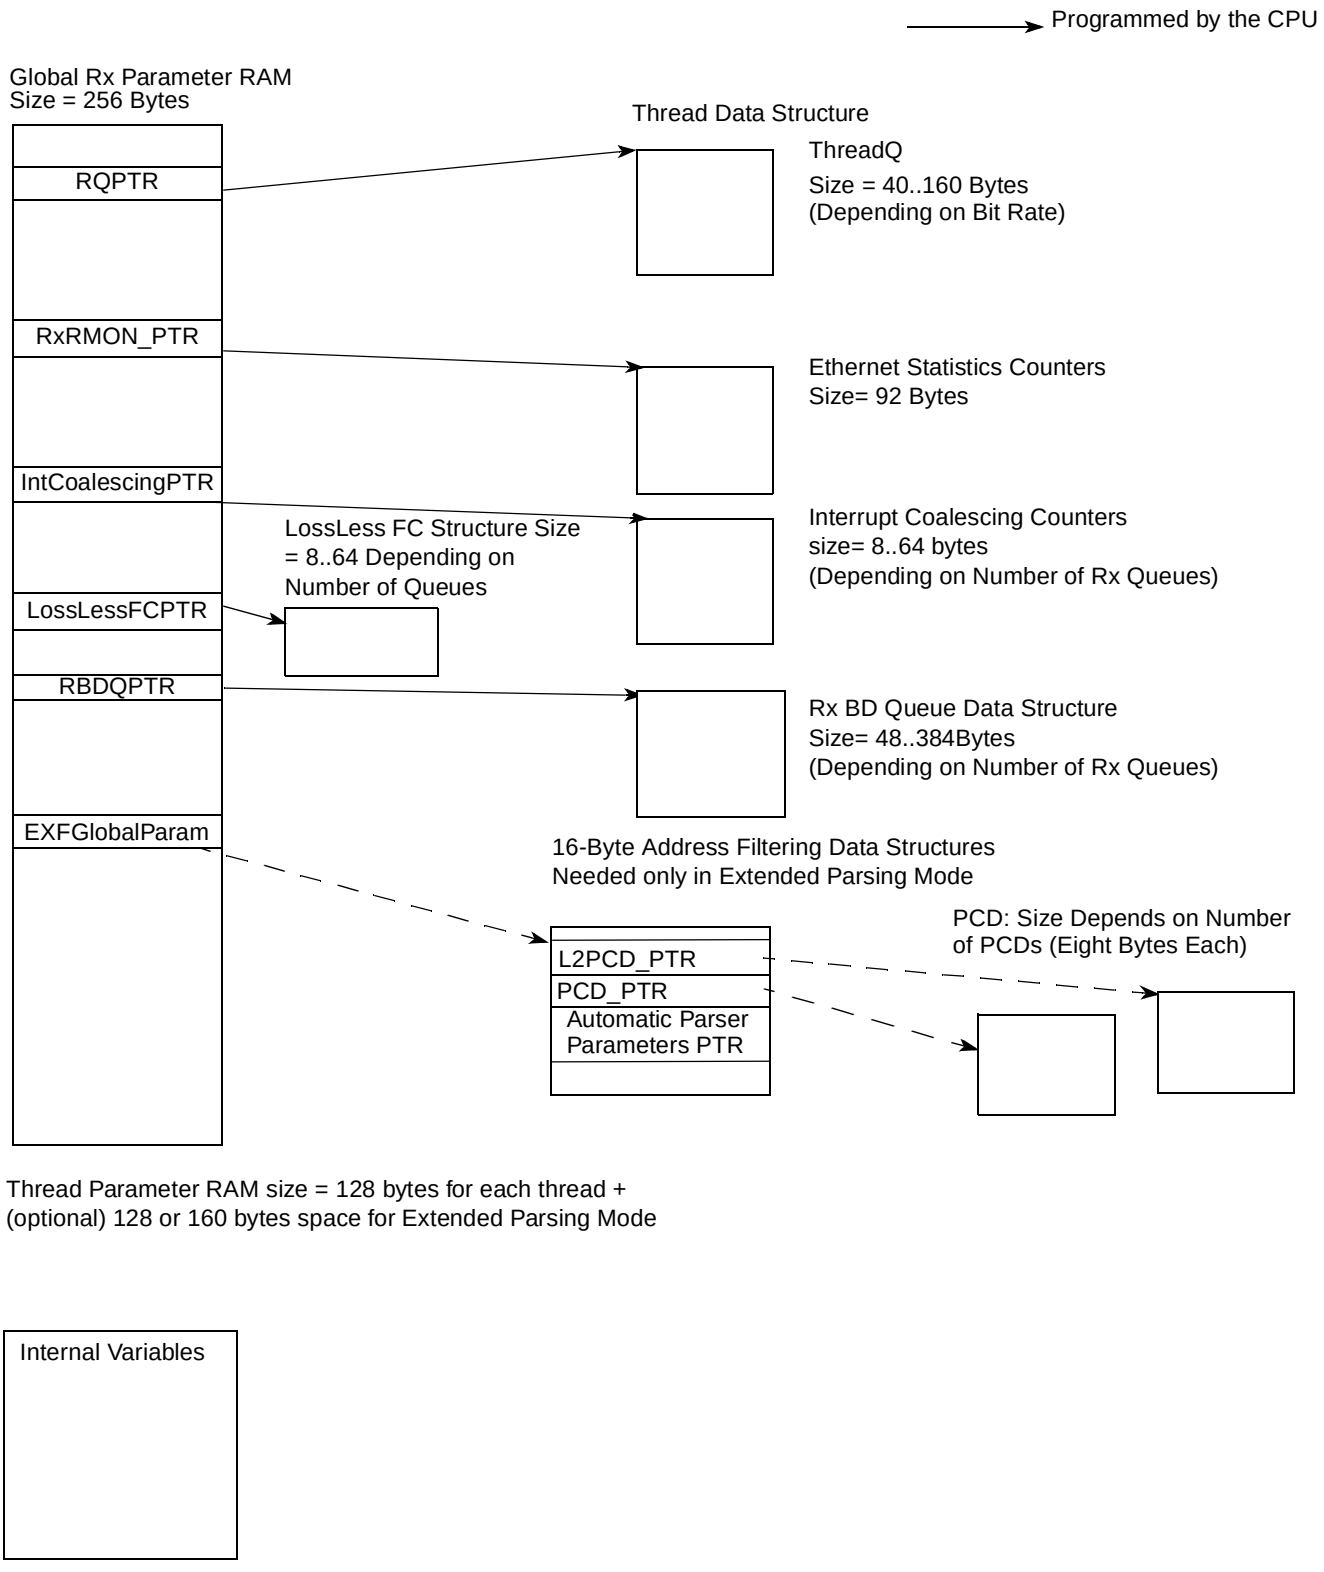

Figure 30-36. Receiver Parameter RAM Data Structures for Termination

30.5.3.3 Tx Global Parameter RAM

The following table describes the Tx Global Parameter RAM:

Table 30-31. Tx Global Parameter RAM

Offset	Bits	Name	Description	Initialized by
0x0-0x1 TEMODER		TEMODER	Transmit Ethernet Mode Register.	CPU
	0	StartOfFrame	Internal variable. Initialize to 1.	CPU
	1	StartOfBD	Internal variable. Initialize to 1.	CPU
	2	SchedEnable	When set the frame scheduler is enabled otherwise the scheduler is disabled. When the number of send queues is 1 the scheduler shall be disabled.	CPU
	3	PrefAndContFlag	Internal variable.	CPU
	4	Reserved	Internal variable.	CPU
	5	IPCHK	Enable IP Checksum Generate 0 - Do not generate IP checksum in IPv4 frames 1 - Generate IP checksum in IPv4 frames Note: The value of the IP checksum in the IP header placed by the CPU in memory must be zero Note: The IP header must reside in the first TxBD of the frame, and in the first 128 bytes of the frame.	CPU
	6	Reserved	Internal variable.	CPU
	7	RMONEN	When set RMON statistics counters are enabled.	CPU
	8-9	Res	Set to zero	CPU
	10-12	Reserved	Reserved. Initialize to zero.	CPU
	13-15	NumOfQueues	Number of Tx queues 000 - One Tx queue 001 - Two Tx queues ... 111 - Eight Tx queues	CPU
0x2-0x37	53 bytes	Reserved		QE
0x38-0x3B	0:15	SQPTR	Base address of the send queue memory region. See Section 30.5.3.3.2, “Tx Send Queue Memory Region.”	CPU
	0:15			
0x3C-0x3F	0:15	SchedulerBasePointer	Base address of the scheduler memory region (SCBASE) located in internal Multiuser RAM. See Section 30.5.3.3.3, “Scheduler Programming Model and Data Structures”. This address must be eight bytes aligned.	CPU
	0:15			
0x40-0x43	0:15	TxRMONBasePointer	Base address of the Tx RMON statistic counter located in internal Multiuser RAM. See Section 30.7.4.1, “TX Firmware Counters.” This address must be four bytes aligned.	CPU
	0:15			

Table 30-31. Tx Global Parameter RAM (continued)

Offset	Bits	Name	Description	Initialized by
0x44 - 0x47	0:31	TSTATE	Transmit internal state. The high byte of TSTATE, bit 0 to 7, contains the Bus Mode Register which is programmed by the Host CPU at initialization. Other bits in this register are for internal QE usage. See Section 30.5.4, "Bus Mode Register (BMRx)." The rest of the bits are initialized to zero.	CPU
0x48-4F	0:31	IPH_Offset0,1...7	Offset (in bytes) from the beginning of the packet to the beginning of the IP header. IPH_Offset0,1...7 value is used if TxBD[IPCHI0,IPCHI1,IPCH12] = 000,001...111 respectively. The following restrictions apply: 1. The IP header offset is the offset from the TxBD[Tx Data Buffer Pointer] 2. Minimum value is 0 maximum value is 128-size of IP header. 3. 0xFF means that no checksum is calculated	CPU
0x50-0x6f	0:15 0:15	VTAGTable	VLAN Tag Table. Consists of up to 8 4-byte VLAN tags. The table must be initialized after reset if VLAN insertion is employed.	CPU
0x70-0x73	0:31	TQPTR	Base Address of theThread Data Structure located in internal Multiuser RAM. This address must be aligned to: 64 bytes in case of one thread is used. 128 bytes in case of four threads are used.	CPU
0x74-0x77		Reserved	Internal variable.	N/A

30.5.3.3.1 Thread Data Structure

This data structure is located at base address TQPTR. The data structure is initiated by the QE upon issuing an INIT Tx Ethernet Command.

30.5.3.3.2 Tx Send Queue Memory Region

The send queue memory region is pointed by the SQPTR in the Tx Global Parameter RAM, consists of queue descriptor per every send queue (SQQD). Up to 8 send queues are supported. SQQDs are placed in a consecutive order in the Send Queue Memory region as illustrated by the following table:

Table 30-32. Send Queue Descriptors

Offset	Bits	Name	Description
0x00-0x3f		SQQD0	Send queue 0 queue descriptor.
0x40-0x7f		SQQD1	Send queue 1 queue descriptor.
0x80-0xbf		SQQD2	Send queue 2queue descriptor.
0xc0-0xff		SQQD3	Send queue 3 queue descriptor.
0x100-0x13f		SQQD0	Send queue 4 queue descriptor.
0x140-0x17f		SQQD1	Send queue 5 queue descriptor.
0x180-0x1bf		SQQD2	Send queue 6 queue descriptor.
0x1c0-0x1ff		SQQD3	Send queue 7 queue descriptor.

Every SQQD is 64 bytes long and is described in detail by the following table:

Table 30-33. Tx Send Queue Descriptor (SQQD)

Offset	Bits	Name	Description (Data structure must be 32 bytes aligned).	Initialized by
0x00-0x03	0:31	BDRingBase	A pointer to the BD ring base address located in external memory. This field must be initialized to the base address of the BD ring.	CPU
0x04-0x07		Reserved	Set to zero	QE
0x08-0x09	0:31	BDRConsumerAddress	Points to the next entry in the BD ring to be executed. This field must be initialized after reset to the first entry in the BD ring.	QE
0x0A - 0x0B		Reserved		QE
0x0C - 0x0D	0:15	LastBDCompletedAddress	This field must be initialized after reset to point to the last entry in the BD ring.	CPU
0x0E-0x3F		Reserved	Set to zero	QE

30.5.3.3.3 Scheduler Programming Model and Data Structures

The following tables summarizes the programming model and data structures. The base address to the scheduler memory region is specified in the Tx Global parameter RAM.

Table 30-34. Scheduler Programming Model

Address (offset from SCBASE)	Name	Width (bit)	Description	Initialized by
0x0	CPUCount0	16	CPU Packet counter. CPU must increment this counter by one every time a frame is placed in TxBD ring #0	QE
0x2	CPUCount1	16	CPU Packet counter. CPU must increment this counter by one every time a frame is placed in TxBD ring #1	
0x4	CECount0	16	QE Packet counter. This entry is updated by the QE. The CPU must no alter its value.	
0x6	CECount1	16	QE Packet counter. This entry is updated by the QE. The CPU must no alter its value.	
0x8	CPUCount2	16	CPU Packet counter. CPU must increment this counter by one every time a frame is placed in TxBD ring #2	
0xA	CPUCount3	16	CPU Packet counter. CPU must increment this counter by one every time a frame is placed in TxBD ring #3	
0xC	CECount2	16	QE Packet counter. This entry is updated by the QE. The CPU must no alter its value.	
0xE	CECount3	16	QE Packet counter. This entry is updated by the QE. The CPU must no alter its value.	
0x10	CPUCount4	16	CPU Packet counter. CPU must increment this counter by one every time a frame is placed in TxBD ring #4	
0x12	CPUCount5	16	CPU Packet counter. CPU must increment this counter by one every time a frame is placed in TxBD ring #5	
0x14	CECount4	16	QE Packet counter. This entry is updated by the QE. The CPU must no alter its value.	

Table 30-34. Scheduler Programming Model (continued)

Address (offset from SCBASE)	Name	Width (bit)	Description	Initialized by
0x16	CECount5	16	QE Packet counter. This entry is updated by the QE. The CPU must no alter its value	QE
0x18	CPUCount6	16	CPU Packet counter. CPU must increment this counter by one every time a frame is placed in TxBD ring #6	
0x1A	CPUCount7	16	CPU Packet counter. CPU must increment this counter by one every time a frame is placed in TxBD ring #7	
0x1C	CECount6	16	QE Packet counter. This entry is updated by the QE. The CPU must no alter its value	
0x1E	CECount7	16	QE Packet counter. This entry is updated by the QE. The CPU must no alter its value	
0x20	WeightStatus0	32	Accumulated Weight factor for queue #0. Initialized by SW to 0	
0x24	WeightStatus1	32	Accumulated Weight factor for queue #1. Initialized by SW to 0	
0x28	WeightStatus2	32	Accumulated Weight factor for queue #2. Initialized by SW to 0	
0x2C	WeightStatus3	32	Accumulated Weight factor for queue #3. Initialized by SW to 0	
0x30	WeightStatus4	32	Accumulated Weight factor for queue #4. Initialized by SW to 0	
0x34	WeightStatus5	32	Accumulated Weight factor for queue #5. Initialized by SW to 0	
0x38	WeightStatus6	32	Accumulated Weight factor for queue #6. Initialized by SW to 0	
0x3C	WeightStatus7	32	Accumulated Weight factor for queue #7. Initialized by SW to 0	
0x40	RTSRShadow	32	Temporary variable handled by the QE	N/A
0x44	Time	32	Temporary variable handled by the QE	N/A
0x48	TTL	32	Temporary variable handled by the QE	N/A
0x4C	MBLInterval	32	Max Burst Length interval. This parameter determines the longest 1Gbps burst allowed by the Traffic Shaper. The user should program this parameter according to the following formula: MBLInterval = INTEGER[MBL * TSRByteTime] Where MBL is the maximum burst size in bytes allows by the receiver side, and TSRByteTime is the transmission time for one data byte expressed in TSR count units.	CPU
0x50	NorTSRByteTime	16	Contains the normalized value of Byte time in TSR units in the desired frequency. Calculated according to the formula: ROUND[TSRByteTime * 2^FracSiz]. See above for further explanation. Also see example calculations in Section 30.15, “Traffic Shaper Programming Considerations.”	CPU
0x52	FracSiz	8	This parameter contains the radix 2 log value of the denominator of NorTSRByteTime, as follows: TSRByteTime = NorTSRByteTime/2^FracSiz. See example calculations in Section 30.15, “Traffic Shaper Programming Considerations.”	CPU
0x53	Reserved	8	Set to zero	CPU

Table 30-34. Scheduler Programming Model (continued)

Address (offset from SCBASE)	Name	Width (bit)	Description	Initialized by
0x54	StrictPriorityQ	8	Strict Priority Mask register. Bit i of this register, i=0..7, corresponds to output queue 0:7 respectively. If the bit is set, the output queue associated with this bit belongs to the Strict Priority group (SP Queue). If the bit is cleared, the queue belongs to the WFQ group of queues (WFQ Queue)	CPU
0x55	TxASAP	8	Transmit ASAP Register. Bit i of this register, i=0..7, corresponds to output queue 0:7 respectively. If the bit is set, the packet in the output queue associated with this bit is transmitted ASAP, without Weighting to the existence of the Traffic Scheduler limitations as maximum burst and average data rate	CPU
0x56	ExtraBW	8	Extra bandwidth register. Bit i of this register, i=0..7, corresponds to output queue 0:7 respectively. If the bit is set, the queue corresponds to this bit is not consuming BW from the budget allowed by the Traffic Shaper. Rather, its consumed BW is added to the general line Bandwidth.	CPU
0x57	OldWFQMask	8	Temporary variable. Initialized to 0.	QE
0x58	WeightFactor0	8	Weight Factor for queue 0. Indicates the size of the Weight period following the transmission of data quantum of size 2^LogBlockLength bytes for Queue 0	CPU
0x59	WeightFactor1	8	Weight Factor for queue 1. Indicates the size of the Weight period following the transmission of data quantum of size 2^LogBlockLength bytes for Queue 1	
0x5A	WeightFactor2	8	Weight Factor for queue 2. Indicates the size of the Weight period following the transmission of data quantum of size 2^LogBlockLength bytes for Queue 2	
0x5B	WeightFactor3	8	Weight Factor for queue 3. Indicates the size of the Weight period following the transmission of data quantum of size 2^LogBlockLength bytes for Queue 3	
0x5C	WeightFactor4	8	Weight Factor for queue 4. Indicates the size of the Weight period following the transmission of data quantum of size 2^LogBlockLength bytes for Queue 4	
0x5D	WeightFactor5	8	Weight Factor for queue 5. Indicates the size of the Weight period following the transmission of data quantum of size 2^LogBlockLength bytes for Queue 5	CPU
0x5E	WeightFactor6	8	Weight Factor for queue 6. Indicates the size of the Weight period following the transmission of data quantum of size 2^LogBlockLength bytes for Queue 6	
0x5F	WeightFactor7	8	Weight Factor for queue 7. Indicates the size of the Weight period following the transmission of data quantum of size 2^LogBlockLength bytes for Queue 7	
0x60	MinW	32	Temporary variable handled by QE. Initialized to 0.	QE

Table 30-34. Scheduler Programming Model (continued)

Address (offset from SCBASE)	Name	Width (bit)	Description	Initialized by
0x64	Reserved	32	Initialized to 0.	QE
0x68-6F	Reserved		Initialized to 0	QE

30.5.3.4 Tx Thread Parameter RAM

The TX thread parameter RAM is summarized by the following table:

Table 30-35. Tx Thread Parameter RAM

Offset	Bits	Name	Description	Initialized by
0x00-0x3F		Reserved	Internal variable.	QE

30.5.3.5 Rx Global Parameter RAM

The RX Global Parameter RAM is summarized by the following table:

Table 30-36. RX Global Parameter RAM

Offset	Bits	Name	Description	Initialized by
0x00	0–31	REMODER	Ethernet Mode Register. See Section 30.5.3.7, “Rx Ethernet Mode Register (REMODER).” Initialize to zero.	CPU
0x04	0–31	RQPTR	Base Address of the Thread Data Structure located in internal Multiuser RAM. This address must be aligned to: 32 bytes in case of one thread is used. 128 bytes in case of four threads are used.	CPU
0x08-0x1F	0–31	Reserved	Initialize to zero	QE
0x20		Type_or_Len	If the value of Type/Len field in the frame is less than Type_or_Len value, then the Type/Len field in the frame indicates the length of the frame. If the value of Type/Len field in the frame is equal or greater than Type_or_Len value, then the Type/Len field in the frame indicates the protocol type of the next header in the frame.	CPU
0x22	0–14	Reserved	Set to zero	CPU
	15	RxGSTPAck	Receive Graceful STOP Host Command acknowledge 0 - Receive Graceful Stop Host Command is not completed by QE 1 - Receive Graceful Stop Host Command is completed, no more frames are received till Receive Restart Host Command is issued, or the UEC is reset and re-enabled. The CPU should reset this bit before issuing the Graceful Stop Host Command.	
0x24	0–31	RxRMONBasePointer	Rx Ethernet Statistics Counters base address located in internal Multiuser RAM. This base address must be four bytes aligned.	CPU

Table 30-36. RX Global Parameter RAM (continued)

Offset	Bits	Name	Description	Initialized by
0x28-0x2F		Reserved	Set to zero	QE
0x30	0–31	IntCoalescingPTR	Base Address to Interrupt Coalescing Table located in internal Multiuser RAM. The user must allocate a data structure of size (in bytes) = 8*number of Rx queues + 4. This base address must be 64 bytes aligned.	CPU
0x34	0–7	Busy_vector	Busy condition. one bit per queue. Set when a frame is received and discarded due to a lack of buffers. Initialize to zero.	N/A
0x35	0–7	Reserved		QE
0x36	0–7	RSTATE	Receive internal state. Reserved for QE use only. This byte contains the bus mode register. See Section 30.5.4, “Bus Mode Register (BMRx).”	CPU
0x37-0x43		Reserved	Set to zero	QE
0X44	0–7	OV_SkipFrame	Number of frames to be discarded (skipped) when a Rx Virtual FIFO overrun condition occurs. Refer to “Section 30.4.5.1, Virtual FIFO Overun Smoother” on page 11for details.	CPU
0X45	0–7	OV_SkipFrame_Cnt	Internal variable. Set to zero	CPU
0x46	0–15	MRBLR	Maximum receive buffer length (a multiple of block size). The number of bytes that the UCC receiver writes to a receive buffer before moving to the next buffer. The receiver can write fewer bytes to the buffer than MRBLR if a condition such as an error or end-of-frame occurs, but it never exceeds the MRBLR value. Therefore, user-supplied buffers should be at least as large as the MRBLR. Note that UCC transmit buffers can have varying lengths by programming TxBD[Data Length], as needed, and are not affected by the value in MRBLR. MRBLR is not intended to be changed dynamically while an UCC is operating. Change MRBLR only when the UCC receiver is disabled. MRBLR must be a multiple of the Virtual FIFO block size. See Section 30.5.2.2, “Receive Buffer Descriptor (RxBD)” for restriction on the buffer size. Note: If EMODER[DNE]=0 MINFLR<MRBLR. If EMODER[DNE]=1 MINFLR < (MRBLR-4)	CPU
0x48	0–31	RBDQPTR	RxBD Parameter Table Base Address located in internal Multiuser RAM. See Section 30.5.3.10, “RxBD Queue data structures”. For each Rx queue the user must allocate 16+32 bytes. This base must be eight byte aligned.	CPU
0x4C	0–15	MFLR	Maximum frame length register (typically1518 decimal)—If the Ethernet controller detects an incoming frame exceeding MFLR, it sets RxBD[LG] (frame too long) in the last RxBD but not discards the rest of that frame. The controller also reports the frame status and length of the received frame MFLR includes all in-frame bytes between the start frame delimiter and the end of the frame.	CPU

Table 30-36. RX Global Parameter RAM (continued)

Offset	Bits	Name	Description	Initialized by
0x4E	0–15	MINFLR	Minimum frame length register (typically 64 decimal)—If the Ethernet receiver detects an incoming frame shorter than MINFLR, it discards that frame unless FPSMR[RSH] (receive short frames) is set, in which case RxBD[SH] (frame too short) is set in the last RxBD. MINFLR value must be smaller than MRBLR value. Note: If EMODER[DNE]=0 MINFLR<MRBLR. If EMODER[DNE]=1 MINFLR < (MRBLR-4)	CPU
0x50	0–15	MAXD1	Max DMA1 length register (typically1520 decimal)—Lets the user prevent system bus writes after a frame exceeds a certain size. The MAXD1 value is valid only if an address match is detected. If the Ethernet controller detects an incoming Ethernet frame larger than the user-defined value in MAXD1, the rest of the frame is discarded. The Ethernet controller waits for the end of the frame and reports the frame status and the frame length in the last RxBD. This value must be greater than block size. The frame length includes the discarded bytes.	CPU
0x52	0–15	MAXD2	Max DMA2 length register (typically1520 decimal)— Lets the user prevent system bus writes after a frame exceeds a certain size. The value of MAXD2 is valid in promiscuous or Extended Parsing mode when no address match is detected and the Last PCD is reached. If the Ethernet controller detects an incoming Ethernet frame larger than the value in MAXD2, the rest of the frame is discarded. The Ethernet controller waits for the end of the frame and reports frame status and length in the last RxBD. In a monitor station, MAXD2 can be much less than MAXD1 to receive entire frames addressed to this station, but receive only the headers of all other frames.This value must be lower than MAXD1. The frame length includes the discarded bytes.	CPU
0x54	0–31	Res	Initialize to zero.	CPU
0x58	0–31	L2QT	VLAN priority mapping table. See Section 30.5.3.11.1, “Rx Layer 2 QoS Table - L2QT.”	CPU
0x5C	32 Bytes	L3QT	IP priority mapping table. See Section 30.5.3.11.2, “Layer 3 QoS Table - L3QT.”	CPU
0x7C	0–15	VLAN_TYPE	VLAN Type. This field is inserted as part of the Q-TAG if enabled. Suggested value is 0x8100.	CPU
0x7E	0–15	TCI	Default TCI [VPri(3bits),CFI(1 bit),VID(12bits)]. This field is inserted or replaces the existing TCI as part of the Q-Tag if enabled.	CPU
0x80-0xBF	64 Bytes	Address Filtering (AF)	Address Filtering Data Structure. This structure definition depends on the address filtering mode: MPC82xx Compatible (REMODER[EXP]=0) or Extended Parsing mode (REMODER[EXP]=1). See Section 30.5.3.8, “Address Filtering (AF) Field Description” for more details.	CPU

Table 30-36. RX Global Parameter RAM (continued)

Offset	Bits	Name	Description	Initialized by
0xC0		EXPGlobalParam	Base Address for Extended Parsing Global Parameters. See Section 30.6.1, "Extended Parsing Mode Global Parameters." The user needs to allocate 16 bytes for this data structure. This base address must be eight bytes aligned.	CPU
0xC4		LossLessFCPtr	Base Address to Lossless Flow Control Data Structure located in internal Multiuser RAM. See Section 30.4.8.1.1, "Loss Less Flow Control." This base address must be four bytes aligned. This base address must be programmed if Lossless Flow Control is enabled in REMODER[LossLessFCEn] OR if Advanced Queue Management is enabled by programming TAD[IWCT Index]>0. If Lossles Flow Control feature is enabled, the user must allocate 8..64 bytes for this data structure depending on the number of queues.	
0xF8-0xFF		Zero	Initialize to zero.	QE

30.5.3.6 Rx Thread Parameter RAM

The RX thread parameter RAM is summarized by the following table:

Table 30-37. Rx Thread Parameter RAM

Offset	Bits	Name	Description	Initialized by
0x0-0x7F		Reserved	Internal variables	N/A
0x80-0xBF OR 0x80-0xFF OR 0x80-0x11F	64 or 128 or 160 bytes	Extended Parsing Thread Parameters	Internal variables. Needed if Extended Parsing Mode is enabled (REMODER[EXP]=1). 0x80-0xBF - No external Hash Lookup 0x80-0xFF - External Hash Lookup and the longest LookupKey is 8 bytes 0x80-0x11F - External Hash Lookup and the longest LookupKey is 16bytes Note: These Parameters are need if the UEC is used in Termination mode only. If Interworking packages are used, these parameters need no to be allocated in this area of memory.	N/A

30.5.3.7 Rx Ethernet Mode Register (REMODER)

The Ethernet Mode Register defines extended modes for the UCC Ethernet Port:

offset	0x4															
Bits	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	EXF	Res		Res	Res		VTagOP				VNonTagOP	Res			RQoS	
R/W	R/W															
Reset	0000_0000_0000_0000															
Bits	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
Field	Res	Loss Less FCEn	Res	RFSE	EXP	NumOfQueues			Reserved		VFSEn	Res	DXE	DNE	IPCHK	IPAE
R/W	R/W															
Reset	0000_0000_0000_0000															

Figure 30-37. UCC Ethernet Mode Register (REMODER)

Table 30-38. REMODER Field Descriptions

Bits	Name	Description
0	EXF	EXtended Feature Mode 0 Extended features are disabled. 1 Extended features are enabled. These features include: VLAN Tag insertion/removal, IP alignment. Some of the features have separate enable bits. In addition, if EXP=0 (MPC82xx like filtering mode) EXF=0 - One individual address programmed in Section 30.5.1.15, “Station Address Part 1 Register (MACSTNADDR1)” and Section 30.5.1.16, “Station Address Part 2 Register (MACSTNADDR2)” registers. EXF=1 - Five individual addresses as programmed in Section 30.5.1.15, “Station Address Part 1 Register (MACSTNADDR1)” and Section 30.5.1.16, “Station Address Part 2 Register (MACSTNADDR2)” registers, and in Global Rx Parameter RAM AF entry as described in Section 30.5.3.8, “Address Filtering (AF) Field Description.” Refer to Figure 30-6 and Figure 30-7 for relationship between EXP and EXF fields.
1-3	Reserved	Set to zero.
4-5	Reserved	Set to zero

Table 30-38. REMODER Field Descriptions (continued)

Bits	Name	Description
6-9	VTagOP	VLAN Operation for tagged income frames 0000 - No VLAN TAG operation is executed (NOP). 0001 - Replace VID portion of Q Tag. Other fields in TCI are left unchanged. 0010 - If VID=0 replace VID with default value. Other fields in TCI are left unchanged. 0011 - Extract Q Tag from Frame 0100..1111 - Reserved Note: REMODER[EXF] must be set if this field is not equal to zero. Note: Frames shorter than 64 bytes which are received (as programmed in UPSMR[RSH] and MINFLR) do not undergo header manipulation. Note: New value for VID depends on mode of operation. If REMODER[EXP]=0 the new value is taken from GlobalRx Parameter RAM[VID] field (or VID portion of this field). Id REMODER[EXP]=1, the new value of this field (VtagOP) an the value of the VID is taken from the Termination Action Descriptor TCI field (TAD[VTgOP] and TAD[VID]), which is the result of the lookup. 10	VNonTagOP	VLAN Operation for non-tagged income packets 0 - No VLAN TAG operation is executed (NOP). 1 - Q TAG Insert. A Q Tag is inserted between the DA and the income T/L field. The new VID is taken from the default TCI (TCI entry in Global Rx Parameter RAM). REMODER[EXF] must be set if this field is not equal to zero. Note: Frames shorter than 64 bytes which are received (as programmed in UPSMR[RSH] and MINFLR) do not undergo header manipulation.
11-13	Reserved	Set to zero
14-15	RQoS	Receive QoS Mode. valid if REMODER[EXP]=0 00 - Use Default Queue for received Frame from Parameter RAM as programmed in TCI[VPri] field in Global Rx Parameter RAM after L2 translation. See Section 30.5.3.11.1, “Rx Layer 2 QoS Table - L2QT.” 01 - Determine queue number in Receive direction using L2 criteria 10 - Determine queue number in Receive direction using L3 criteria 11 - Reserved See Section 30.4.12, “Quality of Service (QoS)” for details. Note: Frames shorter than 64 bytes which are received (as programmed in UPSMR[RSH] and MINFLR) are placed in queue 0.
16	Res	Set to zero
17	LossLessFCEn	Advanced Queue Management : LossLess Flow Control Enable 0 - LossLess Flow Control feature is disabled 1 - LossLess Flow Control feature is enabled. See description of LossLessFCPtr in UEC Global Parameter RAM for more details.
18	Reserved	Set to zero
19	RFSE	Receive Firmware Statistics Counters enable (see Section 30.7.4, “Firmware Counters”.) 0 - Do not perform Firmware statistics on received frames. 1 - Perform Firmware statistics on received frames

Table 30-38. REMODER Field Descriptions (continued)

Bits	Name	Description
20	EXP	EXtended Address Parsing Mode 0 Extended Parsing mode disabled (MPC82xx-like filtering mode). Refer to Figure 30-6 for relationship between EXP and EXF fields. 1 Extended Parsing mode enabled. Refer to Figure 30-8 for relationship between EXP and EXF fields.
21-23	NumOfQueues	Number of Rx queues 000 - One Rx queues 001 - Two Rx queue ... 111 - Eight Rx queues
24-25	Reserved	Set to zero
26	VFSEn	Virtual FIFO Smoother enable 0 - Do not enable Virtual FIFO Smoother 1 - Enable Virtual FIFO Smoother See section “Section 30.4.5.1, Virtual FIFO Overun Smoother” on page 11 for more details.
27	Reserved	Set to zero.
28	DXE	Dynamic Maximum Frame length Enable 0 - Disable Dynamic maximum frame length 1 - Enable Dynamic maximum Frame length See Section 30.7.2, “Dynamic Minimum and Maximum Frame Length” for more details.
29	DNE	Dynamic miNimum Frame length Enable 0 - Disable Dynamic minimum frame length 1 - Enable Dynamic minimum Frame length See Section 30.7.2, “Dynamic Minimum and Maximum Frame Length” for more details.
30	IPCHK	IP Checksum Check 0 - Do not check IP checksum in IPv4 frames on receive 1 - Check IP checksum in IPv4 frames on receive REMODER[EXF] must be set if this field is not equal to zero.
31	IPAE	IP Address Alignment Enable 0 - Do not align IP address 1 - Shift frame by two bytes from the beginning of the buffer to align the IP address to a four byte boundaries. REMODER[EXF] must be set if this field is not equal to zero.

Offset + 3C-3F	Reserved															

Figure 30-38. Address Filtering (AF) Entry Definition

Table 30-39. Address Filtering (AF Field Description)

Offset	Bits	Name	Description
0x0		IADDR_H	Individual Address filters high and low used in the MPC82xx compatible filtering mode (REMODER[EXP]=0). Each bit in this entry is recognized by its index in the 64 bit GADDR vector; if set by the 'SET GROUP ADDRESS' command, causes the reception of a frame whose 6 LSBits of the hashed individual MAC address has the bit in the appropriate index set. The user can write zeros to these values after reset and before the Ethernet channel is enabled to disable all individual hash address recognition functions. Issuing a SET GROUP ADDRESS command enables the hash table. See Section 20.3.1, "QUICC Engine Command Register (CECR)."
0x4		IADDR_L	
0x8		GADDR_H	Group Address filters high and low used in the MPC82xx compatible filtering mode (REMODER[EXP]=0). Same as IADDR field for MAC addresses with the I/G bit to one.
0xC		GADDR_L	
0x10		Reserved	Set to zero.
0x12		TADDR_H	This entry is programmed by the CPU before a set group address command is issued to the RISC CECR Register in the MPC82xx compatible filtering mode (REMODER[EXP]=0). The QE uses this address to store the appropriate bit in the IADDR or GADDR vectors.
0x14		TADDR_M	
0x16		TADDR_L	
0x18-0x37		PADDR1-4	Additional four Individual Station Address. PADDR_L is the lowest order half-word, and PADDR_H is the highest order half-word. (Valid only if REMODR[EXF]==1). The basic individual station address is programmed in MACSTNADDR registers. Note: If less that four addresses are needed, program in invalid fields the value programmed in MACSTNADDR registers. Example of byte ordering: For ethernet address 12-34-56-78-AB-CD where the LSBit of the first byte (0x12) is transmitted first on the line. where I/G Bit is Bit 15 of PADDR L and U/L bit is Bit 14 of PADDR L PADDR_H = 0xCDAB, PADDR_M = 0x7856, PADDR_L = 0x3412 The byte ordering of the TADDR fields is the same.
0x38	16	Reserved	Set to zero.
0x3A	16	TCI2_Type	The value of the type field in the second QTag in the frame. This value is used in Extended Parsing mode, with the GenerateLookupKey_EthFast PCD.
0x3C-0x3F		Reserved	Set to zero.

30.5.3.9 EtherStatsBase Field Description

The EtherStatsBase field defines the pointer of the statistics gathering data structure.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0	Reserved								EtherStatsBase

Table 30-40. Static Parameter (SP) Field Description

Offset	Bits	Name	Description
0x0	0-7	Reserved	Set to zero
0x0	8-15	EtherStatsBase	**Ethernet Statistics Data Structure Base Address** The Ethernet Statistics counters a placed in the Multiuser RAM at this base address. It is up to the user to allocate enough memory space for all the counters.
0x2	0-15		

30.5.3.10 RxBD Queue data structures

The distributor maintains a queue of perfected RxBDs per every send queue. The queue is maintained in the internal memory. Every thread keep pointer to general BD parameters table that define this queue, see RBDQPTR field in thread PRAM. The following figure and table describe the content of entries within the queue and BD parameters table

Table 30-41. RxBD Parameter Table Description

Offset	Bits	Name	Description	Initialized by
Offset + 0	0:31	**PR0_BDBPTR**	BD ring0 Base pointer. The BD ring is located in external memory. RxBD ring0 base pointer. The internal BD ring includes 4 prefetched RxBDs.	QE
Offset + 4	0:31	**PR0_BDPTR**	RxBD ring0 pointer. RxBD ring0 pointer. Points to the next internal BD that the receiver transfers data. User writes: PR0_BDPTR	QE
Offset + 8	0:31	**PR0_EBDBPTR**	External BD ring0 Base pointer. The BD ring is located in external memory. External RxBD ring0 base pointer.	CPU
Offset + C	0:31	**PR0_EBDPTR**	External BD ring0 pointer. External RxBD ring0 pointer. Points to the next BD that the receiver transfers data. User writes:PR0_EBDPTR	QE
.....			Rest of BD Rings	CPU/QE
Offset + 70	0:31	**PR6_BDBPTR**	BD ring7 Base pointer. The BD ring is located in external memory. RxBD ring7 base pointer. The internal BD ring includes 4 perfected RxBDs.	QE
Offset + 74	0:31	**PR6_BDPTR**	RxBD ring7 pointer. RxBD ring7 pointer. Points to the next internal BD that the receiver transfers data. User writes: PR7_BDPTR	QE
Offset + 78	0:31	**PR7_EBDBPTR**	External BD ring7 Base pointer. The BD ring is located in external memory. External RxBD ring7 base pointer.	CPU
Offset + 7C	0:31	**PR7_EBDPTR**	External BD ring7 pointer. External RxBD ring7 pointer. Points to the next BD that the receiver transfers data. User writes:PR7_EBDPTR	QE

30.5.3.11 Rx Priority Mapping Tables

The Ethernet controller support up to eight priority queues. The frame priority can be determined by the VLAN priority (See L2QT, Figure 30-40), IP priority (See L3QT, Figure 30-41) or default priority. See QoS field in Section 30.5.3.7, "Rx Ethernet Mode Register (REMODER)."

30.5.3.11.1 Rx Layer 2 QoS Table - L2QT

The Layer 2 QoS Table converts the frame VLAN priority the actual frame priority.

Offset [1]	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0	PR_0x0				PR_0x1				PR_0x2				PR_0x3

30.5.4 Bus Mode Register (BMR*x*)

This register was named ‘FCR’ in MPC82xx.

Figure 30-43 shows the format of the transmit and receive bus mode registers, which reside at TSTATE[0–7] and RSTATE[0–7].

Bits	0	1	2	3	4	5	6	7
Field	—		GBL	BO		CETM	DTB	BDB

Figure 30-43. Bus Mode Register (BMR*x*)

BMR*x* fields are described in Figure 30-45.

30.5.5 LossLess Flow Control

Table 30-45. BMR*x* Field Descriptions

Bits	Name	Description
0-1	—	Reserved, must be programmed to 0
2	GBL	Global. Indicates whether the memory operation should be snooped. 0 Snooping on the Coherent System Bus (CSB) is disabled. 1 Snooping on the Coherent System Bus (CSB) is enabled.
3–4	BO	Byte ordering. Used to select the byte ordering of the buffer. 00,01,11 Reserved modes. 10 Big-endian byte ordering. As data is sent onto the serial line from the data buffer, the MSB of the buffer word contains data to be sent earlier than the LSB of the same buffer word. These bits must be set to 10 value.
5	CETM	QE Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QE, for debug purposes. See Figure 19-1and Section 5.4.3.7, “Debug Configuration.”
6	DTB	Indicates on what bus the data is located. 0 On the coherent system bus (CSB) 1 On the QE secondary bus. The programming of this bit must be consistent with the System Configuration.See Figure 19-1.
7	BDB	Indicates on what bus the BDs or are located. In Extended Parsing mode see also LookupBMR field in Section 30.6.2.6, “Hash Table Lookup PCDs” and Section 30.8.2, “Add/Remove Entry in Hash Lookup Table.” 0 On the coherent system bus (CSB). 1 On the QE secondary bus. The programming of this bit must be consistent with the System Configuration. See Figure 19-1.

See section Section 30.4.8.1.1, “Loss Less Flow Control,” for description of this feature.

Figure 30-44. LossLess Flow Control Table

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Offset + 4	BD0 LossLess FC Threshold															
Offset + 6	Reserved															
.....																
Offset + 38	RxBD7 CPU Next BD Offset															
Offset + 3A	RxBD7 CPU Last BD Offset															
Offset + 3C	BD7 LossLess FC Threshold															
Offset + 3E	Reserved															

Table 30-46. LossLess Flow Control Table Field Descriptions

Name	Description
RxBDn CPU Next BD Offset	Offset from the Base Address of the RxBD ring to the next RxBD which will be handled by the CPU
RxBDn CPU Last BD Offset	Offset from the Base Address of the RxBD ring to the last RxBD in the BD Ring
RxBDn LossLess FC Threshold	Minimum number of empty RxBDs in the queue in terms of RxBDs*(Size of RxBD). If the number of empty RxBDs is below this number, the UEC automatically transmits a Flow Control frame.

30.6 Extended Parsing Mode

In this mode the UCC Ethernet Controller provides enhancements to the basic filtering mode provided in most Ethernet MACs. The mode is enabled by the user by programming REMODER[EXP]=1. The Global Parameter RAM 16 byte AF field is programmed to point to the first Parse Command Descriptor (PCD). Additional PCDs follow the first PCD in subsequent addresses.

30.6.1 Extended Parsing Mode Global Parameters

The Extended Parsing Mode Parameters are located at base address programmed in EXPGlobalParam entry in the Rx Global Parameter RAM. See Section 30.6.2, “Parsing Command Descriptor (PCD)” for more details on Extended Parsing mode.

Offset + 0	Reserved								L2PCDPTR							
Offset + 2	L2PCDPTR															
Offset + 4-7	Reserved															
Offset + 8-F	Reserved															

Figure 30-45. Extended Parsing Mode Global Parameters Definition

Table 30-47. Extended Parsing Global Parameters Description

Offset	Bits	Name	Description
0x0	8-15	L2PCDPTR	Pointer to first Parse Command Descriptor base address. The user is responsible for allocation of space in the Multiuser RAM for the PCDs.
0x2	0-15		
0x4-7		Reserved	Set to zero.
0x8-F		Reserved	Set to zero

30.6.2 Parsing Command Descriptor (PCD)

The Parsing Command Descriptor (PCD) is a data structure programmed by user, which is used for parsing of the frame, generation of LookupKey and for lookup in Lookup Tables. Multiple PCDs may be used on a given frame. The pointer to the first PCD is located in the multiuser RAM at base address L2PCDPTR

which is programmed in the Extended Parsing Mode parameter RAM data structure. Each PCD is 8 bytes long. PCD commands are executed sequentially until a match occurs or a last PCD is encountered.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0	PCD OPCODE								PCD Specific Parameters							
Offset + 2	PCD Specific Parameters															
Offset + 4																
Offset + 6																

Figure 30-46. PC Opcodes

The following table specifies the PCD Opcodes:

Table 30-48. PCD Opcodes

Opcode Name	PCD Opcode	Comments
GenerateLookupKey_ EthFast	0x0	This PCD is used to generate a LookupKey from the L2 frame header fields. Since all other PCD types use a LookupKey this PCD must be the first one to be invoked.
ChangeMask	0x10	This PCD is used to mask portions of the LookupKey. This PCD can be invoked only when a valid LookupKey has been generated by a previous PCD.
StoreLookupKey	0x11	This PCD is used to store the current LookupKey. This PCD is used before the ChangeMask PCD if the original LookupKey is needed at a later stage for some other lookup.
RestoreLookupKey	0x12	This PCD is used to restore the LookupKey before that last masked key. With this PCD it possible to Generate a LookupKey, and then perform lookup on subsets of the key.
FourWayHashLookup	0x20	This PCD is used to perform a lookup in Four Way Hash Lookup mode. This PCD can be invoked only when a valid LookupKey has been generated by a previous PCD.
EightWayHashLookup	0x21	This PCD is used to perform a lookup in Eight Way Hash Lookup mode. This PCD can be invoked only when a valid LookupKey has been generated by a previous PCD.
Last PCD	0x3F	This PCD is the last one. If UPSMR[ECM]=1 receive the frame in queue number 0. In this case MAXD2 bytes of he frame are received.

30.6.2.1 Last PCD

This PCD is used at the end of PCD flow. It specifies the actions taken in case of lookup miss.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0	PCD OPCODE=0x3F								Reserved							
Offset + 2	DBM	Reserved						BDM	Reserved							

Figure 30-47. Last PCD Field Descriptions

Offset + 4	Reserved
Offset + 6	

Figure 30-47. Last PCD Field Descriptions

The PCD fields are described in Table 30-50.

Table 30-49. Last PCD Field Descriptions

Offset	Bits	Name	Description
PCD_BASE+0	0-7	Opcode	0x3F
	8-15		Reserved bits. Must be cleared to zero.
PCD_BASE+2	0	DBM	Debug Mode 0 - Discard Frame. RMON counter is updated MisMatchDrop. 1 - Receive Frame in queue number 0
	0-5		Reserved bits. Must be cleared to zero.
	6	BDM0	RxBD Mark The value of these bits is copied into the RxBD[6].
	7	BDM1	RxBD Mark The value of these bits is copied into the RxBD[7].
	8-15		Reserved bits must be cleared to zero.
PCD_BASE+4			Reserved bits must be cleared to zero.

30.6.2.2 GenerateLookupKey_EthFast PCD

This type of PCD is used to generate a LookupKey from the L2Frame header fields. The LookupKey is used by subsequent PCDs to perform a table Lookup.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
PCD_BASE + 0	PCD OPCODE=0x00								PCDIDValue							
PCD_BASE + 2	MACdst	MACsrc	TCI1	TCI2	Reserved										SrcPort	PCD ID
PCD_BASE+ 4	Reserved															
PCD_BASE + 6	Reserved															

Figure 30-48. Generate L2 LookupKey PCD

The PCD fields are described in Table 30-50.

Table 30-50. Generate L2 LookupKey PCD Field Descriptions

Offset	Bits	Name	Description
PCD_BASE+0	0-7	OPCODE	OPCODE = 0x0 for Generate Lookup PCD
	8-15	PCDID value	PCDIDvalue User Programmable byte to be optionally used as part of the LookupKey. This field must contain a valid value if PCD[PCDID] bit is set. This field is useful if the same LookupTable is used for many types of LookupKeys or if it necessary to distinguish between a masked LookupKey and a non-masked LookupKey with zeroes in the same bits as the mask.
PCD_BASE+2	0	MACdst	Extract 48 bit MAC Destination Address for LookupKey 0 - Disable Extraction of this field 1 - Enable Extraction of this field
	1	MACsrc	Extract 48 bit MAC Source Address for LookupKey 0 - Disable Extraction of this field 1 - Enable Extraction of this field
	2	TCI1	Extract 16 bit TCI1 from Q-Tag 0 - Disable Extraction of this field 1 - Enable Extraction of this field. If a Q-TAG is not present in the frame, a value of zero is used in the LookupKey. Parts of this field may be masked to generate VID or VPri subset, by invoking the PCD with change mask opcode. The type field of the QTag is compared with 0x8100.
	3	TCI2	Extract 16 bit TCI2 from Q-Tag (stacked VLAN tags). 0 - Disable Extraction of this field 1 - Enable Extraction of this field. If a second Q-TAG is not present in the frame, a value of zero is used in the LookupKey. Parts of this field may be masked to generate VID or VPri subset, by invoking the PCD with change mask opcode. The type field of the QTag is compared with the user programmable value programmed in the TCI2_Type field in the AF data structure in the Ethernet Global Rx Parameter RAM.
	4-13	Res	Reserved bits must be cleared to zero.
	14	SrcPort	Add one byte of Serial Number (SNUM) of the source port in LookupKey. This is used to identify the source port (UCC) of the frame. See Section 30.8.2.1, “Explanation on the LookupKey to be placed in this Host Command” for more details. 0 - Disable 1 - Enable
	15	PCDID	Add user programmable PCDIDValue in LookupKey 0 - Disable 1 - Enable
PCD_BASE+4-7	0-15	—	Reserved bits must be cleared to zero.

The LookupKey is temporarily stored in internal Memory. The header fields are placed in order of parsing; if MACdst field and the VID are enabled for parsing the MACdst field is placed first at bytes 0-5, and the VID is placed starting from byte number 6.

30.6.2.3 Change Mask PCD

This type of PCD is used to mask parts of a LookupKey that was generated by the ‘Generate LookupKey PCD’.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
PCD_BASE + 0	PCD OPCODE=0x10								Reserved							
PCD_BASE + 2	Reserved												MaskIndex			
PCD_BASE + 4	MaskValue															
PCD_BASE + 6																

Figure 30-49. Change Mask PCD

The PCD fields are described in Table 30-50.

Table 30-51. Change Mask PCD Field Descriptions

Offset	Bits	Name	Description
PCD_BASE+2	0-11		Reserved bits. Must be cleared to zero.
	12-15	MaskIndex	Index in the LookupKey where the four byte mask is applied 000 - Apply Mask at the beginning of the LookupKey on bytes 0,1,2,3 001 - Apply Mask on bytes 4,5,6,7 of the LookupKey 010 - Apply Mask on bytes 8,9,10,11 of the LookupKey 011 - Apply Mask at the end of the LookupKey on bytes 12,13,14,15 Reset Reserved
PCD_BASE+4		MaskValue	Bitwise value of Mask that is applied to the LookupKey before the lookup is performed. 0 - Mask appropriate bit of the LookupKey to zero 1 - Do not alter the value of the appropriate bit in the lookupkey
			Reserved bits must be cleared to zero.

30.6.2.4 Store LookupKey PCD

This type of PCD is used to store the current the LookupKey. This PCD is useful if the original LookupKey is needed after a ‘ChangeMask’ PCD is applied on the current LookupKey.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
PCD_BASE + 0	PCD OPCODE=0x11								Reserved							
PCD_BASE + 2	Reserved

Offset	Bits	Name	Description
PCD_BASE+2	0-15		Reserved bits. Must be cleared to zero.
PCD_BASE+4	0-15		

30.6.2.5 Restore LookupKey PCD

This type of PCD is used to restore the LookupKey that was generated before the ‘Change Mask PCD’.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
PCD_BASE + 0	PCD OPCODE=0x12								Reserved							
PCD_BASE + 2	Reserved															
PCD_BASE + 4																
PCD_BASE + 6																

Figure 30-51. Restore LookupKey PCD

The PCD fields are described in Table 30-50.

Table 30-53. Restore LookupKey PCD Field Descriptions

Offset	Bits	Name	Description
PCD_BASE+2	0-15		Reserved bits. Must be cleared to zero.
PCD_BASE+4	0-15		

30.6.2.6 Hash Table Lookup PCDs

The Hash Table Lookup PCDs are commands used to enable a lookup in a hashed based lookup table that resides either in internal or in external memory. This type of lookup is used for large tables and/or long LookupKeys. The FourWayHashLookup PCD is used when the lookup table has four ways per set, the EightWayHashLookup PCD is used for two four sets tables (in effect eight way hash).

30.6.2.6.1 Four Way Hash Lookup PCD

This type of PCD is used to perform a lookup using the LookupKey that was generated by the ‘Generate LookupKey’ PCD and optionally masked by the ‘Change Mask’ PCD.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
PCD_BASE + 0	PCD OPCODE=0x20								LookupBMR							
PCD_BASE + 2	LookupKeySize								Reserved			EXT	HaskKeySize			
PCD_BASE + 4	LookupTableBase															
PCD_BASE + 6																

Figure 30-52. Four Way Hash Lookup PCD

The PCD fields are described in Table 30-50.

Table 30-54. Four Way Hash Lookup PCD Field Descriptions

Offset	Bits	Name	Description
PCD_BASE+0	0-7	OPCODE	Opcode for this PCD
	8-15	LookupBMR	Bus Mode Register for Lookup Table. See Section 30.5.4, "Bus Mode Register (BMRx)" for details. Note that BDB bit detemines which bus the LookupTable is located. Note that DTB bit is not used for lookup.
PCD_BASE+2	0-7	LookupKeySize	Lookup KeySize This field specifies the size of the LookupKey. The LookupKey parsed by the Generate LookupKey PCD is truncated to the size programmed in this field. 0x3F - 8 bytes 0x5F - 16 bytes Rest - not allowed
	8-10	Reserved	Set to zero
	11	EXT	External Lookup Table 0 - The Lookup Table resides in internal Multiuser RAM 1 - The Lookup Table resides in external Multiuser RAM
	12-15	HashKeySize	HaskKeyMask. This field determines the size of the hash key (i.e. the number of sets in the Lookup Table). 0000 - 1 bit Hask Key (2 sets in the Lookup Table) 0001 - 2 bit Hask Key (4 sets in the Lookup Table) 0010 - 3 bit Hash Key (8 sets in the Lookup Table) 0011 - 4 bit Hash Key (16 sets in the LookupTable) 0100 - 5 bit Hash Key 0101 - 6 bits Hash Key ..... (all valid values) 1110 - 15 bit Hash Key (32K sets in the Lookup Table) 1111- 16 bit Hash Key (64K sets in the Lookup Table)
PCD_BASE+4		LookupTableBase	This field determines the base address of the Lookup Table in internal or external memory as determined by opcode of the PCD. Perform a hash on the LookupKey. Use LookupTableSize field as a pointer to a table located in internal Multiuser RAM. Use HashResult to access the lookup table pointed by LookupTableBase. HashKeySize determines the size of the table (i.e. the number of bits from the HashResult to be used as an index). A successful match occurs if valid entry is found and exact match to value in table occurs. See Section 30.6.2.6.3, "Four Way and Eight Way Hash Mode Lookup Table Entry (HLUT)" for details on this lookup algorithm.

30.6.2.6.2 Eight Way Hash Lookup PCD

This type of PCD is used to perform a lookup using the LookupKey that was generated by the ‘Generate LookupKey’ PCD and optionally masked by the ‘Change Mask’ PCD.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

PCD_BASE + C	Reserved															
PCD_BASE + E																

Figure 30-53. Eight Way Hash Lookup PCD

The PCD fields are described in Table 30-50:

Table 30-55. Eight Way Hash Lookup PCD Field Descriptions

Offset	Bits	Name	Description
PCD_BASE+0	0-7	OPCODE	Opcode for this PCD
	8-15	LookupBMR	Bus Mode Register for Lookup Table. See Section 30.5.4, "Bus Mode Register (BMRx)" for details. Note that BDB bit detemines which bus the LookupTable is located. Note that DTB bit is not used for lookup.
PCD_BASE+2	0-7	LookupKeySize	Lookup KeySize This field specifies the size of the LookupKey. The LookupKey parsed by the Generate LookupKey PCD is truncated to the size programmed in this field. 0x3F - 8 bytes 0x5F - 16 bytes Rest - not allowed
	8-10	Reserved	Set to zero
	11	EXT	External Lookup Table 0 - The Lookup Table resides in internal Multiuser RAM 1 - The Lookup Table resides in external Multiuser RAM
	12-15	HashKeySize	HaskKeyMask. This field determines the size of the hash key (i.e. the number of sets in the Lookup Table). 0000 - 1 bit Hask Key (2 sets in the Lookup Table) 0001 - 2 bit Hask Key (4 sets in the Lookup Table) 0010 - 3 bit Hash Key (8 sets in the Lookup Table) 0011 - 4 bit Hash Key (16 sets in the LookupTable) 0100 - 5 bit Hash Key 0101 - 6 bits Hash Key ..... (all valid values) 1110 - 15 bit Hash Key (32K sets in the Lookup Table) 1111- 16 bit Hash Key (64K sets in the Lookup Table)
PCD_BASE+4		LookupTableBase	This field determines the base address of the first four ways Lookup Table in internal or external memory as determined by PCD[EXT] bit. Perform a hash on the LookupKey. Use LookupTableSize field as a pointer to a table located in internal Multiuser RAM. Use HashResult to access the lookup table pointed by LookupTableBase. HashKeySize determines the size of the table (i.e. the number of bits from the HashResult to be used as an index). A successful match occurs if valid entry is found and exact match to value in table occurs. See Section 30.6.2.6.3, "Four Way and Eight Way Hash Mode Lookup Table Entry (HLUT)" for details on this lookup algorithm.
PCD_BASE+8		SecondaryLookupTableBase	This field determines the base address of the Secondary Lookup Table in internal or external memory as determined by PCD[EXT] bit This tale contains additional four ways for the hash lookup. The format of his table is identical to the format of the table pointed by LookupTableBase.
PCD_BASE+C-F		Reserved	Set to zero.

30.6.2.6.3 Four Way and Eight Way Hash Mode Lookup Table Entry (HLUT)

The hash mode lookup table is split into two parts, termination action descriptors (TADs) and exact match tags. The table is organized into sets, which are lookup table entries indexed by the HashKey. Each set has four ways. Each way contains an 8- or 16-byte exact match tag that contains the LookupKey and an 8-byte TAD field. The LookupKey is compared to the four ExactMatch Tags in its set corresponding to the four ways, assuming the way is valid (TAD[V] = 1). A match yields to table hit. A mismatch in the comparison of all four tags yields a table lookup miss.

Depending on the application, the user may need either a four way or an eight way hash lookup table. The eight way hash lookup table is composed of two four-way lookup tables. In EightwayHash mode lookup, the secondary lookup table is accessed if the LookupKey does not compare to any of the four ExactMatchTags in the first LookupTable. The pointer to this table located in the PCD.

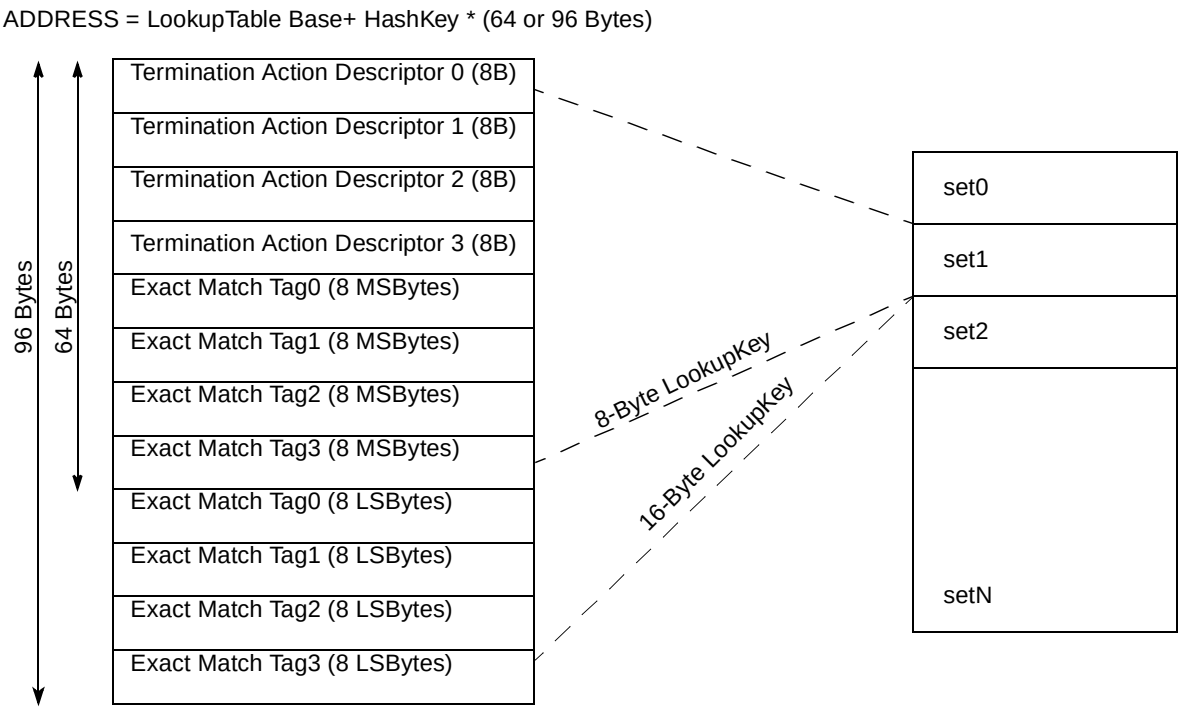

Figure 30-54. 4-Way Hash Mode Lookup Table Format

30.6.2.6.4 Exact Match Tags

The exact Match Tag is 8 or 16 bytes long, according to the LookupKeySize. See Section 30.14, " Exact Match Tags Memory Organization" for details.

30.6.2.6.5 Termination Action Descriptor (TAD)

A match event is defined by exact match between the look up key created by the PCD (Or by a PCD pair in the case of masked key) from the income frame to one of the Exact Match Tag fields in the table. The case of non-match is handled by the PCD.

Following a Match event, Frame termination takes place. The termination actions are defined in the Termination Action Descriptor found in the lookup table. Each Exact Match Tag has an Termination Action Descriptor associated with it.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0	EXF	V	Rej	Res	Res	Res	VTagOP				VNonVTagOP	Res			RQoS	
Offset + 2	VPriority			CFI	VID											
Offset + 4		Reserved														
Offset + 6																

Figure 30-55. Termination Action Descriptor (TAD)

Table 30-56. TAD Field Descriptions

Offset	Bits	Name	Description
	0	EXF	EXtended Feature Mode (for termination). 0 Extended features are disabled. 1 Extended features are enabled. These features include: VLAN Tag insertion/removal, IP alignment. Some of the features have separate enable bits. See description in REMODER register. Section 30.5.3.7, “Rx Ethernet Mode Register (REMODER)
	1	V	Valid Entry 0 - The Exact Match Tag in this entry is not valid and should be ignored 1 - The Exact Match Tag in this entry is valid and should be compared to the LookupKey
	2	Rej	Reject Frame 0 - Receive Frame 1 - Reject Frame For proper operation, if TAD[Rej]=1 the user must program bits TAD[VPriority,CFI,VID]=0
	3	—	Reserved. Clear to zero.
0x0	6-15		See description in REMODER register. Section 30.5.3.7, “Rx Ethernet Mode Register (REMODER)
0x2	0-15	QTag	QTag (VPriority,CFI,VID) to be inserted.
0x4		Reserved	Set to zero

30.7 Ethernet Statistics

There are three type of statistical counters:

- Hardware Counters
- Firmware Counters
- Software counters.

The Hardware counters are always available to the user. The firmware counters are updated if UPSMR[MON] is set by the user. The Software counters are calculated by the Host CPU, based on the Hardware and Firmware counters. The software counters are specified in this document for completeness.

30.7.1 Features

- Supports IEEE Std. 802.3-2002 Layer management for DTE
  - IEEE 1GE Management Enhancements
  - MAC Entity managed Objects
  - MAC Control entity managed object
  - PAUSE entity managed objects
- Supports IEEE Std. 802.3-2002 Layer Management for Base Band repeaters
- Supports IETF RFC 2819 / STD0059- RMON MIB
- Supports IETF RFC 3635 Managed Object for Ethernet like Interface
- Extensions to the standard statistics is added in order to adapt it to an environment with non-standard length (Jumbo frames, Tagged frames)
- Enhanced transmitter statistics for non-CPU operation

30.7.2 Dynamic Minimum and Maximum Frame Length

The MFLR entry in the Global Parameter RAM defines the length of the largest frame, excluding Q TAG but including FCS, that is still valid. When REMODER[DXE]=1, a tagged frame that has length equals MaxLength+4 considered valid, and a non tagged frame that has length equals MaxLength is the longest that is still considered valid. When REMODER[DXE]=0, any frame longer than MaxLength consider erroneous frame.

For systems with only tagged frames, set REMODER[DXE]=0 and set MaxLength = Max LLC size+4.

The MINFLR entry in the Parameter RAM defines the length of the shortest frame, excluding Q TAG but including FCS, that is still valid frame. The user decides what is considering “Shortest valid frame” in his system: Some users may decide its 68 bytes, some will decide its 64 bytes, and some would decide its dynamic: 68 bytes for tagged frame, 64 bytes for un-tagged frames. In the last case, the user should set the REMODER[DNE] bit and program MinLength to the length of valid un-tagged frame.

See also IEEE Std. 802.3-2002. In 3.2.7 “n” is client data length, and 802.1Q is defined as MAC client and thus Q-Tagg is counted within “n” (that is, 64). In figure 3-3 there “Tagged Frame Format” IEEE shows MAC client data excluding Q-Tag (i.e. 68). In 3.5.7 IEEE adds another comment that leaves interpretation open.

In this last section, a priority-tagged frame considered a tagged frame.

30.7.3 Error Hierarchy

The following error hierarchy is defined by IEEE (In-coherency relative to IETF):

- Frame too Long / Short
- Alignment error
- FCS error
- Length error

30.7.4 Firmware Counters

This section defines the MIB items located in the Multiuser RAM, at the address space defined by SP[EtherStatsBase] field in the Global Parameter RAM. This space in the RAM can be used for any other purpose if Statistics gathering function is disabled. The firmware counters are initialized to zero by the CP

The following error hierarchy is implemented:

Frame too long/short: FrTooLongRx,FrTooShortRx

Alignment error: FrAlignEr

CRC error FrRxF: CSEr

When an error is relevant to more than one counter it is registered only in the highest priority counter.

The user is allowed to reset the Firmware counters dynamically by writing a zero in the corresponding memory location. Since the atomicity of this operation is not guaranteed, the user must read the counter and verify that its value is zero or slightly larger.

30.7.4.1 TX Firmware Counters

Table 30-57. TX Firmware Counters

Address TxEtherStats Base=TESBASE	Name	Width (bit)	Description
TESBASE+0	SiColTx	32	M: Single Collision. Number of Frames that where transmitted OK after a single collision event. Not relevant in full duplex mode. (30.3.1.1.3)
TESBASE+4	MulColTx	32	M: Multiple Collision. Number of Frames that where involved in more than one collision and than transmitted succesfully (30.3.1.1.4)
TESBASE+8	LateColTxFr	32	Late collision. Counts all frames that were involved in late collision event during frame transmission (30.3.1.1.10)
TESBASE+C	FrAbortDueCol	32	Frames aborted due to transmit collision. Counts all frames that were aborted either due to repeatedly collision events or due to late collision (30.3.1.1.11)
TESBASE+10	FrLostInMACTxEr	32	Frames that lost due to internal MAC error transmission, that is not counted on any other counter. Counts all frames that were lost due to any other reason e.g. OV/UN (30.1.1.12)
TESBASE+14	CarrierSenseERTx	32	Carrier Sense Error Counter. Counts the times CS was negated during frame transmission including the case of transmission while CS is negated (30.3.1.13)
TESBASE+18	FrTxOK	32	M: Number of frames transmitted OK (30.3.1.1.2)
TESBASE+1C	TxFrExcessiveDiffer	32	Conts frames that their differal time was greater than a specified threshold. May (3.1.1.20)
TESBASE+20	TxPkts256	32	Total number of packets (Including bad packets) transmitted that were between 256 (Including FCS length==4) and 511 octets
TESBASE+24	TxPkts512	32	Total number of packets (Including bad packets) transmitted that were between 512 (Including FCS length==4) and 1023 octets
TESBASE+28	TxPkts1024	32	Total number of packets (Including bad packets) Transmitted that were between 1024 (Including FCS length==4) and 1518 octets
TESBASE+2C	TxPktsjumbo	32	Total number of packets (Including bad packets) transmitted that were between 1024 (Including FCS length==4) and MAXLength octets, considering the programmed value MAXLength and the DXE bit defined above. For the case where DXE is set, and MAXLength=1518, all un-tagged packets with length 1518 will be counted by the previous counter. For packets length 1518 or smaller, this counter has the lowest priority.

30.7.4.2 RX Firmware Counters

Table 30-58. RX Firmware Counters

Address EtherStatsBase= RESBASE	Name	Width (bit)	Description
RESBASE+0	FrRxFCSEr	32	M: Number of frames received with CRC error, excluding (does not count) frames which are too long error, too short error, or alignment error, regardless those frames FCS situation. (30.3.1.1.6)
RESBASE+4	FrAlignEr	32	M:Alignment Errorrs Counter. Number of frames received that had Alignment errors (30.3.1.1.7). Note this counter is not updated for frame shorter that 64 bytes.
RESBASE+8	InRangLenRxER	32	In Rang Length error counter. Counts received frames with L/T field in length mode, that the length of their data field is not equal to the specified length, or that the specified length is less than the minimum LLC frame length regardless of the actual length (30.3.1.1.23)
RESBASE+C	OutRangLenRxER	32	Out of Range length Error. Counts all frames with length field greater than the maximum allowed for LLC frame. frames with L/T = T are not included. (Probably reflects a dont care value in the case of a Jumbo frame) (3.1.1.24)
RESBASE+10	FrTooLongRx	32	Counts all received frames with length greater than the programmable parameter MaxLength (see above) (3.1.1.25)
RESBASE+14	Runt	32	Total number of received frames with length smaller than MINLength (as defined above and considering the DNE bit) that incorporates either FCS error or Alignment error, but not frames that would be fine otherwise (Except from the CRC/ALIGN error)
RESBASE+18	VeryLongEventRx	32	Counts all frames received with length greater than MAXLength as defined above and with either FCS error or Alignment error (30.4.3.1.13)
RESBASE+1C	SymbolErrorRx	32	Number of received frames in which a received error symbol is reported from the PHY layer device during frame reception (30.4.3.1.17)
REBASE+20	EtherStatsDropRxBsy	32	This includes the total count of drop event due to lack of resources of type BD not ready in the receive process. This counter is a part of the sum composing EtherStatsDropEvent. It can be extracted by summing FrLostInMACTxEr, FrLossInMACRxEr, and EtherStatsDropRxBsy together with the counters below. However, 2819 does not specify exactly which resources it is talking about. (2819 p.17) The UC should count all cases it found BD not ready on Rx. SW should calculate the sum
REBASE+24	Reserved	32	
REBASE+28	Reserved	32	
REBASE+2C	MisMatchDrop	32	Counts number of frames dropped due to MAC filtering process, (e.g. Address Mismatch, Type mismatch) and that would otherwise considered good frame that would be transfered to upper layers

Table 30-58. RX Firmware Counters (continued)

Address EtherStatsBase= RESBASE	Name	Width (bit)	Description
REBASE+30	EtherStatsUnderPkts	32	Total number of frames received that were less than 64 octets long but are a good frames otherwise (i.e. except from the error of being too short, they are good frames)
REBASE+34	EtherStatsPkts256	32	Total number of frames (Including bad frames) received that were between 256 (Including FCS length==4) and 511 octets . If MACCFG2[CRC]=1 in and the additional 4 bytes for the CRC cross the boundary between 511 and 512 bytes, the RMON counter is incremented for 256 bytes instead of for 512 bytes.
REBASE+38	EtherStatsPkts512	32	Total number of frames (Including bad frames) received that were between 512 (Including FCS length==4) and 1023 octets
REBASE+3C	EtherStatsPkts1024	32	Total number of frames (Including bad frames) received that were between 1024 (Including FCS length==4) and 1518 octets
REBASE+40	EtherStatsPktsJumbo	32	Total number of frames (Including bad frames) received that were between 1024 (Including FCS length==4) and MAXLength octets, considering the programmed value MAXLength and the DXE bit defined above. For the case where DXE is set, and MAXLength=1518, all un-tagged frames with length 1518 will be counted by the previous counter. For frames length 1518 or smaller, this counter has the lowest priority.
REBASE+44	FrLossInMACRxEr	32	Frames that lost due to internal MAC error occured during reception, that is not counted on any other error counter. Counts all frames that were lost due to any error (e.g. OV) (30.3.1.1.15)
REBASE+48	PausFrRx	32	Counts the total number of PAUSE frames received by thi sMAC (30.3.4.3)
REBASE+4C	Reserved		
REBASE+50	RxRVLANcnt	32	Counts the total number of fames that their VLAN tag was removed.
REBASE+54	RxRepVLANcnt	32	Counts the total number of fames that their VLAN tag was replaced.
REBASE+58	RxInVLANcnt	32	Counts the total number of fames that VLAN tag was inserted to their header.
REBASE+5C	RxIPChcksumErr	32	Counts the total number of fames that have an IPChecsum Error.

30.7.5 UCC Statistics (Hardware Counters)

This section defines the MIB items located at the UCC.

Table 30-59. UCC Statistics

Address	Name	Standard Name	Width (bit)	Description
UCC*x*_BASE+ 0x180	TX64	TxframeMiin	32	Total number of frames Transmitted including bad frames that were exactly 64 bytes (Including FCS length==4) Note: Frames with underrun, max collision, late collision errors are not counted
UCC*x*_BASE+ 0x184	TX127	TxPkts65	32	Total number of frames (Including bad frames) transmitted that were between 65 bytes (Including FCS length==4) and 127 octets. Note: Frames with underrun, max collision, late collision errors are not counted
UCC*x*_BASE+ 0x188	TX255	TxPkts128	32	Total number of frames (Including bad frames) transmitted that were between 128 (Including FCS length==4) and 255 octets. Note: Frames with underrun, max collision, late collision errors are not counted
UCC*x*_BASE+ 0x18C	RX64	EtherStatsframe64	32	Total number of frames received including bad frames that were exactly in the minimal length (64 bytes)
UCC*x*_BASE+ 0x190	RX127	EtherStatsPkts65	32	Total number of frames (Including bad frames) received that were between 65bytes (Including FCS length==4) and 127 octets
UCC*x*_BASE+ 0x194	RX255	EtherStatsPkts128	32	Total number of frames (Including bad frames) received that were between 128 (Including FCS length==4) and 255 octets
UCC*x*_BASE+ 0x198	TXOK	OcTxOK	32	Octet Transmitted OK. Total number of octet residing in frames that where involved succesful transmission (30.3.1.1.8)
UCC*x*_BASE+ 0x19C	TXCF	PausFrTx	32	Counts the total number of PAUSE control frame transmitted by this MAC (30.3.4.2)
UCC*x*_BASE+ 0x1A0	TMCA	MulCastFrTxOK	32	Multicast Frame transmitted OK. Counts all frames that were transmitted succesfully with the group address bit set that are not broadcast frames (30.1.1.18). Frames longer than 1518 bytes (if untagged) or 1522 bytes (if tagged) are not counted.
UCC*x*_BASE+ 0x1A4	TBCA	BroadCastFrTxOK	32	Broadcast frames that transmitted OK. Counts all frames transmitted succesfully that had DA field equals to the broadcast address (30.3.1.1.19). Frames longer than 1518 bytes (if untagged) or 1522 bytes (if tagged) are not counted.

Table 30-59. UCC Statistics (continued)

Address	Name	Standard Name	Width (bit)	Description
UCC*x*_BASE+ 0x1A8	RXFOK	FrRxOK	32	Number of frames received OK (30.3.1.1.5)
UCC*x*_BASE+ 0x1AC	RBYT	OCRxOK	32	Octets received OK. Counts the total number of octets received OK in this probe. (30.1.1.14)
UCC*x*_BASE+ 0x1B0	RXBOK	EtherStatsOctet	32	Total number of octets received including octets in bad frames. Cannot be calculated by summing the histogram data. Note that it cannot be extracted from the IEEE statistics because the first counts octets only good frames. It has to be implemented in HW because it includes octets in frames that never even reach the UCC
UCC*x*_BASE+ 0x1B4	RMCA	MulCastFrRxOK	32	Multicast Frame Received OK. Counts all frames that were received succesfully with the group address bit set that are not broadcast frames (3.1.1.21). Frames longer than 1518 bytes (if untagged) or 1522 bytes (if tagged) are not counted.
UCC*x*_BASE+ 0x1B8	RBCA	BroadCastFrRxOK	32	Broadcast frames that received OK. Counts all frames received succesfully that had DA field equals to the broadcast address (3.1.1.22). Frames longer than 1518 bytes (if untagged) or 1522 bytes (if tagged) are not counted.
UCC*x*_BASE+ 0x1BC-0x1C0	SCAR/SCAM	SCAR/SCAM/CMR	32	These registers holds the carry bits and mask of the HW counters. See Section 30.7.7.17, “Statistic Counters Carry Register (SCAR)” and Section 30.7.7.18, “ Statistic Counters Mask Register.”
UCC*x*_BASE+ 0x1C4	RxDiscOV	RxDiscOV	32	Frames discarded due to overrun condition in the RxFIFO.

30.7.6 SW Statistics

The following MIB items can be implemented in SW by the CPU. The QE terminates the control frames. PAUSE control frames are terminated by the MAC, and statistics is gather by the QE. Non-PAUSE control frames are sent to the CPU termination queues.

Table 30-60. MIB

Address	Name	Width (bit)	Description
SW	MACControlFrTx	32	Counts number of control frames either passed to the MAC by higher layers or generated by the MAC (e.g. by host command or RISC command) (30.3.3.3)
SW	MACControlFrRx	32	Counts number of control frames received by the MAC (30.3.3.4)

Table 30-60. MIB (continued)

Address	Name	Width (bit)	Description
SW	UnSprtOpcdRx	32	Counts all received control frames (T field = CONTROL) with op-code field that un suported by this device, including non-valid op-code field, and that are trasfered to upper layers as a result (
UC (+SW)	EtherStatsDropEvents	32	This includes the total count of drop event due to lack of resources. The definition is very soft and it can be extracted by summing EtherStatsDropRxBsy, FrLostInMACTxEr, FrLossInMACRxEr,PolicingDrop, QueueManDrop: However, 2819 does not specify exactly which resources it is talking about. (2819 p.17)
SW	EtherStatsPkts	32	Total number of frames including bad frames received. This can be calculated from the histogram data by the CPU
SW	EtherStatsBrdCstPkts	32	Total number of frames received that were directed to a BCST address. Can be calcuilated by the IEEE item BroadCastFrRxOK
SW	EtherStatsMCSTPkts	32	Total number of frames received that were directed to a MCST address. Can be calcuilated by the IEEE item MulCastFrRxOK
SW	EnetStatsAlignCRCEr	32	The total number of frames received that does not have length error and have either CRC or alignment error [Can be calculated from IEEE items FrRxFCSEr, FrAlignEr]
SW	EtherStatsOverPkts	32	Total number of frames received that were longer than 1518 octets long [IEEE item FrTooLongRx]
SW	EtherStatsFrgmnt	32	Total number of frames received that were less than 64 octets long and has either CRC or ALGN error [IEEE item RUNt]
SW	EtherStatsJabbers	32	Total number of frames received that were longer than MAXLength (Considering the DXE value and MAXLength bvalue) and had either a bad FCS or Alignment error [can be extracted from IEEE VeryLongEventRx]
SW	EtherStatsCollisions	32	Best Estimation of collision on this ethernet port [IEEE SiColTx, MulColTx, CollisionRx]
SW	LastSRCADDRx	48	Header of BD ring A latch that holds the source address of the last frame received succesfully (30.4.3.1.19)
SW	EtherStatsPkts	40	The total number of frames received, including bad frame. Can be calculated by summing all receive distribution counters

30.7.7 Detailed Description of HW Statistics Counters

30.7.7.1 Total Transmit 64-byte Frame Counter

NOTE

When one of the above mask bits are set to zero, the corresponding interrupt bit is allowed to cause interrupt indication on the carry bit in the event register UCCE[carry]

30.8 Ethernet Command Set

The transmit and receive commands described in the following sections are issued to the CECR. Please refer to Section 20.3.1, “QUICC Engine Command Register (CECR)” for detailed description of the command format.

The commands are described in Table 30-79.

Table 30-79. Transmit Commands

Command	Description
STOP TRANSMIT	When used with the Ethernet controller, this command violates a specific behavior of an Ethernet/IEEE 802.3 station. It should not be used.
GRACEFUL STOP TRANSMIT	This command is used to smoothly stop transmission after the current frame finishes sending or undergoes a collision (immediately if there is no frame being sent). UCCE[GRA] is set once transmission stops. Then the Ethernet transmit parameters (including BDs) can be modified by the user. TheSQQD[BDRConsumerAddress] points to the next TxBD in the table. Transmission begins when the R bit of the next BD is set and the RESTART TRANSMIT command is issued. Note that if the GRACEFUL STOP TRANSMIT command is issued and the current transmit frame ends in a collision, the SQQD[BDRConsumerAddress] points to the beginning of the collided frame with TxBD[R] still set (the frame looks as if it was never sent).
RESTART TRANSMIT	This command enables transmission of characters on the transmit channel. It is expected by the Ethernet controller after a GRACEFUL STOP TRANSMIT command. The Ethernet controller resumes transmission from the current SQQD[BDRConsumerAddress] in the channel TxBD table.
INIT TX PARAMETERS	This command initializes all the transmit parameters in this serial channel parameter RAM to their reset state. This command should be issued only when the transmitter is disabled. Note that the INIT TX AND RX PARAMETERS command can also be used to reset the transmit and receive parameters. See Section 20.3.1.1, “QUICC Engine Commands.”

Receive commands are described in Table 30-80.

Table 30-80. Receive Commands

Command	Description
INIT RX PARAMETERS	This command initializes all the receive parameters in this serial channel parameter RAM to their reset state and should only be issued when the receiver is disabled. Note that the INIT TX AND RX PARAMETERS command can also be used to reset the receive and transmit parameters.
INIT TX AND RX PARAMETERS	This command initializes all the receive and transmit parameters in this serial channel parameter RAM to their reset state and should only be issued when the receiver and transmitter are disabled. Note that the INIT TX AND RX PARAMETERS command can also be used to reset the receive and transmit parameters.
SET GROUP ADDRESS	The SET GROUP ADDRESS command is used to set one of the 64 bits of the four individual/group address hash filter registers (GADDR[1–4] or IADDR[1–4]). The individual or group address (48 bits) to be added to the hash table should be written to TADDR_L, TADDR_M, and TADDR_H in the parameter RAM prior to executing this command. The CP checks the I/G bit in the address stored in TADDR to determine whether to use the individual hash table or the group hash table. A 0 in the I/G bit indicates an individual address; 1 indicates a group address. This command can be executed at any time, regardless of whether the Ethernet channel is enabled.
ADD/REMOVE ENTRY IN HASH LOOKUP TABLE	This command is used in Extended Parsing mode (REMODER[EXP]=1) in order to add or remove an entry in the Hash Lookup Table. The SBC field in CECR register must contain the value 0x1E0 as defined in the entry named ‘General’ in the SBC table.
SET LAST RECEIVE REQUEST THRESHOLD	This commands result in programming the DRREQ Register in the UCC. The value in this register determines the timeout value for interrupt coalescing. After this timeout, an interrupt is issued to the CPU also if the interrupt coalescing counter has not reached its value. The user programs the value in CECDR Register.
START FLOW CONTROL	In full duplex mode this command results in sending a flow control frame with MAC parameter as programmed in UEMPT[PT] field. In half duplex mode the UEC send preambles on the line unless data is available for transmit.

Table 30-80. Receive Commands (continued)

Command	Description
STOP FLOW CONTROL	In full duplex mode this command results in sending a flow control frame with MAC parameter set to zero. In half duplex mode the UEC stops sending preambles on the line.
GRACEFUL STOP RECEIVE	This command is used to smoothly stop reception. Once the CPU issues this command, the UEC receiver stops reception after it has smoothly received all frames which are currently being processed. If the command is issued after the UEC has stopped reception, the UEC sets RxGlobalParameterRAM[RXSTPAck]. Therefore, in order to be sure that all receive activity is complete, the CPU must issue this command multiple times, check the RxGlobalParameterRAM[RXSTPAck] until it is set. Reception begins when the E bit of the next BD is set and the RESTART RECEIVE command is issued.
RESTART RECEIVE	This command is used to restart receiving frames after the GRACEFUL STOP RECEIVE is issued.

30.8.1 Init Tx, Init Rx and InitTx and Rx Parameters Command

The INIT TX PARAMETERS Command is issued in order to initialize the Transmit Hardware, and some internal parameters. This command must be issued after the Tx Global Parameter page has been initialized and before the GUMR[ENT] bit is set.

The INIT RX PARAMETERS Command is issued in order to initialize the Transmit Hardware, and some internal parameters. This command must be issued after the Rx Global Parameter page has been initialized and before the GUMR[ENR] bit is set.

The INIT TX AND RX PARAMETERS Command is used to initialize Transmit and Receive Hardware, and some internal parameters. This command must be issued after the Rx and Tx Global Parameter page have been initialized and before the GUMR[ENR,ENT] bit are set.

The commands are issued by writing to the CECR register. The command parameters reside in the Multi-user RAM in the InitEnet data structure pointed by the value programmed in the CECDR Register (see Section 20.3.2, “QUICC Engine Command Data Register (CECDR)”section 4.4.2). The data structure is 56 bytes long, and is used by the QE for executing the command. Once the command is completed, this data structure may be overwritten. The CECDR register must be programmed before programming the CECR. See Section 20.3.1, “QUICC Engine Command Register (CECR)” for details.

The SBC (Sub Block Code) used in the CECR is taken from Table 20-3, and it corresponds to the UCC running the Ethernet.

The InitEnet Data structure comprises of the data necessary to initialize the UEC. The user programs the InitEnet structure as described in Table 30-81. The table is divided into the Rx and Tx. The user fills in a certain number of entries depending on the Rx and Tx bit rates. The user needs to program part of the Tx and part of the Rx entries in the table or both, depending on the command given. Blank spaces are left in the Data Structure if less than the maximum number of the entries are required or if only the Tx or only the Rx are initialized. The number of entries that need to be initialized depend on the mode programmed in INIT RX PARAMETERS[RGF] or INIT TX PARAMETERS[TGF] fields. The number of entries in the table for Tx is one more than the number of threads, and for Rx is two more that the number of threads. See Section 30.4.4, “Multithreading” for an explanation.

The InitEnet fields are described in Table 30-81.

Table 30-81. InitEnet Command Parameter

Offset	Bits	Name	Description
CECDR+0	0:7	Res	Internal variable. Intialize to value = 0x06
CECDR+1	0:7	Res	Internal variable. Intialize to value = 0x30
CECDR+2	0:7	Res	Internal variable. Intialize to value = 0xFF
CECDR+3	0:7	Res	Intialize to value = 0x00
CECDR+4	0:15	Res	Internal variable. Intialize to value = 0x400.
CECDR+6	0:7	Res	Intialize to value = 0x00
	8:15	LargestLookupKeySize	Largest Lookup KeySize. Needed only if REMODER[EXP]=1 and ExternalHashLookup PCD is used. This field specifies the size of the largest LookupKey used for any of the ExternalHashLookup performed in Extended Parsing Mode. 0x00 - ExternalHashLookup PCD is not used. (Allocate 64 bytes in Extended Parsing Thread Parameter RAM) 0x3F - 8 bytes (Allocate 64+64 bytes in Extended Parsing Thread Parameter RAM) 0x5F - 16 bytes (Allocate 64+96 bytes in Extended Parsing Thread Parameter RAM) Rest - not allowed

Table 30-81. InitEnet Command Parameter (continued)

Offset	Bits	Name	Description
CECDR+8	0:3	RGF	Rx Gigabit or Fast. This bit is used to determine the maximum nominal Rx bit rate running on the UEC. T UEC e data structures are programmed during initialization according to this bit. The user must allocate memory in the Multiuser RAM accordingly. See Section 30.8, "Ethernet Command Set" for more details. 0000 - Suggested value for maximum Rx nominal bit rate of 1000/100/10Mbps (4 threads) 0001 - Suggested value for maximum Rx nominal bit rate of 10/100bps (1 thread)0010 - 2 thread 0011 - 6 threads 0100 - 8 threads
	4:7	TGF	Tx Gigabit or Fast. This bit is used to determine the maximum nominal Rx bit rate running on the UEC. The UEC e data structures are programmed during initialization according to this bit. The user must allocate memory in the Multiuser RAM accordingly. See Section 30.8, "Ethernet Command Set" for more details. 0000 - Suggested value for maximum Tx nominal bit rate of 1000/100/10Mbps (4 threads) 0001 - Suggested value for maximum Tx nominal bit rate of 10/100bps (1 thread) 0010 - 2 thread 0011 - 6 threads 0100 - 8 threads
	8-25	Rx Global Parameter RAM Page	Base Address of the Global Receiver Parameter RAM Page. The address is aligned to 64 bytes. This field contains bits [11:25] of the address. Bits [8:10] are always zero. The user needs to allocate 256 bytes for this page. The address must be aligned to the page size.
	26-27	Reserved	Initialize to zero
	28-31	RISC Allocation	0000 - Reserved 0001 - RISC 1 0010 -RISC 2 0011 -RISC1 and RISC2. Suggested value.
CECDR+c	0-7	Rx_Global_SNUM	SNUM of a Global task chosen for UEC Receiver. Refer to Table 20-15. One of the SNUMs is allocated for this thread; each SNUM is used once in the system. This entry must always be initialized.
	8-25	Reserved	Initialize to zero
	26-27	Reserved	Initialize to zero
	28-31	RISC Allocation	Suggested value is 0x3. See description in entry for Rx Global Parameter RAM.

Table 30-81. InitEnet Command Parameter (continued)

Offset	Bits	Name	Description
CECDR+10 This entry must be always initialized for at least one thread	0-7	Rx Th1_SNUM	SNUM of a thread chosen for UEC Receiver. Refer to table 4-4 ‘SNUM Table in section 4.5.15. One of the threads is allocated; each thread is used once in the system. This entry must be always initialized.
	8-25	Rx Thread1 Parameter RAM Page	Base Address of the Thread Parameter RAM Page. The address is aligned to 64 bytes. This field contains bits [11:25] of the address.Bits [8:10] are always zero.The user needs to allocate 128 bytes for this page. The address must be aligned to the page size.
	26-27	Reserved	set to zero
	28-31	RISC Allocation	Suggested value is 0x3. See description in entry for Rx Global Parameter RAM.
CECDR+14	0-7	Rx Th2_SNUM	Optional thread. Refer to description of Rx Th1_SNUM
	8-25	Rx Thread2 Parameter RAM Page	Refer to description of Rx Thread1 Parameter RAM Page.
	26-27	Reserved	set to zero
	28-31	RISC Allocation	Suggested value is 0x3. See description in entry for Rx Global Parameter RAM.
CECDR+18	0-7	Rx Th3_SNUM	Optional thread. Refer to description of Rx Th1_SNUM
	8-25	Rx Thread3 Parameter RAM Page	Refer to description of Rx Thread1 Parameter RAM Page
	26-27	Reserved	set to zero
	28-31	RISC Allocation	Suggested value is 0x3. See description in entry for Rx Global Parameter RAM.
CECDR+1c	0-7	Rx Th4_SNUM	Optional thread. Refer to description of Rx Th1_SNUM
	8-25	Rx Thread4 Parameter RAM Page	Refer to description of Rx Thread1 Parameter RAM Page
	26-27	Reserved	set to zero
	28-31	RISC Allocation	Optional thread. Suggested value is 0x3. See description in entry for Rx Global Parameter RAM.
CECDR+20	0-7	Rx Th5_SNUM	Refer to description of Rx Th1_SNUM.
	8-25	Thread5 Parameter RAM Page	Refer to description of Rx Thread1 Parameter RAM Page
	26-27	Reserved	set to zero
	28-31	RISC Allocation	Suggested value is 0x3. See description in entry for Rx Global Parameter RAM.

Table 30-81. InitEnet Command Parameter (continued)

Offset	Bits	Name	Description
CECDR+24	0-7	Rx Th6_SNUM	Optional thread. Refer to description of Rx Th1_SNUM.
	8-25	Rx Thread6 Parameter RAM Page	Refer to description of Rx Thread1 Parameter RAM Page
	26-27	Reserved	set to zero
	28-31	RISC Allocation	Suggested value is 0x3. See description in entry for Rx Global Parameter RAM.
CECDR+28	0-7	Rx Th7_SNUM	Optional thread. Refer to description of Rx Th1_SNUM.
	8-25	Rx Thread7 Parameter RAM Page	Refer to description of Rx Thread1 Parameter RAM Page
	26-27	Reserved	set to zero
	28-31	RISC Allocation	Suggested value is 0x3. See description in entry for Rx Global Parameter RAM.
CECDR+2c	0-7	Rx Th8_SNUM	Optional thread. Refer to description of Rx Th1_SNUM.

CECDR+5c	0-7	Reserved	set to zero

30.8.1.1 Init Rx Parameters Command

The INIT RX PARAMETERS Command is issued in order to initialize the Receive Hardware, and some internal parameters. This command must be issued after the Rx Global Parameter page has been initialized and before the GUMR[ENR] bit is set.

30.8.2 Add/Remove Entry in Hash Lookup Table

This command is used to add or remove an entry in the Hash Lookup Table. The command is issued by writing to the CECR register (see Section 20.3.1, “QUICC Engine Command Register (CECR)” and Section 20.3.1.1, “QUICC Engine Commands”), and to CECDR registers (see Section 20.3.2, “QUICC Engine Command Data Register (CECDR)”).
The SBC field in CECR register must contain the value 0x1E0 as defined in the entry named ‘General’ in the SBC table, see Table 20-3. The CECDR register contains the base address in multiuser RAM where the data structure in Figure 30-74 resides. See Section 30.6.2.6, “Hash Table Lookup PCDs” for more details.

NOTE

The base address programmed in the CECDR must be aligned to a 64 byte boundary.

If the command execution is not able to remove and entry in the lookup table and HTFI bit is set, CETER[0] is set. If the command execution is not able to add an entry from the lookup table and HTFI bit is set CETER[1] bit is set. An interrupt is issued to the CPU if the corresponding CETMR bit is set. The user needs to ensure that there is no conflict with the usage of Timer1 and

Timer2 respectively. See Section 20.4.4, “RISC Timer Event Register (CETER)/Mask Register (CETMR).”

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Offset 20-2F	LookupKey (up to 16 bytes)															
Offset 30-3F	Reserved															
Offset + 0x40-0x9F or 0x40-0x7F	Reserved (size depends on LookupKeySize: 16 or 8 bytes respectively)															

Figure 30-74. Set entry in Hash Lookup Table Command Parameters

Table 30-82. Set entry in Hash Lookup Field Descriptions

Offset	Bits	Name	Description
0	0-1	ADDE	Add Entry 00 - Reserved 01 - Remove Entry from Lookup Table. 10 - Add entry in lookup Table 11 - Remove entry (if it exists) and then add entry to LookupTable Note: The remove and then add may be used to guarantee that he same LookupKey does not appear twice in the lookup table.
	2	EXLT	External Lookup Table 0 - Lookup Table resides in internal Multiuser RAM 1 - Lookup Table resides in External Memory
	3	SLTE	Secondary Lookup Table Enable 0 - No secondary lookup table 1 - Secondary lookup table is used if all four ways of the lookup table are filled.
	4	HTFI	Hash Table Full Interrupt Enable 0 - No interrupt is issued if Hash Table is full 1 - Enable CETER[0] or CETER[1] interrupts. The user needs to ensure that there is no conflict with the usage of Timer1 and Timer2 respectively.
	5-7	Reserved	Set to zero
	8-15	LookupBMR	Bus Mode Register. This register defines the bus where the LookupTable resides. See Section 30.5.4, “Bus Mode Register (BMRx).” The BDB bit determines the bus where the LookupTable is resides. Note that the value of this bit must match the value programmed in the relevant HashLookup PCD. See Section 30.6.2.6, “Hash Table Lookup PCDs.”
2	0-7	LookupKeySize	Lookup KeySize This field specifies the size of the LookupKey. The LookupKey parsed by the Generate LookupKey PCD is truncated to the size programmed in this field. 0x3F - 8 bytes 0x5F - 16 bytes Rest - not allowed
	8-11	Reserved	Set to zero
	12-15	HashKeySize	HaskKeyMask. This field determines the size of the hash key (i.e. the number of sets in the Lookup Table). 0000 - 1 bit Hask Key (2 sets in the Lookup Table) 0001 - 2 bit Hask Key (4 sets in the Lookup Table) 0010 - 3 bit Hash Key (8 sets in the Lookup Table) 0011 - 4 bit Hash Key (16 sets in the LookupTable) 0100 - 5 bit Hash Key 0101 - 6 bits Hash Key ..... (all valid values) 1110 - 15 bit Hash Key (32K sets in the Lookup Table) 1111- 16 bit Hash Key (64K sets in the Lookup Table)
4		LookupTableBase	This field determines the base address of the Lookup Table in internal or external memory as determined by EXLT bit.

Table 30-82. Set entry in Hash Lookup Field Descriptions (continued)

Offset	Bits	Name	Description
8		Secondary LookupTableOffset	Base address of the secondary lookup table. The secondary lookup table is accessed if SLTE bit is set and the lookup table based at LookupTableBase is full (for insert new entry), or if the entry was not found in the same table (for remove).
C		Reserved	Set to zero.
E		Reserved	Set to zero.
10-17		TAD	Termination Action Descriptor
18-1F		Reserved	Set to zero.
Offset 20-2F		LookupKey	This is the Lookup Key used to generate the new entry in the Lookup Table, or the LookupKey that needs to be removed from the table. The LookupKey is aligned to the low addresses. For lookup keys shorter than 16 bytes, the user must fill the low order bytes with zeroes.
Offset 30-3F		Reserved	Set to zero.
Offset + 0x40-0x9F or 0x40-0x7F		Reserved	Set to zero. This space is reserved for temporary storage. Its size (64 or 96 bytes) depends on the size of the LookupKey (8 or 16 bytes). This space is needed in the HashLookupTable is in external memory. If ADDE=10 (add entry), only 64 bytes are needed.

30.8.2.1 Explanation on the LookupKey to be placed in this Host Command

The LookupKey is comprised of all header fields corresponding to the bits set in the GenerateLookupKey PCD that is used to perform the Lookup using this Hash Lookup Table. The fields in the LookupKey appear in the same order as their respective enable bits in the GenerateL2 LookupKey PCD. The LookupKey is padded with zeroes to the right up to its programmed size (8 or 16 bytes). If the PCD has a bit set, that corresponds to afield which is not found in the frame, a value of ‘zero’ replaces the missing field. For example: If in the PCD TCI1 is set, and the frame has not VLAN Tag. the lookupkey contains 2 bytes of ‘zero’ in place of the missing VLAN tag. Therefore if the user wishes to have a match on frame with or without VLAN Tag, two entries in the lookup table must be inserted (one with the desired VLAN Tag, and one with 2 bytes of zeroes in place of the VLAN Tag in the lookup Key).

Regarding the SourcePort and PCDID fields. If the user chooses to include these fields in the lookup key, the following instructions must be followed:

The source port values are taken from the following table:

Table 30-83. Source Port Values (SNUMs)

Source Port	SNUM
UCC1	0x01
UCC2	0x11
UCC3	0x21
UCC4	0x31

Table 30-83. Source Port Values (SNUMs)

Source Port	SNUM
UCC5	0x81
UCC6	0x91
UCC7	0xa1
UCC8	0xb1

Note that these are the SNUM the values as in The PCDID field is user programmable. For a ‘hit’ in the hash table lookup, the user needs to make sure that the value of the PCDID in the corresponding GenerateLookupKey PCD matches the value programmed in this host command.

30.9 Controlling PHY Links (Management Interface)

The support for MII Ethernet Management can be done by the SPI or by one UCC which can be selected using CMXGCR[SMI]. Control and status to and from the PHY is provided via the two-wire MII management interface described in IEEE 802.3u. The MII management registers (MII management configuration, command, address, control, status, and indicator registers) are used to exercise this interface between a host processor and one or more PHY devices.

The UEC MII registers provide the ability to perform continuous read cycles (called a scan cycle); although, scan cycles are not explicitly defined in the standard. If requested (by setting MIIMCOM[scan cycle]), the part performs repetitive read cycles of the PHY status register, for example. In this way, link characteristics may be monitored more efficiently. The different fields in the MII management indicator register (scan, not valid and busy) are used to indicate availability of each read of the scan cycle to the host from MIIMSTAT[PHY scan].

Yet another parameter that can be modified through the MII registers is the length of the MII management interface preamble. After establishing that a PHY supports preamble suppression, the host may so configure the UEC. While enabled, the length of MII management frames are reduced from 64 to 32 clocks. This effectively doubles the efficiency of the interface.

30.10 External Signal Description

30.10.1 Overview

This section defines the UCC Ethernet MAC to chip pin I/O. The UEC network interface supports multiple options. One is the MII option which requires 18 I/O pins and supports both data and a management interface to the PHY (transceiver) device. The MII option supports both 10 and 100 Mbps Ethernet rates. The second is referred to as the GMII option and is a superset of the MII signals. The GMII option supports the 1000 Mbps Ethernet rate and TBI interface which shares pins with the GMII interface signals. Other interface options are the RMII which is a reduced pin implementation of the MII interface, the RGMII which is a reduced pin implementation of the GMII interface, and the RTBI which is a reduced pin implementation of the TBI interface. Table 30-84 provides a list of the external signal properties. The

assignment of the signals to the pins of the device is described in the signals chapter, parallel I/O, see Section 3.4, “Parallel I/O Ports.”See Chapter 3, “Signal Descriptions.”

Table 30-84. Signal Properties

Name	Function	I/O	Pull Up
RX_CLK	MII —receive clock GMII, TBI,RGMII,RTBI,RMII—not in use	Input	—
GRX_CLK	GMII, RGMII—receive clock TBI,RTBI—PMA receive clock 0 (125Mhz or 62.5Mhz) MII,RMII—not in use	Input	—
RX_CLK1	TBI—PMA receive clock 1(second receive TBI 62.5Mhz clock) GMII,MII,RGMII,RTBI,RMII—not in use	Input	—
COL	MII—collision GMII, RMII, RGMII, RTBI—not in use	Input	—
CRS	MII—carrier sense TBI—signal detect (SDET) GMII,RMII,RGMII,RTBI—not in use	Input	—
RX_DV	G/MII—RX_DV TBI—receive code group (RCG[8]) bit 8 RMII—carrier sense data valid (CRS_DV) RGMII—(RX_CLK rising edge) - receive data valid RGMII—(RX_CLK falling edge)- receive error RTBI—(RX_CLK rising edge) receive code group(RCG[4]) bit 4 RTBI—(RX_CLK falling edge) receive code group(RCG[9]) bit 9	Input	—
RXD[7:4]	GMII—receive data bits 7:4 (RXD[7:4]) TBI—receive code group (RCG[7:4]) bits 7:4 MII, RMII, RGMII, RTBI—not in use	Input	—
RXD[3:0]	GMII,MII—receive data bits 3:0, (RXD[3:0]) TBI—receive code group (RGC[3:0]) bits 3:0 RGMII—RX_CLK rising edge - RXD[3:0] RGMII—RX_CLK falling edge - RXD[7:4] RTBI—RX_CLK rising edge - RCG[3:0] RTBI—RX_CLK falling edge - RCG[8:5] RMII—receive data 1:0 (RXD [1:0])	Input	—
RX_ER	GMII,MII—receive error (RX_ER) RMII— receive error (RX_ER) TBI—receive code group (RCG[9]) RGMII, RTBI—not in use	Input	—
TX_CLK	MII—TX_CLK (transmit clock) RMII—REF_CLK (reference clock) This signal usually comes from an external oscillator or PHY GMII,RGMII,TBI,RTBI-oscillator source for transmit clock	Input	Passive
GTX_CLK	GMII/TBI - continuos transmit clock feedback RGMII/RTBI-inverted transmit clock feedback	Output	Passive
TXD[4:7]	GMII - transmit data bits 7:4 (TXD[7:4]) TBI—transmit code group (TCG[7:4]) bits 7:4 RMII, RGMII, RTBI—not in use	Output	Passive

Table 30-84. Signal Properties (continued)

Name	Function	I/O	Pull Up
TXD[3:0]	GMII,MII - transmit data bits 3:0 TBI- transmit code group (TCG[3:0]) bits 3:0 RMII—transmit data bits 1:0 RGMII—(TX_CLK rising edge) (transmit data bits 3:0) RGMII—(TX_CLK falling edge) (transmit data bits 7:4) RTBI—(TX_CLK rising edge) transmit code group (TCG[3:0]) bits 3:0 RTBI—(TX_CLK falling edge) transmit code group (TCG[8:5]) bits 8:5	Output	Passive
TX_EN	GMII,MII—TX_EN (transmit data enable) RMII—TX_EN (transmit data enable) TBI—transmit code group (TCG[8]) bit 8 RGMII—(TX_CLK rising edge) -transmit enable RGMII—(TX_CLK falling edge) -transmit error RTBI—(TX_CLK rising edge) - transmit code group (TCG[4]) bit 4 RTBI—(TX_CLK falling edge) - transmit code group (TCG[9]) bit 9	Output	Passive
TX_ER	GMII,MII- transmit error TBI—transmit code group (TCG[9]) bit 9 RMII, RGMII, RTBI—not in use	Output	Passive
Management signals	Refer to MII management signals. Management signals are common to all PHY interface.	Input/Output	Passive

30.10.2 Detailed Signal Descriptions

Table 30-85 provides the UCC Ethernet Controller interface signal descriptions.

Table 30-85. Signal Descriptions

Signal	I/O	Description	
RX_CLK	I	Receive Clock from PHY. MII mode—A continuous clock (2.5, 25MHz)	
		State Meaning	
		Timing	Provides a timing reference for RX_DV, RXD, and RX_ER.
RX_CLK1	I		TBI—PMA receive clock 1(second receive TBI 62.5Mhz clock) GMII,MII,RGMII,RTBI,RMII—not in use
		State Meaning	
		Timing	Provides a timing reference for RCG[9:0] in TBI mode
GRX_CLK	I	Receive Clock from PHY. GMII, RGMII—receive clock from PHY TBI mode—Depending on the PHY being used, this is the input for a 62.5 MHz PMA receive clock 0 split phase with PMA_RX_CLK1 and is supplied by SERDES, or it is a 125 MHz receive clock. RTBI- PMA receive clock 0 works in 125 MHz receive clock	
		State Meaning	
		Timing	Provides a timing reference for RX_DV, RXD, and RX_ER or RCG[9:0] in TBI mode
COL	I	Collision	
		State Meaning	Asserted— asserted by PHY on detection of a collision on the medium. Negated—No collision detect in the medium
		Timing	Assertion—Shall remain asserted while the collision condition persists. Negation—Must negate while no collision condition persists. COL is not required to transition synchronously with respect to either TX_CLK or RX_CLK.

Table 30-85. Signal Descriptions (continued)

Signal	I/O	Description	
CRS	I	Carrier Sense	
		State Meaning	Asserted— Either the transmit or receive medium is nonidle. PHY shall ensure that Negated—Both the transmit and receive media are idle.
		Timing	Assertion/Negation—Remains asserted throughout the duration of a collision condition.
RX_DV	I	Receive Data Valid GMII,MII mode—When this signal is asserted, PHY is indicating that valid data is present on the G/MII interface. RGMII mode—Rising edge (RX_DV), falling edge (RX_ER) TBI mode—Represents receive code group (RCG[8]). Together with RCG[9] and RCG[0:7], they represents the 10-bit encoded symbol of GMII receive signals. RTBI mode—Rising edge (RCG[4]), falling edge (RCG[9]) RMII mode—Represents carrier sense data valid, shall be asserted by PHY when the receive medium is nonidle.	
		State Meaning	Asserted— PHY is presenting recovered and decoded nibbles/octets on the RXD<3:0> bundle.
		Timing	Assertion—Shall remain asserted continuously from RST recovered byte/nibble of the frame through the final recovered data byte/nibble. Negation—Negated prior to RST RX_CLK that follows the final byte/nibble.
RXD[3:0]	I	Receive Data GMII,MII mode—RXD[3:0] represents a nibble of data to be transferred from PHY to MAC when RX_DV is asserted. A completely formed SFD must be passed across When RX_DV is not asserted, RXD has no meaning. RGMII mode—Rising edge (RXD[3:0]), falling edge (RXD[7:4]) RMII—RXD[1:0] represents a di-bit of data to be transferred from PHY to MAC when CRS_DV is asserted. TBI mode—RXD[3:0] represents RCG[3:0]. Together with RCG[9:4], they represent the 10-bit encoded symbol of G/MII receive signals. RTBI mode—Rising edge (RCG[3:0]), falling edge (RCG[8:5])	
		State Meaning	RXD is a bundle of data signals (RXD<3:0>). RXD<3:0> are driven by PHY.
		Timing	That transition synchronously with respect to RX_CLK in MII, GRX_CLK for GMII/RGMII/TBI/RTBI and TX_CLK in RMII
RXD[7:4]	I	Receive Data GMII—RXD[7:4] represents a nibble of data to be transferred from PHY to MAC when RX_DV is asserted. A completely formed SFD must be passed across TBI mode—RXD[7:4] represents RCG[7:4]	
		State Meaning	RXD is a bundle of data signals (RXD<7:4>). RXD<7:4> are driven by PHY.
		Timing	That transition synchronously with respect to GRX_CLK.

Table 30-85. Signal Descriptions (continued)

Signal	I/O	Description	
RX_ER	I	Receive Error GMII/MII and RMII mode—When RX_ER and RX_DV are asserted, PHY has detected an error in the current frame. TBI mode—Represents RCG[9]. Together with RCG[8:0], they represent the 10-bit encoded symbol of GMII receive signals.	
		State Meaning	Asserted—RX_ER is asserted for one or more RX_CLK periods to indicate to the reconciliation sublayer that an error (e.g., a coding error, or any error that PHY is capable of detecting, and that may otherwise be undetectable at the MAC sublayer) was detected somewhere in the frame presently being transferred from PHY to the reconciliation sublayer. Note: While RX_DV is de-asserted, RX_ER shall have no effect on the reconciliation sublayer.
		Timing	That transition synchronously with respect to RX_CLK in MII and GRX_CLK for GMII/RGMII/TBI/RTBI
TX_CLK	I	Transmit Clock MII mode—continuous clock (2.5 or 25 MHz) which provides a timing reference for TX_EN, TXD, and TX_ER GMII mode- oscillator source for transmit clock RMII mode— reference clock to TX_EN, TXD, TX_ER, RXD, RX_ER and RX_DV Note that in GMII/RMII/RGMII/TBI/RTBI is not the reference clock to TX_EN,TXD and TX_ER	
		State Meaning	MII - Continuous clock that provides the timing reference for the transfer of TX_EN, TXD, and TX_ER signals from the reconciliation sublayer to PHY. TX_CLK is sourced by PHY. GMII/RGMII/TBI/RTBI - oscillator source for transmit clock
		Timing	—
TXD[7:0]	O	Transmit Data GMII mode—TXD[7:0] represent one complete octet of data to be sent from MAC to PHY when TX_EN is asserted and has no meaning when TX_EN is de-asserted. TBI mode—TXD[7:0] represents transmit code group (TCG) bits 7:0. Together with TCG[9:8], they represent the 10-bit encoded symbol or concatenation of G/MII transmit signals. MII mode—TXD[3:0] represent a nibble of data to be sent from MAC to PHY when TX_EN is asserted and have no meaning when TX_EN is de-asserted. RMII mode—TXD[1:0] represents one complete di-bit of data to be sent from MAC to PHY when TX_EN is asserted and has no meaning when TX_EN is de-asserted. RGMII mode—Rising edge (transmit data bit 3:0), falling edge (transmit data bit 7:4) RTBI mode—Rising edge (TCG bit 3:0), falling edge (TCG bit 8:5)	
		State Meaning	TXD is a bundle of data signals (TXD<0:7>) that are driven by the reconciliation sublayer.
		Timing	TXD<0:7> shall transition synchronously with respect to TX_CLK in MII mode and GTX_CLK in GMII/RGMII/TBI/RTBI modes

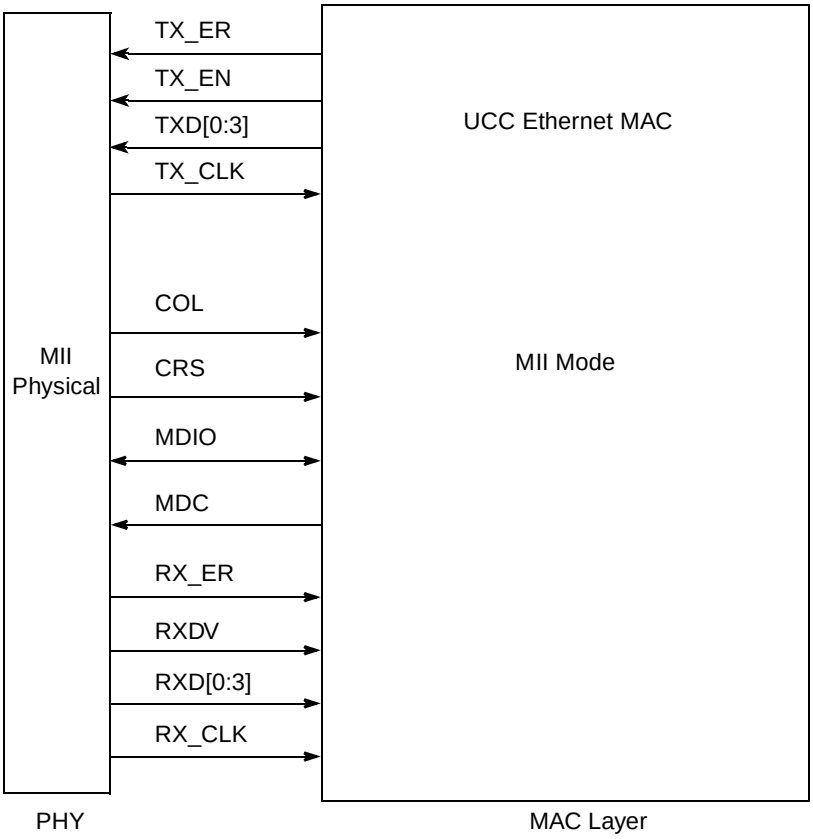
Table 30-85. Signal Descriptions (continued)

Signal	I/O	Description	
TX_EN	O	Transmit Enable GMII/MII/RMII mode—When this signal is asserted, MAC is indicating that valid data is present on the physical line RGMII - represent TX_EN on GTX_CLK rising edge and TX_ER on GTX_CLK falling edge RTBI - represent TCG[4] on GTX_CLK rising edge and TCG[9] on GTX_CLK falling edge TBI mode—represents TCG[8]. Together with TCG[9] and TCG[7:0], they represent the 10-bit encoded symbol or concatenation of GMII transmit signals.	
		State Meaning	Asserted— TX_EN indicates that the reconciliation sublayer is presenting nibbles on the MII for transmission. TX_EN shall be negated prior to RST TX_CLK following the nal nibble of a frame. TX_EN is driven by the reconciliation sublayer and shall transition synchronously with respect to TX_CLK.
		Timing	Assertion—synchronously with RST nibble/octet of the preamble and shall remain asserted while all nibbles/octets to be transmitted are presented to the G/MII Negation—negated prior to RST TX_CLK following the nal nibble/octet of a frame.
TX_ER	O	Transmit Error GMII/MII mode—Assertion of this signal for one or more clock cycles while TX_EN is asserted shall cause PHY to transmit one or more illegal symbols. Asserting TX_ER has no affect when operating at 10 Mbps or when TX_EN is de-asserted This signal transitions synchronously with respect to TX_CLK. TBI - represent transmit code group (TCG[9]) bit 9	
		State Meaning	Asserted—PHY shall emit one or more symbols that are not part of the valid data or delimiter set somewhere in the frame being transmitted. The relative position of the error within the frame need not be preserved.
		Timing	TX_ER is asserted for one or more TX_CLK/GTX_CLK periods while TX_EN is also asserted,
MDC	O	Management data clock In GMII/MII/RGMII/RMII/TBI or RTBI mode, this signal is a clock supplied by the MAC (typically 2.5 MHz). The frequency can be modified by writing to MIICFG[28:31] Note: In order to increase MDC frequency, UPSMR[20] might be used as a prescale by 8	
		State Meaning	MDC is sourced by the station management entity to PHY as the timing reference for transfer of information on the MDIO signal. MDC is an aperiodic signal that has no maximum high or low times.
		Timing	The minimum high and low times for MDC shall be 160 ns each, and the minimum period for MDC shall be 400 ns, regardless of the nominal period of TX_CLK and RX_CLK.
MDIO	I/O	Management data Bi-directional pin to input PHY supplied status during management read cycles and output control during MII management write cycles.	
		State Meaning	MDIO is a bidirectional signal between PHY and STA. It is used to transfer control information and status between PHY and STA.
		Timing	MDIO shall be driven through three-state circuits that enable either STA or PHY to drive the signal.

30.11 UCC Ethernet Controller Connections

30.11.1 Media Independent Interface (MII)

The UCC Ethernet Controller implements the IEE 802.3 standard MII interface for Fast Ethernet. Figure 30-75 describes the MII interface signals and shows the basic components, including the signals required to make a UEC module connection with a PHY.



Note: Signal names are according to the IEEE 802.3 standard (total:16 ports).

Figure 30-75. MII MAC-PHY Interface

Table 30-86 provides a list of the MII signals.

Table 30-86. MII Signal Descriptions

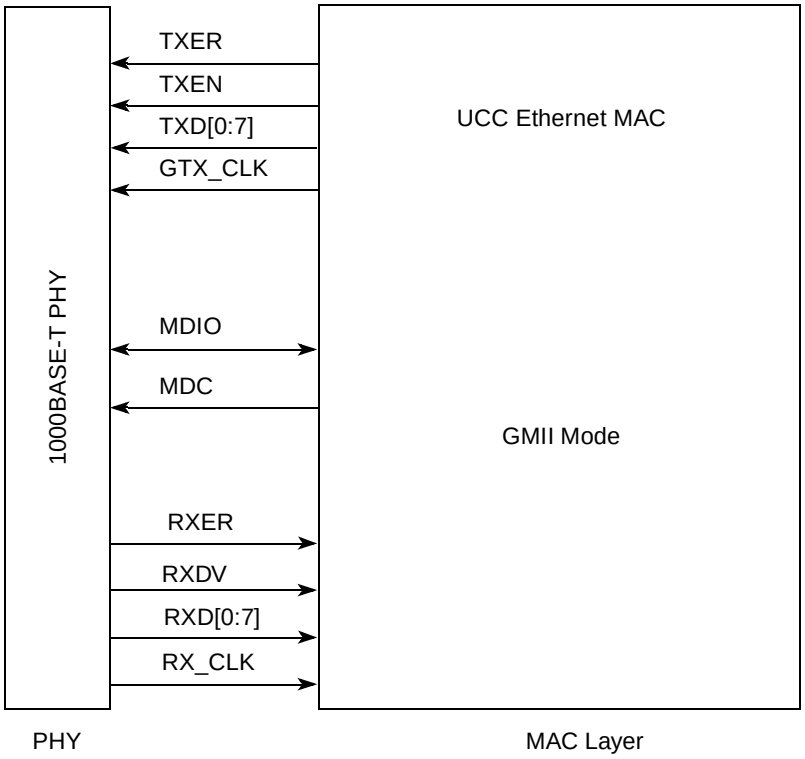
IEEE Name	I/O	Size	Function	Reference Clock
TX_ER	O	1	Transmit error, asserted by the MAC layer to generate a coding error on the byte currently being transferred over TXD[0:3].	TX_CLK
TX_EN	O	1	Transmit enable, asserted by the MAC sublayer when the first transmit preamble byte is driven over the MII. It remains asserted for the remainder of the frame, up to the last CRC byte.	TX_CLK
TXD[0:3]	O	4	Transmit data	TX_CLK

Table 30-86. MII Signal Descriptions (continued)

IEEE Name	I/O	Size	Function	Reference Clock
TX_CLK	I	1	25 MHz clock, which provides the timing reference for the transfer of the TX_EN, TX_ER, and TXD signals.	—
COL	I	1	This signal is asserted on detection of a collision.	TX_CLK
CRS	I	1	This signal is asserted when the transmit or receive medium is not idle.	—
RX_ER	I	1	Receive error, asserted by the PHY layer to indicate an error the MAC can not detect. If asserted during frame reception, indicates a coding error on the frame currently being transferred on RXD[0:3].	RX_CLK
RX_DV	I	1	Receive data valid, asserted by the PHY layer when the first received preamble byte is driving over the MII. It remains asserted for the remainder of the frame, up to the last CRC byte	RX_CLK
RX_CLK	I	1	Receive clock, synchronized all receive signals (RX_DV, RXD, RX_ER)	—
RXD[0:3]	I	4	Receive data	RX_CLK
MDIO	I/O	1	Management data input/output, used to transfer control signals between the PHY layer and the manger entity.	Management Clock
MDC	I	1	Management data clock, the MDIO signal clock reference (25 MHz clock)	—

30.11.2 Gigabit Media Independent Interface (GMII)

The UCC Ethernet Controller implements the IEE 802.3 standard GMII interface for Gigabit Ethernet. Figure 30-76 describes the GMII interface signals and shows the basic components of the GMII including the signals required to make a UEC module connection with a PHY.



Note: Signal names are according to the IEEE 802.3 standard (total: 22 ports for full-duplex operation).

Figure 30-76. GMII MAC-PHY Interface

Table 30-87 provides a list of the GMII signals.

Table 30-87. GMII Signals

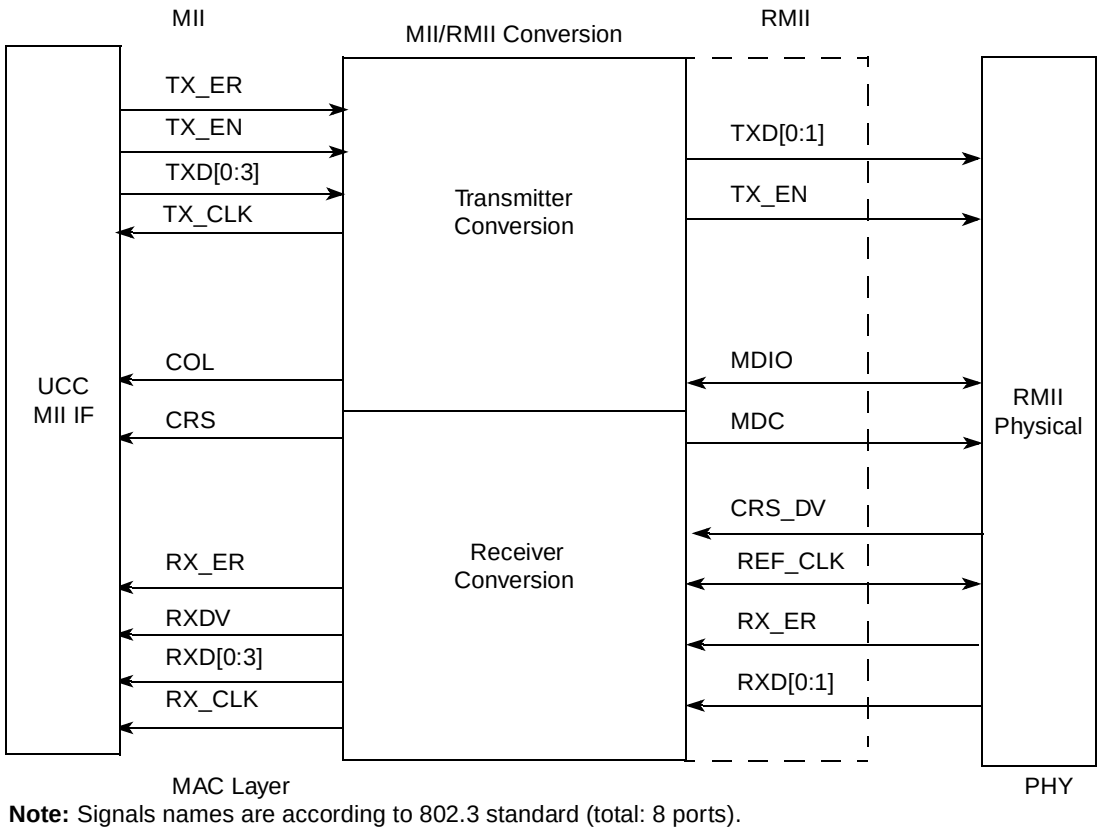
IEEE Name	I/O	Size	Function	Reference Clock	Timing
TX_ER	O	1	Transmit error, asserted by the MAC layer to generate a coding error on the byte currently being transferred over TXD[7:0].	GTX_CLK	max–2.5 n min–0.5 n
TX_EN	O	1	Transmit enable, asserted by the MAC sublayer when the first transmit preamble byte is driven over the GMII. It remains asserted for the remainder of the frame, up to the last CRC byte.	GTX_CLK	max–2.5 n min–0.5 n
TXD[0:7]	O	8	Transmit data	GTX_CLK	max–2.5 n min–0.5 n
GTX_CLK	O	1	125-MHz clock which provides the timing reference for the transfer of the TXEN, TXER, and TXD signals	—	—
RX_ER	I	1	Receive error, asserted by the PHY layer to indicate an error the MAC can not detect. If asserted during frame reception, indicates a coding error on the frame currently being transferred on RXD[7:0].	RX_CLK	max–2.5 n min–0.5 n

Table 30-87. GMII Signals (continued)

RX_DV	I	1	Receive data valid, asserted by the PHY layer when the first received preamble byte is driving over the GMII. It remains asserted for the remainder of the frame, up to the last CRC byte	RX_CLK	max–2.5 n min–0.5 n
RX_CLK	I	1	Receive clock, synchronized all receive signals (RX_DV, RXD, RX_ER).	—	—
RXD[0:7]	I	8	Receive data	RX_CLK	max–2.5 n min–0.5 n
MDIO	I/O	1	Management data input/output, used to transfer control signals between the PHY layer and the manager entity.	Management Clock	—
MDC	I	1	Management data clock, the MDIO signal clock reference (25 MHz clock)	—	—

30.11.3 Reduced Media Independent Interface (RMII)

The UCC Ethernet Controller MAC implements the MII/RMII Conversion to achieve pin-out reduce interface. Figure 30-77 shows the basic components of the RMII including the signals required to make a UEC module connection with a PHY.



Note: Signals names are according to 802.3 standard (total: 8 ports).

Figure 30-77. RMII MAC-PHY Interface

Table 30-88 provides a list of the GMII signals.

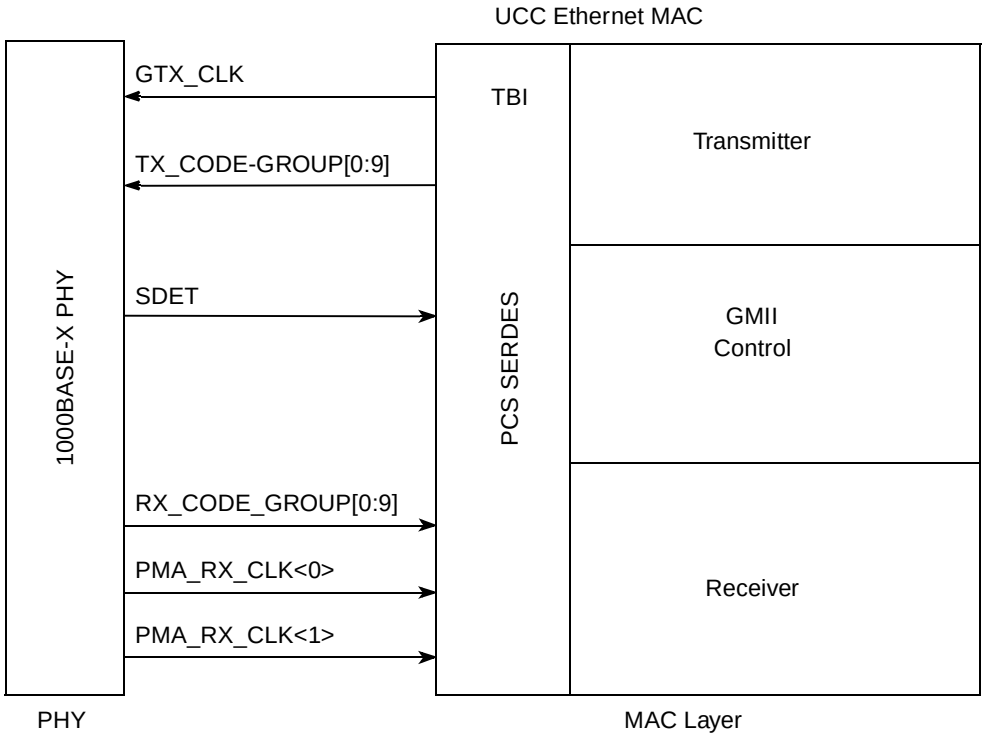
Table 30-88. RMII Signals

IEEE Name	I/O	Size	Function	Reference Clock	Timing
TX_EN	O	1	Transmit enable, asserted by the MAC sublayer when the first transmit preamble byte is driven over the RMII. It remains asserted for the remainder of the frame, up to the last CRC byte	REF_CLK	max–4 n min–2 n
TXD[0:1]	O	2	Transmit data	REF_CLK	max–4 n min–2 n
REF_CLK	I	1	50-MHz synchronous clock reference for receive, transmit, and control interface.	—	—
RX_ER	I	1	Receive error, asserted by the PHY layer to indicate an error the MAC can not detect. If asserted during frame reception, indicates a coding error on the frame currently being transferred on RXD[1:0].	REF_CLK	max–4 n min–2 n
CRS_DV	I	1	Receive data valid, asserted by the PHY layer when the first received preamble byte is driving over the RMII. It remains asserted for the remainder of the frame, up to the last CRC byte.	REF_CLK	max–4 n min–2 n
RXD[0:1]	I	2	Receive data	REF_CLK	max–4 n min–2 n
MDIO	I/O	1	Management data input/output, used to transfer control signals between the PHY layer and the manger entity.	Management Clock	—
MDC	I	1	Management data clock, the MDIO signal clock reference (25 MHz clock).	—	—

[1] Signals names are according to 802.3 standard (Total: 4 ports)

30.11.4 TBI (Ten-Bit Interface)

Figure 30-78 shows the ten-bit interface (TBI) intended to be used between PHY and the UCC Ethernet Controller MAC to implement a standard SERDES interface for optical-fiber devices in 1000BASE-SX/LX applications. Figure 30-78 also shows the basic components of the TBI including the signals required to make a UEC module connection with a PHY. PMA_RX_CLK0 and PMA_RX_CLK1 are differential 62.5 MHz receive clocks.



Note: Signal names are according to 802.3 and ANSI standards (total: 24 ports).

Figure 30-78. TBI MAC-PHY Interface

Table 30-89 provides a list of the TBI signals.

Table 30-89. TBI Signals

Signal	I/O	Size	Function	Reference Clock	Timing
TCG[0:9]	O	10	Transmit data, driving symbol each clock	TX_CLK	max–2 n min–1 n
RCG[0:9]	I	10	Receive data, driving symbol each clock	PMA_RX_CLK	max–2 n min–1 n
TX_CLK	O	1	Transmit clock (125 MHz)	—	—
COM_DET	I	1	Comma detect	PMA_RX_CLK	max–2 n min–1 n
PMA_RX_CLK[0]	I	1	Receive clock 0—The 62.5-MHz recover receive byte clock. Used to latch odd numbered bytes of receive data.	—	—
PMA_RX_CLK[1]	I	1	62.5-MHz recover receive byte clock. This clock is 180° out-of-phase with PMA_RX_CLK<0>, and is used to latch even numbered bytes of receive data.	—	—

30.11.5 Reduced Gigabit Media Independent Interface (RGMII)

The RGMII is intended to be an alternative to the IEEE802.3u MII, the IEEE802.3z GMII, and the TBI. The principle objective is to reduce the number of pins required to interconnect the MAC and PHY from a maximum of 26 pins (GMII) to 13 pins (GTX_CLK125 included) in a cost effective and technology independent manner. In order to accomplish this objective, the data paths and all associated control signals will be reduced, control signals will be multiplexed together, and both edges of the clock will be used.

Figure 30-79 shows the basic components of the RGMII including the signals required to make UCC Ethernet Controller module connection with a PHY.

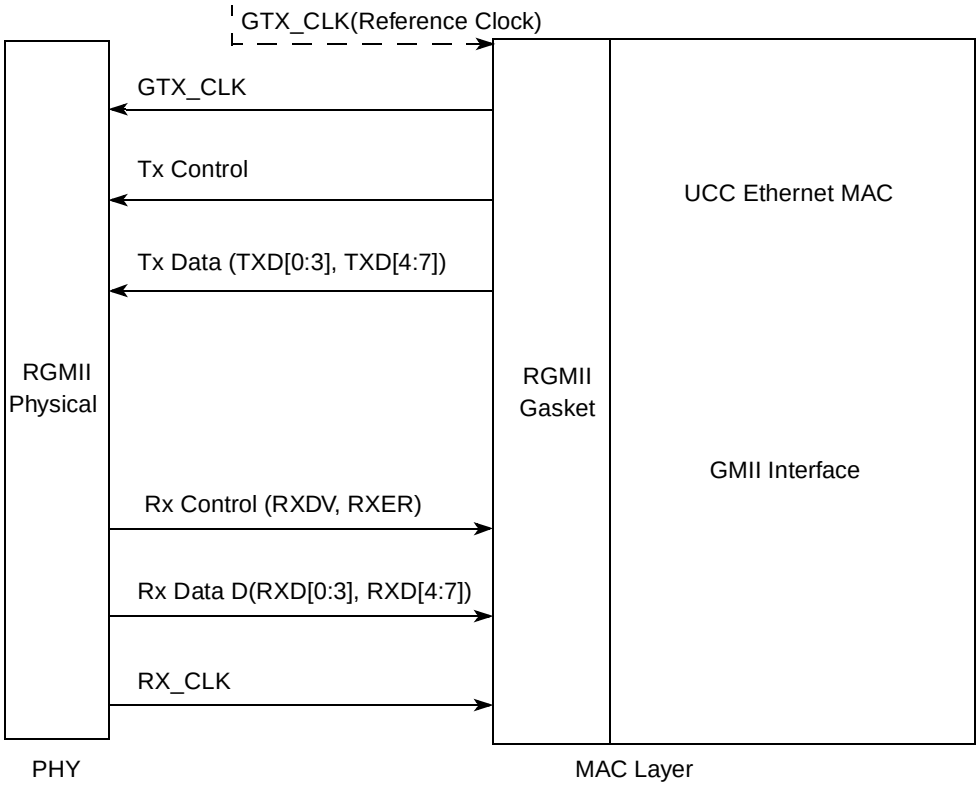


Figure 30-79. RGMII MAC-PHY Interface

Table 30-90 provides a list of the RGMII signals.

Table 30-90. RGMII Signals

IEEE Name	I/O	Size	Function	Reference Clock	Timing
TXC	I	1	Transmit reference clock will be 125 MHz	—	—
TD[0:3]	O	4	TXD[0:3] on clock posedge TXD[4:7] on clock negedge	TXC	max–2 n min–1 n
TX_CTL	O	1	TX_EN on clock posedge TX_ER on clock negedge	TXC	max–2 n min–1 n
RXC	I	1	Continuous receive reference clock will be 125 MHz	—	

Table 30-90. RGMII Signals (continued)

IEEE Name	I/O	Size	Function	Reference Clock	Timing
RD[0:3]	I	4	RXD[0:3] on clock posedge RXD[4:7] on clock negedge	RXC	max–2 n min–1 n
RX_CTL	O	1	RX_DV on clock posedge RX_ER on clock negedge	RXC	max–2 n min–1 n
MDIO	I/O	1	Management data input/output, used to transfer control signals between the PHY layer and the manager entity.	Management Clock	—
MDC	I	1	Management data clock, the MDIO signal clock reference (25 MHz clock).	—	—

30.11.6 Reduced Ten Bit Interface (RTBI)

An RTBI interface has 15 signals (GTX_CLK125 included), as defined by the RGMII specification Version 1.2a 9/22/00, and is intended to be an alternative to the IEEE 802.3u MII, the IEEE 802.3z GMII and the TBI standard for connecting to an Ethernet PHY.

Figure 30-80 shows the basic components of the RGMII including the signals required to make UCC Ethernet Controller module connection with a PHY.

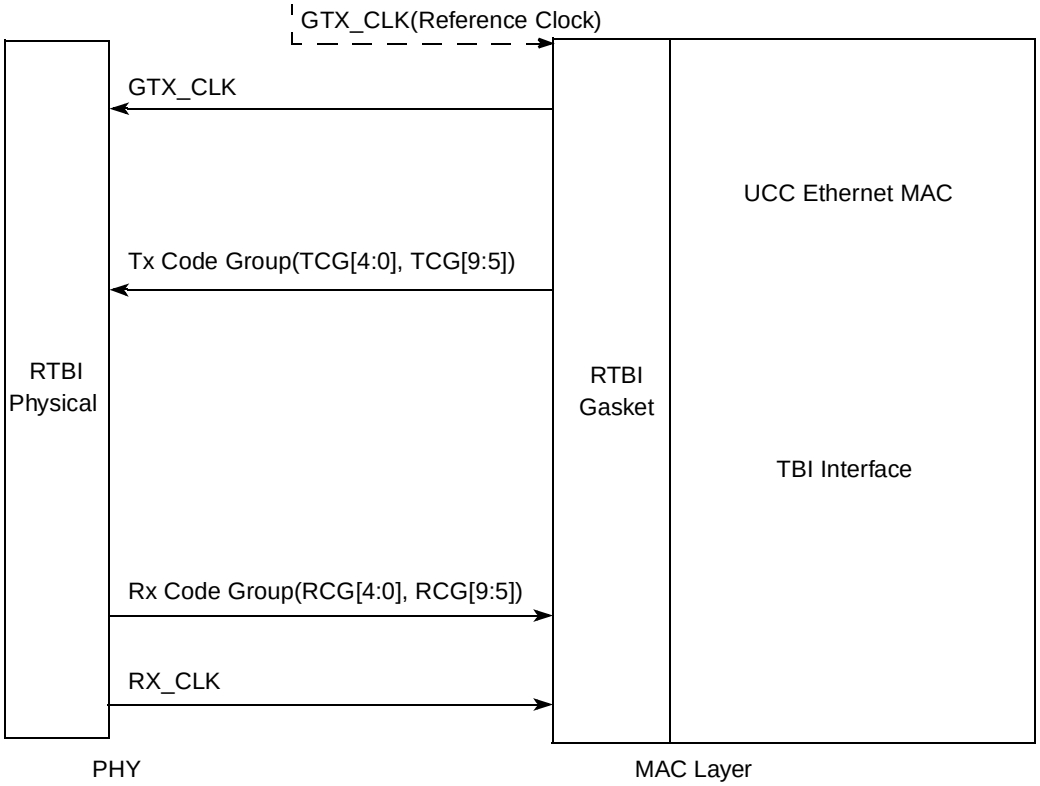

Figure 30-80. RTBI MAC-PHY Interface

Table 30-91 provides a list of the RGMII signals.

Table 30-91. RTBI Signals

IEEE Name	I/O	Size	Function	Reference Clock	Timing
TXC	I	1	Transmit reference clock will be 125 MHz	—	—
TCG[4:0]	O	4	TCG[4:0] on clock posedge TCG[9:5] on clock negedge	TXC	max–2 n min–1 n
RXC	I	1	Continuous receive reference clock will be 125 MHz	—	
RCG[4:0]	I	4	RXD[4:0] on clock posedge RXD[9:5] on clock negedge	RXC	max–2 n min–1 n

30.11.7 Ten-Bit Interface (TBI)

This section describes the ten-bit interface (TBI) and the TBI MII set of registers

30.11.7.1 TBI Transmit Process

The UEC's TBI Implements the Transmit portion of the Physical Coding Sublayer as found in Clause 36 of IEEE 802.3z. In SERDES mode, packets conveyed across the GMII are encapsulated and encoded into 10-bit symbols and output to the SERDES. In GMII mode, the GMII signals are passed through to the attached GMII PHY.

30.11.7.1.1 Packet Encapsulation

If TX_EN is de-asserted the UEC outputs an idle stream. If TX_EN asserts, a Start_of_Packet symbol is output. This symbol replaces the first byte of the preamble field. All other bytes of the packet pass through an 8B10B encoding module. After the last byte of the FCS field is signaled via the GMII, the MAC de-asserts TX_EN. The UEC then outputs an End_of_Packet symbol. Then, depending on the position of the End_of_Packet symbols (being in either an odd or even position) the UEC outputs one or two Carrier_Extend symbols. Following the last Carrier_Extend symbol, the UEC resumes sending idle codes. If, during a packet, the UEC wishes to mark a byte invalid, TX_ER is asserted. The UEC, upon detection of TX_ER, substitutes the data symbol for an Error_Propagation symbol.

30.11.7.1.2 8B10B Encoding

Every eight-bit data octet has two (not necessarily different) ten-bit symbols associated with it. Depending on the running disparity (the cumulative difference of ones and zeroes) the UEC module chooses the appropriate symbol.

Special encapsulation symbols are called ordered_sets. Ordered_sets are comprised of one to four ten-bit symbols. Ordered_sets can be found in Clause 36 of the IEEE 802.3z specification.

30.11.7.1.3 Preamble Shortening

Because the idle ordered_set comprises two symbols and begins on an even symbols boundary, packets can only begin on an even boundary. However, the GMII has no such restriction and may signal TX_EN

on an odd boundary. If this happens, the UEC delays the Start_of_Packet symbol, effectively ignoring the first byte of preamble; thus, a seven octet preamble becomes six octets on the Ten-Bit Interface.

30.11.7.2 TBI Receive Process

The UEC's TBI Implements the Receive portion of the Physical Coding Sublayer as found in Clause 36 of IEEE 802.3z. The Receive portion includes the Synchronization state machine. In SERDES mode, the UEC first attempts to acquire synchronization on the link by examining received symbols. Once synchronization is acquired, received packets are decoded and sent across the Receive GMII interface. In GMII mode, the GMII signals are passed through to the MAC.

30.11.7.2.1 Synchronization

The UEC examines received symbols looking for the seven bit 'comma' string embedded in some special symbols. Both the idle ordered_set and the Configuration ordered_set contain a symbol which has the comma. Once a certain number of codes with comma are detected, the TSEEC is considered to have acquired synchronization.

30.11.7.2.2 Auto-Negotiation for 1000BASE-X

Once synchronization is acquired, ordered_sets are decoded. If Configuration ordered_sets are received, the UEC decodes the two octet data field and the sixteen-bit Configuration data is stored and used to Auto-Negotiate with the link partner. in the Receive Configuration Register (RXCR[15:0]) an internal register used to receive all the link partners informations and used to compare to local ability during negotiation. Not visible to user.If, during Auto-Negotiation an invalid symbol is detected, Auto-Negotiation re-starts. After Auto-Negotiation is completed the TBI MII Status Register SR[AN done] in set. In this mode, packets may be received from the link partner.

30.11.7.3 TBI MII Set Register Descriptions

This section describes the TBI MII registers. All of the TBI registers are 16 bits wide. The TBI registers are accessed at the offset of the TBI physical address. The UEC's TBI physical address is stored in the UTBIPA register. Writing to the TBI registers is performed in a way similar to writing to an external PHY; by using the MII management interface. By using UTBIPA in place of the PHY address, in the MIIMADD[PHY Address] field, and setting the MIIMADD[Register Address] to the appropriate address offset that corresponds to the register that one wants to read or write (see Table), the user can read (set MIIMCOM[read cycle]) or write (writing to MIIMCON[PHY control]) to the TBI block.

Table 30-92. TBI MII Register Set

Offset Address	Name	Access	Size	Section/Page
TEN-BIT INTERFACE (TBI) REGISTERS				
0x00	Control (CR)	R/W[1]	16 bits	30.11.7.4/30-142
0x01	Status (SR)	R, LH, LL	16 bits	30.11.7.5/30-143
0x02–0x03	Reserved	R	2 bytes	—

Table 30-92. TBI MII Register Set (continued)

Offset Address	Name	Access	Size	Section/Page
0x04	AN advertisement (ANA)	RW, R	16 bits	30.11.7.5/30-143
0x05	AN link partner base page ability (ANLPBPA)	R	16 bits	30.11.7.7/30-146

Reset	0001_0001_0100_0000															
Offset	0x00															

Figure 30-81. Control Register Definition

Table 30-93 describes the fields of the CR register.

Table 30-93. CR Field Descriptions

Bits	Name	Description
0	PHY Reset	PHY reset. This bit is cleared by default. This bit is self-clearing. 0 Normal operation. 1 The control and status registers are returned to their default value. This in turn may change the internal state of the TBI and its link partner.
1	—	Reserved
2	Speed[0]	Speed selection. This bit defaults to a cleared state and should always be cleared, which corresponds to 1000 Mbps speed. Setting this field controls the speed at which the TBI operates. The following table provides the appropriate encoding. Its default is bit[2]='0';bit[9]='1'
3	AN Enable	Auto-negotiation enable. This bit is set by default. 0 The values programmed in bits 2, 7 and 9 determine the operating condition of the link. 1 Auto-negotiation process enabled.
4–5	—	Reserved

Table 30-93. CR Field Descriptions (continued)

Bits	Name	Description
6	Reset AN	Reset auto-negotiation. This bit is cleared by default and is self-clearing. 0 Normal operation. 1 The auto-negotiation process restarts. This action is only available if auto-negotiation is enabled.
7	Full Duplex	Duplex mode. This bit is set by default. 0 Half-duplex operation. 1 Full-duplex operation.
8	—	Reserved, should be cleared.
9	Speed[1]	Speed selection. This bit defaults to a set state and should always be set, which corresponds to 1000 Mbps speed. **Maximum Operating Speed / Bit 2 / Bit 9** Reserved / 0 / 0 Reserved / 1 / 0 1000 Mbps / 0 / 1 Reserved / 1 / 1
10–15	—	Reserved

30.11.7.5 Status Register (SR)

Figure 30-82 describes the definition for the SR register.

	0						6	7	8	9	10	11	12	13	14	15

Table 30-94 describes the fields of the SR register.

Table 30-94. SR Descriptions

Bits	Name	Description
0–6	—	Reserved, should be cleared.
7	Extend Status	This bit indicates that PHY status information is also contained in the Extended Status Register. Returns 1 on read. This bit is read-only.
8	—	Reserved, should be cleared.

Table 30-94. SR Descriptions (continued)

Bits	Name	Description
9	No Pre	MF preamble suppression enable. This bit indicates whether or not the PHY is capable of handling MII management frames without the 32-bit preamble field. Returns 1, indicating support for suppressed preamble MII management frames. This bit is read-only.
10	AN Done	Auto-negotiation complete. This bit is read-only and is cleared by default. 0 Either the auto-negotiation process is underway or the auto-negotiation function is disabled. 1 The auto-negotiation process has completed.
11	Remote Fault	Remote fault. This bit is read-only and is cleared by default. Each read of the status register clears this bit. 0 Normal operation. 1 A remote fault condition was detected. This bit latches high in order for software to detect the condition.
12	AN Ability	Auto-negotiation ability. While read as set, this bit indicates that the PHY has the ability to perform auto-negotiation. While read as cleared, this bit indicates the PHY lacks the ability to perform auto-negotiation. Returns 1 on read. This bit is read-only.
13	Link Status	Link status. This bit is read-only and is cleared by default. 0 A valid link is not established. This bit latches low allowing for software polling to detect a failure condition. 1 A valid link is established.
14	—	Reserved, should be cleared.
15	Extend Ability	Extended capability. This bit indicates that the PHY contains the extended set of registers (those beyond control and status). Returns 1 on read. This bit is read-only.

30.11.7.6 AN Advertisement Register (ANA)

Figure 30-83 describes the definition for the ANA register.

	0	1	2 3	4		6	7 8	9	10	11				15

Table 30-99 describes the fields of the ANNPT register.

Table 30-99. ANNPT Field Descriptions

Bits	Name	Description
0	Next Page	Next page indication. [Reference MII bit 7.15 in IEEE 802.3, 2000 Edition Clause 28.2.4] 0 Last page. 1 Additional next pages to follow.
1	Ack	Write 0, ignore on read. [Reference MII bit 7.14] This bit is read-only.
2	Msg Page	Message page. [Reference MII bit 7.13] 0 Unformatted page. 1 Message page.
3	Ack2	Acknowledge 2. Used by the next page function to indicate that the device has the ability to comply with the message. [Reference MII bit 7.12] 0 The local device cannot comply with message. 1 The local device complies with message.
4	Toggle	Toggle. Used to ensure synchronization with the link partner during next page exchange. This bit always takes the opposite value of the toggle bit of the previously-exchanged link code word. The initial value in the first next page transmitted is the inverse of bit 11 in the base link code word. [Reference MII bit 7.11] This bit is read-only. 0 Toggle bit of the previously-exchanged link code word was set. 1 Toggle bit of the previously-exchanged link code word was clear.
5–15	Message / Un-formatted Code Field	Message pages are formatted pages that carry a pre-defined message code, which is enumerated in IEEE 802.3u/Annex 28C. Unformatted code fields take on an arbitrary value. [Reference MII field 7.10:0]

30.11.7.10 AN Link Partner Ability Next Page Register (ANLPANP)

Figure 30-88. Extended Status Register Definition

Table 30-101 describes the fields of the EXST register.

Table 30-101. EXST Field Descriptions

Bits	Name	Description
0	1000X Full	1000X full-duplex capability. Returns 1 on read. This bit is read-only. 0 PHY cannot operation in 1000BASE-X full-duplex mode. 1 PHY can operate in 1000BASE-X full-duplex mode.
1	1000X Half	1000X half-duplex capability. Returns 0 on read. This bit is read-only. 0 PHY cannot operation in 1000BASE-X half-duplex mode. 1 PHY can operate in 1000BASE-X half-duplex mode.
2	1000T Full	1000T full-duplex capability. Returns 1 on read. This bit is read-only. 0 PHY cannot operation in 1000BASE-T full-duplex mode. 1 PHY can operate in 1000BASE-T full-duplex mode.
3	1000T Half	1000T half-duplex capability. Returns 0 on read. This bit is read-only. 0 PHY cannot operation in 1000BASE-T half-duplex mode. 1 PHY can operate in 1000BASE-T half-duplex mode.
4–15	—	Reserved

30.11.7.12 Jitter Diagnostics Register (JD)

Annex 36A in IEEE 802.3z describes several jitter test patterns. These can be configured to be sent by writing the jitter diagnostics register. See the register description for more information. In may be wise to auto-negotiate and advertise a remote fault signaling of offline prior to beginning the test patterns. Figure 30-89 describes the definition for the JD register.

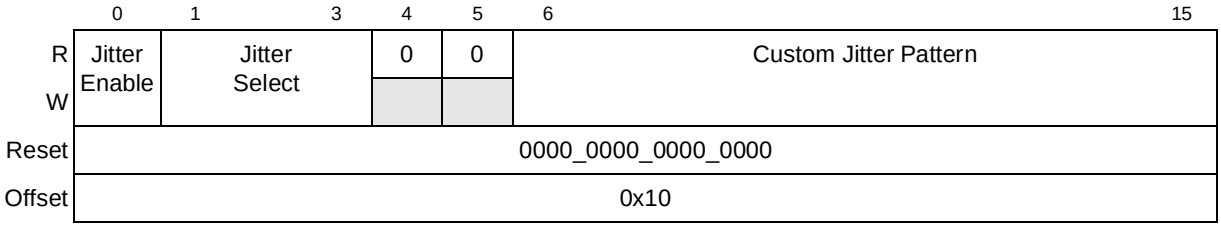

Figure 30-89. Jitter Diagnostics Register Definition

Table 30-102 describes the fields of the JD register.

Table 30-102. JD Field Description

Bits	Name	Description
0	Jitter Enable	Jitter enable. This bit is cleared by default. 0 Normal transmit operation. 1 Enable the TBI to transmit the jitter test patterns defined in IEEE 802.3z 36A.
1–3	Jitter Select	Selects the jitter pattern to be transmitted in diagnostics mode. Encoding of this field is shown in the following table. Default is 00.

Jitter Pattern Select	bit[1]	bit[2]	bit[3]
User defined uses custom jitter pattern, bits 6–15	0	0	0
High frequency (+/- D21.5) 1010101010101010101010101010101010101010…	0	0	1
Mixed frequency (+/- K28.5) 1111101011000001010011111010110000010100…	0	1	0
Low frequency 1111100000111110000011111000001111100000…	0	1	1
Complex pattern (10’h17c,10’h0c9,10’h0e5,10’h2a3, 10’h17c,...)	1	0	0
Square Wave (- K28.7) 0011111000001111100000111110000011111000…	1	0	1
Reserved	1	1	0
Reserved	1	1	1

Bits	Name	Description
4–5	—	Reserved
6–15	Custom Jitter Pattern	Used in conjunction with jitter (pattern) select and jitter (diagnostic) enable; set this field to the desired custom pattern which is continuously transmitted. Its default is 0x000.

30.11.7.13 TBI Control Register (TBICON)

Figure 30-90 describes the definition for the TBICON register.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

W																
Reset	0000_0000_0000_0000															
Offset	0x11															

Figure 30-90. TBI Control Register Definition

Table 30-103 describes the fields of the TBICON register.

Table 30-103. TBICON Field Description

Bits	Name	Description
0	Soft_Reset	Soft reset. This bit is cleared by default. 0 Normal operation. 1 Resets the functional modules in theTBI.
1	—	Reserved. (Ignore on read)
2	Disable Rx Dis	Disable receive disparity. This bit is cleared by default. 0 Normal operation. 1 Disables the running disparity calculation and checking in the receive direction.
3	Disable Tx Dis	Disable transmit disparity. This bit is cleared by default. 0 Normal operation. 1 Disables the running disparity calculation and checking in the transmit direction.
4–6	—	Reserved
7	AN Sense	Auto-negotiation sense enable. This bit is cleared by default. 0 IEEE 802.3z Clause 37 behavior is desired, which results in the link not completing. 1 Allow the auto-negotiation function to sense either a Gigabit MAC in auto-negotiation bypass mode or an older Gigabit MAC without auto-negotiation capability. If sensed, auto-negotiation complete becomes true; however, the page received is low, indicating no page was exchanged. Management can then act accordingly.
8–9	—	Reserved
10	Clock Select	Clock select. This bit is cleared by default. 0 Allow the TBI to accept dual split-phase 62.5 MHz receive clocks. 1 Configure the TBI to accept a 125 MHz receive clock from the SERDES/PHY. The 125 MHz clock must be physically connected to ‘PMA receive clock 0’.
11	MII Mode	This bit describes the configuration mode of the TBI. The user reads a 1 while the TBI is configured in GMII/MII mode (connected to a GMII/MII PHY) and a 0 while configured in TBI mode (connected to a 1000BASE-X SERDES). Its value is the inverse of ECNTRL[TBIM]. 0 TBI mode. 1 GMII mode.
12–13	—	Reserved
14–15	—	Reserved

30.12 Multiuser RAM usage

The multiuser RAM consumption is dependent on several parameters. This section presents the way the multiuser RAM usage can be calculated according to the setting of these parameters. The calculation is presented by an example, which can be easily modified to reflect the actual parameters values. In addition, each parameter is accompanied by its allowed range, for the user convenience.

Table 30-104 presents the various parameters that impact the multiuser RAM usage.

Table 30-104. Tx and Rx Multiuser RAM Parameters

Parameter	Description	Range	Example for Gigabit Ethernet	Example for Fast Ethernet
TxT	Number of Tx threads	1, 2, 4, 6	4	1
TxQ	Number of Tx queues	1 to 8	4	4
RxT	Number of Rx threads	1, 2, 4, 6	4	1
TxVF	Tx Virtual FIFO size [bytes]	408 or more	2048	272
RxQ	Number of Rx queues	1 to 8	4	4
RxP	Number of PCDs	0 to 3	2	0
RxL	Rx lookup table size [bytes]	32, 48, 80	80	0
RxVF	Rx Virtual FIFO size [bytes]	272 or more	3072	272

Table 30-105 presents the Tx Parameter RAM memory consumption, according to the setting of the appropriate parameters.

Table 30-105. Tx Parameter RAM Usage

Data structure	Size [bytes]	Multiply by	Gigabit Ethernet example		Fast Ethernet example	
			Value	Total	Value	Total
Global Tx Parameter RAM	128	1	1	128	1	128
Thread Data Structure	136	TxT	4	416	1	136
Queues Data Structure	64	TxQ	4	256	4	256
Scheduler Data Structure	112	1	1	112	1	112
Ethernet Statistics counters	48	1	1	48	1	48
Thread Parameter RAM	64	TxT	4	256	1	64
Total Tx Parameter RAM usage:				1216		744

Table 30-106 presents the Tx Parameter RAM memory consumption, according to the setting of the appropriate parameters.

Table 30-106. Rx Parameter RAM Usage

Data structure	Size [bytes]	Multiply by	Gigabit Ethernet example		Fast Ethernet example	
			Value	Total	Value	Total
Global Rx Parameter RAM	256	1	1	256	1	256
ThreadQ	40	RxT	4	160	1	40
Ethernet Statistics counters	92	1	1	92	1	92

Table 30-106. Rx Parameter RAM Usage (continued)

Data structure	Size [bytes]	Multiply by	Gigabit Ethernet example		Fast Ethernet example	
			Value	Total	Value	Total
Interrupt Coalescing Counters	8	RxQ	4	32	4	32
Rx BD Queues	16	RxQ	4	64	4	64
Temporary storage for prefetched BDs	32	RxQ	4	128	4	128
Address Filtering Data Structure	8	RxP	2	16	0	0
Lookup table	1	RxL	80	80	0	0
Thread parameter RAM	128	RxT	4	512	1	128
Total Rx Parameter RAM usage:				1340		740

Table 30-107 presents the overall usage of multiuser RAM, by a single Tx port and a single Rx port of Ethernet, according to a specific setting of the various parameters, as presented in Table 30-104.

Table 30-107. Ethernet Multiuser RAM Usage

Data structure	Gigabit Ethernet example size [bytes]	Fast Ethernet example size [bytes]
Tx Parameter RAM usage	1216	744
Tx Virtual FIFO	2048	272
Rx Parameter RAM usage	1340	740
Rx Virtual FIFO	3072	272
Total Multiuser RAM usage:	7676	2028

In order to evaluate the actual multiuser RAM consumption, the user should instantiate the actual values of the various parameters presented in Table 30-104 and follow the example in the tables, Table 30-105 to Table 30-107.

30.13 Header Parsing

The following sections describe in detail the headers being parsed in the Extended Parsing Mode enabled by setting REMODER[EXP]=1. The header extract field in the PCD is programmed to extract one (or more) fields in frame headers as described in the sections below. The shaded fields may be extracted to form a LookupKey.

Note that if the parser is not able to identify one of the frames described in this appendix, the frame is received in Queue number 0, and RxBD[PE] bit is set to mark a parsing error.

30.13.1 Ethernet/802.3 without VLAN

The Next Header PID in an Ethernet or 802.3 frame is located in variable offset from the start of frame, depending on the type of frame. The parser locates the PID for the following types of frames.

30.13.1.1 Ethernet no LLC Header Format

Table 30-108. Ethernet no LLC Header Format

MAC Destination Address	
MAC Destination Address (cont)	MAC Source Address
MAC Source Address (cont)	
EType (>1536)	

30.13.1.2 802.3, 802.2 SAP LLC

This mode is not supported by the parser, and is assumed not to appear in the network. Frames with size > 1536 and NOT SNAP header are forwarded to CPU in queue 0.

Table 30-109. 802.3, 802.2 SAP LLC

30.14 Exact Match Tags Memory Organization

This appendix describes the memory organization of the Exact Match Tags in Hash Mode Table Lookup. See Section 30.6.2.6, “Hash Table Lookup PCDs,” for details on this mode.

The following data structure is used in the Table Lookup set for eight byte LookupKey:

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0	Exact Match Tag 0															
Offset + 2																
Offset + 4																
Offset + 6																
Offset + 8	Exact Match Tag 1															
Offset + A																
Offset + C																
Offset + E																
Offset + 10	Exact Match Tag 2															
Offset + 12																
Offset + 14																
Offset + 16																
Offset + 18	Exact Match Tag 3															
Offset + 1A																
Offset + 1C																
Offset + 1E																

Figure 30-91. Eight Bytes Exact Match Tag (4 Sets)

Table 30-117. Eight Bytes Exact Match Tag Entry Field Descriptions

Offset	Bit	Name	Description
0x0-0x1F		ExactMatchTag0-3	Each exact match tag is compared the Lookup Key. If a a match occurs, the Termination Action Descriptor (TAD) is used to determine the action taken on this frame. LookupKey shorter than Eight bytes are aligned to the MSBytes. Unused LSBytes are padded with zeroes.

The following data structure is used in the Table Lookup set for sixteen byte LookupKey:

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0	Exact Match Tag 0 (eight MSBytes)															
Offset + 2

Offset + 32																
Offset + 34																
Offset + 36																
Offset + 38	Exact Match Tag 3 (eight LSBytes)															
Offset + 3A																
Offset + 3C																
Offset + 3E																

Figure 30-92. Sixteen Bytes Exact Match Tag (4 Sets)

Table 30-118. Sixteen Bytes Exact Match Tag Entry Field Descriptions

Offset	Bit	Name	Description
0x0-0x1F		ExactMatchTag0-3 eight MSBytes	Most Significant Bytes: Each exact match tag is compared the Lookup Key. If a a match occurs, the Termination Action Descriptor (TAD) is used to determine the action taken on this frame. LookupKey shorter than sixteen bytes are aligned to the MSBytes. Unused LSBytes are padded with zeroes.
0x20-0x3F		ExactMatchTag0-3 eight LSBytes	Least Significant Bytes: Each exact match tag is compared the Lookup Key. If a a match occurs, the Termination Action Descriptor (TAD) is used to determine the action taken on this frame. LookupKey shorter than sixteen bytes are aligned to the MSBytes. Unused LSBytes are padded with zeroes.

30.15 Traffic Shaper Programming Considerations

Definitions

- AvBR - Average Bit Rate. The average bit rate desired at the port during transmission
- MBL - Maximum Burst Length. The longest 1Gbps burst the receiver can absorb. Burst is a group of packets transmitted with minimal IPG (12 Bytes) Between them.
- TSRUnit - The duration of a single TSR count in seconds
- ByteTime - The length it takes to transmit one Byte in data rate equals AvBR in seconds
- TSRByteTime - The length it takes to transmit one Byte in data rate equals AvBR in TSR count units
- MBLInterval = Integer Part of (MBL * TSRByteTime)
- NorTSRByteTime, FracSiz- Normalized TSRByteTime and Fraction Size respectively. Defined by the following two conditions:

1. 256 > NorTSRByteTime > 127

2. NorTSRByteTime = ROUND(TSRByteTime*2^FracSiz)

Example - System requirements are given by the following data rate and burst length:

AvBR = 0.75e9; TSRUnit=1e-6;

MBL = 128KB

Calculation (Programming model parameters are bolded):

ByteTime = 8/AvBR = 1.06667e-8

TSRByteTime = ByteTime/TSRUnit = 0.0106667

NorTSRByteTime = Round[TSRByteTime*2^14]=ROUND[174.763]=175=0xAF

FracSize=14=0xE

The resulting data rate is:

1/((175/2^14)*1e-6/8)=0.74898Gbps, in the range of 1/256 accuracy.

MBLInterval = ROUND[MBL* TSRByteTime] = ROUND[128KB * 0.0106667] = 1365=0x555

Example 2

AvBR = 64kbps; TSRUnit=1e-6;

MBL = 128KB

Calculation (Programming model parameters are bolded):

ByteTime = 8/AvBR = 0.000125

TSRByteTime = ByteTime/TSRUnit = 125

NorTSRByteTime = Round[TSRByteTime*2^1]=250=0xFA

FracSize=1

The resulting data rate is:

1/((250/2^1)*1e-6/8)=64000.

MBLInterval = ROUND[MBL* TSRByteTime] = ROUND[128KB * 125] = 1.6e007 = 0xF42400

30.15.1 Programming Examples for the Traffic Shaping Characteristics of the Ethernet Tx Distributor

Table 30-119 and Table 30-120 show the user-defined variables.

Table 30-119. Rate Limiting

Name	Type	Units	Description
ExtraBW	8 bits	Set/Clear	Set to indicate a queue's bandwidth will not be taken from the bandwidth allocated
TxASAP	8 bits	Set/Clear	Set to indicate that the queue's frames are never rate limited
NorTSRByteTime	16-bit unsigned integer	Fractions/byte	Time to elapse per byte sent
FracSize	8-bit unsigned integer, 0-32		$\log_2$ (fractions per clock)
MBLInterval	32-bit unsigned integer	Clocks	Longest frame burst allowed

Table 30-120. Weighted Fair Queueing

Name	Type	Units	Description
StrictPriorityQ	8 bits	Set/Clear	Set to indicate that a queue will not be subject to weighted fair queuing
WeightFactor	8 8-bit unsigned integers		Relative priority of queue (higher value = lower priority)

30.15.1.1 Example: Pass all frames without any Rate Limiting or WFQ

Pass all frames immediately, without either Rate Limiting or Weighted Fair Queuing, prioritized only by queue number.

- Set **StrictPriorityQ** = 0xFF to disable Weighted Fair Queuing on all queues
- Set **TxASAP** = 0xFF to not rate limit any queues
- Set **ExtraBW** = 0xFF to not count bandwidth on any queues
- All other values are ignored

30.15.1.2 Example: Rate Limit all Queues without Maximum Burst Length

Frames are prioritized by queue number, but the total average bandwidth is limited.

Assuming:

Desired average bandwidth: AvBW = 0.75 Gigabits/second

Clock frequency: Freq = 1MHz

Average time elapsed per byte: bytetime = 8 * Freq/AvBW = 0.0106667 cycles/byte

$$\frac{8bits}{byte} \times \frac{1{,}000{,}000cycles}{\sec ond} \times \frac{1\sec ond}{750{,}000{,}000bits} = 0.010\overline{6}\frac{cycles}{byte}$$

The value for NorTSRByteTime should be roughly between 256 and 128 such that:

$$bytetime \times 2^{Fracsize} \approx NorTSRByteTime$$
$$0.010\overline{6} \times 2^{14} \approx 175$$

The value for NorTSRByteTime should be roughly between 256 and 128 such that:

$$bytetime \times 2^{Fracsize} \approx NorTSRByteTime$$
$$0.010\overline{6} \times 2^{14} \approx 175$$

FracSize = 14

NorTSRByteTime = 175

- Set **StrictPriorityQ** = 0xFF to disable Weighted Fair Queuing on all queues
- Set **TxASAP** = 0x00 to rate limit all queues
- Set **ExtraBW** = 0x00 to count bandwidth on all queues
- Set **FracSize** = 0x0E (from above)
- Set **NorTSRByteTime** = 0xAF (from above)
- Set **MBLInterval** - 0xFFFFFFFF to disable burst limiting

30.15.1.3 Example: Rate Limit All Queues with Maximum Burst Length

Frames are prioritized by queue number, but the total average bandwidth is limited.

Assuming:

Desired average bandwidth: AvBW = 0.5 Gigabits/second

Clock frequency: Freq = 10MHz

Maximum burst length: MBL = 128kB

Average time elapsed per byte:

$$bytetime = \frac{8bits}{byte} \times Freq \div AvBW$$

$$\frac{8bits}{byte} \times \frac{10{,}000{,}000cycles}{\sec ond} \times \frac{1\sec ond}{500{,}000{,}000bits} = 0.16\frac{cycles}{byte}$$

The value for NorTSRByteTime should be roughly between 256 and 128 such that:

$$bytetime \times 2^{Fracsize} \approx NorTSRByteTime$$

$$\frac{0.16cycles}{byte} \times \frac{2^{10}\ fractions}{cycle} \approx \frac{164\,fractions}{byte}$$

FracSize = 10
NorTSRByteTime = 164

$$MBLInterval \approx MBL \times bytetime$$

$$131{,}072bytes \times 0.16\frac{cycles}{byte} \approx 20{,}972cycles$$

MBLInterval = 20,972

- Set **StrictPriorityQ** = 0xFF to disable Weighted Fair Queuing on all queues
- Set **TxASAP** = 0x00 to rate limit all queues
- Set **ExtraBW** = 0x00 to count bandwidth on all queues
- Set **FracSize** = 0x0A (from above)
- Set **NorTSRByteTime** = 0xA4 (from above)
- Set **MBLInterval** - 0x000051EC (from above)

30.15.1.4 Example: Disable Rate Limiting Per Queue

Queues 0 and 1 are high priority Voice-over-IP traffic that must always be sent immediately, but the total average bandwidth including all queues is limited.

Assuming:

Desired average bandwidth: AvBW - 0.5 Gigabits/second

Clock frequency: Freq = 10MHz

Maximum burst length: MBL = 128kB

- Set **StrictPriorityQ** = 0xFF to disable Weighted Fair Queuing on all queues
- Set **TxASAP** = 0xC0 to rate limit queues 2-7 and send immediately on queues 0 and 1
- Set **ExtraBW** = 0x00 to count bandwidth on all queues
- Set **FracSize** = 0x0A (from Section 30.15.1.3, “Example: Rate Limit All Queues with Maximum Burst Length”)
- Set **NorTSRByteTime** = 0xA4 (from Section 30.15.1.3, “Example: Rate Limit All Queues with Maximum Burst Length”)
- Set **MBLInterval** - 0x000051EC (from Section 30.15.1.3, “Example: Rate Limit All Queues with Maximum Burst Length”)

30.15.1.5 Example: Extra Bandwidth per Queue

Queues 0-5 and 7 belong to a customer that is promised 0.5 Gbps. Queue 6 traffic is for internal ISP use and does not count against the customer’s total bandwidth.

Assuming:

Desired average bandwidth: AvBW - 0.5 Gigabits/second, not including queue 6

Clock frequency: Freq = 10MHz

Maximum burst length: MBL = 128kB

- Set **StrictPriorityQ** = 0xFF to disable Weighted Fair Queuing on all queues
- Set **TxASAP** = 0x02 to rate limit all queues
- Set **ExtraBW** = 0x02 to count bandwidth on all queues except queue 6

- Set **FracSize** = 0x0A (from Section 30.15.1.3, “Example: Rate Limit All Queues with Maximum Burst Length”)
- Set **NorTSRByteTime** = 0xA4 (from Section 30.15.1.3, “Example: Rate Limit All Queues with Maximum Burst Length”)
- Set **MBLInterval** - 0x000051EC (from Section 30.15.1.3, “Example: Rate Limit All Queues with Maximum Burst Length”)

30.15.1.6 Example: Weighted Fair Queuing without Rate Limiting

Rate limiting is disabled. Weighted Fair Queuing is enabled on all queues.

Table 30-121. Example Traffic Rate Assumptions

Queue Number	0	1	2	3	4	5	6	7
Traffic Rate	50%	20%	5%	5%	5%	5%	5%	5%

Each WeightFactor should be inversely proportional to the traffic rate desired per queue, with any common factors divided from each value.

$$WeightStatus \propto \frac{1}{trafficrate}$$

Table 30-122. Example Traffic Rate Weight Status

Queue Number	0	1	2	3	4	5	6	7
Traffic Rate	50%	20%	5%	5%	5%	5%	5%	5%
WeightStatus	2	5	20	20	20	20	20	20

- Set **StrictPriorityQ** = 0x00 to enable Weighted Fair Queuing on all queues
- Set **TxASAP** = 0xFF to not rate limit any queues
- Set **ExtraBW** = 0xFF to not count bandwidth on any queues
- Set **WeightStatus** as shown above in Table 30-122

30.15.1.7 Example: Mixed Weighted Fair Queuing and Strict Priority

Rate Limiting is disabled. Queue 4 has the highest priority, then queue 7, then the remaining divided evenly.

Table 30-123. Example Traffic Rate WeightStatus

Queue Number	0	1	2	3	4	5	6	7
Traffic Rate	1/5		1/5	1/5		1/5	1/5	
WeightStatus	1		1	1		1	1	

- Set **StrictPriorityQ** = 0x49 to enable Weighted Fair Queuing on queues 0, 2, 3, 5, and 6
- Set **TxASAP** = 0xFF to not rate limit any queues
- Set **ExtraBW** = 0xFF to not count bandwidth on any queues
- Set **WeightStatus** as shown above in Table 30-123

30.15.1.8 Example: All Concepts

Queues 0-5 belong to a customer who requires 0.8Gbps. Queue 0 is for Voice-over-IP traffic and must be sent at highest priority. Queues 1-5 are weighted as in Table 30-124. Queues 6 and 7 are used internally by the ISP, and do not count against the customer's usage. The maximum burst for the customer is 1 Megabyte.

Table 30-124. Example Traffic Rate WeightStatus

Queue Number	0	1	2	3	4	5	6	7
Traffic Rate	1/2	1/10	1/10	1/10	1/10	1/10		
WeightStatus	1	5	5	5	5	5		

Assuming:

Desired average bandwidth: AvBW = 0.8 Gigabits/second

Clock frequency: Freq = 1MHz

Maximum burst length: MBL = 128MB

Average time elapsed per byte:

$$bytetime = \frac{8bits}{byte} \times Freq \div AvBW$$

$$\frac{8bits}{byte} \times \frac{1{,}000{,}000cycles}{\sec ond} \times \frac{1\sec ond}{800{,}000{,}000bits} = 0.01\frac{cycles}{byte}$$

The value for NorTSRByteTime should be roughly between 256 and 128 such that:

$$bytetime \times 2^{Fracsize} \approx NorTSRByteTime$$

$$\frac{0.01cycles}{byte} \times \frac{2^{14}\ fractions}{cycle} \approx \frac{164\ fractions}{byte}$$

FracSize = 14
NorTSRByteTime = 164

$$MBLInterval \approx MBL \times bytetime$$

$$134{,}217{,}728bytes \times 0.01\frac{cycles}{byte} \approx 1{,}342{,}177cycles$$

MBLInterval = 1,342,177

- Set **StrictPriorityQ** = 0xFF to disable Weighted Fair Queuing on all queues
- Set **TxASAP** = 0x00 to rate limit all queues
- Set **ExtraBW** = 0x00 to count bandwidth on all queues
- Set **FracSize** = 0x0E (from above equations)
- Set **NorTSRByteTime** = 0xA4 (from above equations)
- Set **MBLInterval** - 0x00147AE1 (from above equations)

Chapter 31
QUICC Engine IEEE1588 Assist

31.1 Introduction

The objective of the IEEE1588 standard is to specify a protocol to synchronize independent clocks running on separate nodes of a distributed measurement and control system to a high degree of accuracy and precision. The clocks communicate with each other over a communication network. The protocol generates a master-slave relationship among the clocks in the system. Within a given subnet of a network, there will be a single master clock. All clocks ultimately derive their time from a clock known as the grandmaster clock.

The protocol will enable heterogeneous systems that include clocks of various inherent precision, resolution, and stability to synchronize. The protocol will support systemwide synchronization accuracy in the sub-microsecond range with minimal network and local clock computing resources.

Measurement and control applications are increasingly using distributed system technologies such as network communication, local computing, and distributed objects. Many of these applications will be enhanced by having an accurate systemwide sense of time achieved by having local clocks in each sensor, actuator, or other system device. Existing protocols for clock synchronization are not optimal for these applications. For example, Network Time Protocol (NTP) targets large distributed computing systems with millisecond synchronization requirements.

Although IEEE1588 allows software-only implementations, hardware-assisted implementations deliver more precise clock synchronization.

The simplest IEEE1588 implementations include ordinary applications at the top of the network protocol stack and generate timestamps at the application level. Typically, this implementation incurs the largest protocol stack delay fluctuation, thus yielding the least accuracy as the largest amount of error is introduced into the timestamp.

Hardware-assisted methods achieve the greatest accuracy due to the fact that they generate timestamps as close to the wire as possible, at the physical layer. Network-protocol-delay fluctuations for these implementations typically range from nanoseconds to sub-microseconds.

In the QUICC Engine block, the IEEE1588 implementation is a Hardware-assisted method. The hardware assist includes a time stamp unit to recognize PTP frames and transfer relevant timestamps, and a real time clock with high resolution.

31.2 QUICC Engine IEEE1588 Block Diagram

Figure 31-1 shows the TSU (Time Stamp Unit) and the IEEE1588 RT (Realtime Clock) modules integrated into the QUICC Engine.

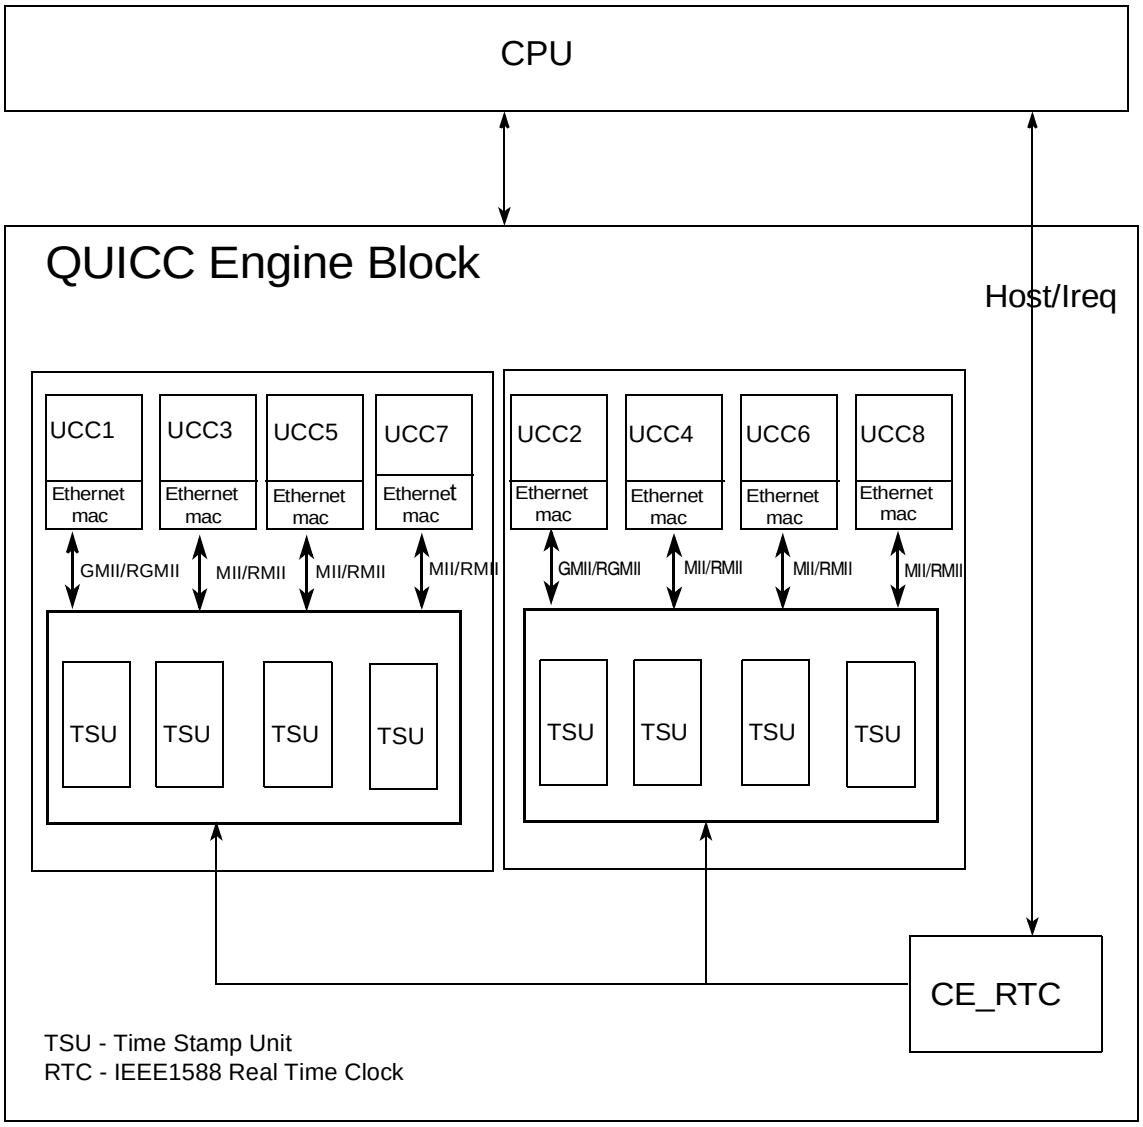

Figure 31-1. QUICC Engine IEEE1588 Block Diagram

31.3 Time Stamp Unit Key Features:

Key Features of the Time Stamp Unit are:

- Supports Ethernet systems
- Support IEEE1588 timestamping on all UCC ports
- Recognition of PTP frames on receive side
  - — Sync type
  - — Delay_req type
  - — Delay_resp type
  - — Follow_Up type
  - — Management type

- Support PTP frame with VLAN tag (single VLAN)
- Supports MII/RMII/GMII/RGMII Physical I/F
- Support Ethernet frame monitoring on full and half duplex modes
- Supports slave and master mode
- Support single- or multi- IEEE1588 masters
- Support out-of-band and in-band modes of operation.
  - in-band (timestamp is attached to each Ethernet frame buffer)
  - out-of-band
- Timestamp capture close to the physical line (symmetric for transmitter and receiver)
- Supports user configured values for PTP header fields.
- Support user configured value for fields offset.
- Support timestamp overrun report for Tx and RX
- Supports interrupt notification due to following:
  - Rx PTP frame detection (only delay_req or sync)
  - Tx PTP frame transmission which was marked by the Software as a PTP frame
  - Rx and Tx Timestamp overrun error

31.4 RTC Key Features (IEEE1588 Real Time Clock)

- Support single IEEE1588 Real Time Clock
- Support timer frequency compensation.
- Support timer offset update.
- Support nanosecond resolution time stamps.
- Support configured source of clock
  - External oscillator
  - Transmitter serial clock up to 125MHz.
  - Half System clock
  - BRG divided clock
- Time stamp capture on two general purpose external triggers through new GPIO connection
  - Maskable interrupts on GPIO timestamp trigger
  - Programmable polarity of external trigger (GPIO) edge
- Two 64-bit alarm (future time) registers for future time comparison
  - Maskable interrupts on alarm
- Three programmable timer output pulse period phase aligned with IEEE1588 timer clock
  - Maskable interrupts associated with each pulse
- Separate maskable timer interrupt event register
- Phase aligned adjustable (divide by N) clock output

31.5 IEEE1588 Implementation Assumptions

The Version 1 PTP standard makes several assumptions about the environment in which it operates. The following assumptions must be met to ensure correct operation of the Version 1 protocol:

- The network must support multicast communication.
- It must be possible to prevent multicast messages from propagating beyond a subnet.
- Each clock implementing the protocol must meet the physical performance requirements, including oscillator frequency and time adjustment range.
- A clock's stated properties, including its stratum and identifier, must accurately describe the clock.

The following assumptions must be met to achieve optimal clock synchronization performance:

- Network delay between master and slave on a subnet must be symmetric.
- A clock may contain asymmetric delays in its timestamp mechanism or protocol path. If these asymmetries are not negligible, they must be correctly accounted for.
- Network delay between master and slave on a subnet must be constant.
- Boundary clocks must be used to synchronize across subnets.
- The timestamps used in PTP are generated as close to the physical layer as practical for a given clock implementation. In cases where the most accurate timestamps can be generated only after a message has actually been transmitted, the actual value is communicated in the Follow_Up message from the master clock.
- The computing power of clocks implementing the protocol must be great enough, and the number of clocks per subnet must be small enough, to meet the standard constraints.
- The inherent stability of a clock s oscillator must be adequate.

31.6 Modes of Operation

- In-band - This mode is determined in the TSMR register. The receiver's timestamps are transferred as part of the data payload. The user sets the PTP bit in the TxBD while sending a PTP frame, and gets a PTP indication in the RxBD when a PTP frame has received.
- Out-of-band - This mode is determined in the TSMR register. All the timestamps are transferred through the host interface, using dedicated registers.The host reads the transmitter's timestamps after last indication in the buffer descriptor, and the receiver's timestamps when a PTP bit is set in the RxBD. The user is responsible for setting the PTP bit in the TxBD. In both receiver and transmitter the user can set an interrupt before accessing the timestamps.
- PTP frame parsing options - All of the relevant parsing values and fields can be configured using TSPDR1-4 registers, retaining high flexibility.
- Loopback - The TSU Rx monitored frame is the Tx frame which being transmitted by the same UCC. In order to work in this mode, the user should set the loopback bit in the UCC GUMR mode register (GUMR[DIAG] = 01).
- Pulse per second - The user can configure the fiper registers (TMR_FIPERn) in order to generate the pulse per second outputs.

- Alarm mode - The user can configure a dedicated register as an alarm value. When the IEEE1588 RTC reaches this value, an interrupt is generated to the core, and a dedicated output trigger signal will be asserted.
- Input trigger - The user can synchronously trigger the IEEE1588 RTC in order to capture a timestamp.
- Source clock select - This mode is configured in the Timer Control Register (TMR_CTRL).The user can connect an external clock to the IEEE1588 RTC. In addition, the RTC can work with the system clock or with the Ethernet physical interface clock.

31.7 Memory Map/Register Definition

All IEEE1588 registers are 32-bits wide, are located on 32-bit address boundaries, and should only be accessed as 32-bit quantities.

All addresses used in this chapter are offsets from RTC Base, PTP1 Base and PTP2 Base. Table 31-1 lists the PTP1 Registers.

Table 31-1. PTP1 Registers

Offset	Name	Address	Size	R/W	Destination
Time Stamp Unit Mode Registers					
0x0	PTP1_TSPDR1	0x4880	32 bit	R/W	internal
0x4	PTP1_TSPDR2	0x4884	32 bit	R/W	internal

31.8 Time Stamp Unit Mode Registers

31.8.1 Time Stamp Unit Parsing Definitions Register 1 (PTPn_TSPDR1)

The Time Stamp Unit Parsing Definition Register (PTPn_TSPDR1) is shown in Figure 31-2.

In order to detect a PTP frame, the TSU should parse several fields in the Ethernet frame. The PTPn_TSPDR1 register is used to determine the values of the Ethernet type field (12th–13th octets) and the IP type(23rd octet). The default values are set to 0x0800 and 0x11.

The user can modify the values for the parsing.

16–23	IPT	IP frame type. UDP frame by default. This field indicates if observed frame is UDP frame(0x11).
24–31	—	Reserved

31.8.2 Time Stamp Unit Parsing Definitions Register 2(PTPn_TSPDR2)

The Time Stamp Unit Parsing Definition Register 2(PTPn_TSPDR2) is shown in Figure 31-3.

In order to detect a PTP frame, the TSU should parse several fields in the Ethernet frame. The PTPn_TSPDR2 register is used to determine the values of the destination port number field (36th-37th octets). For PTP sync and delay_req messages the port number should 0x13f (319). For the rest, 0x140 (320).

The user can modify the values for the parsing.

Bits	Name	Description
0–15	DPNGE	Destination port number of a PTP general messages - Follow_up, Delay_resp and management. (0x140).
16–31	DPNEV	Destination port number of a PTP event messages - Sync and delay_req(0x13f).

31.8.3 Time Stamp Unit Parsing Definitions Register 3 (PTPn_TSPDR3)

The Time Stamp Unit Parsing Definition Register 3 (PTPn_TSPDR3) is shown in Figure 31-4.

In order to detect a PTP frame, the TSU should parse several fields in the Ethernet frame.

The specific type of frame is derived from the control field, 0x0 for sync message, 0x1 for Delay_req message, 0x2 for follow up, 0x3 for delay_resp.

The user can modify the values for the parsing.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Bits	Name	Description
0–7	SYCTL	Control field value represents sync message(0x0).
7–15	DRCTL	Control field value represents Delay_Req message(0x1).
16–23	DRPCTL	Control field value represents delay_resp message(0x2).
24–31	FUCTL	Control field value represents follow_up message(0x3).

31.8.4 Time Stamp Unit Parsing Definitions Register 4 (PTPn_TSPDR4)

The Time Stamp Unit Parsing Definition Register 4 (PTPn_TSPDR4) is shown in Figure 31-5.

In order to detect a PTP frame, the TSU should parse several fields in the Ethernet frame.

The specific type of frame is derived from the control field, 0x4 for management message.

In addition, PTPn_TSPDR4 register provides a configured value to detect a VLAN field. This value can be detected during bytes 12-13 and cause a shifting of 4 bytes for all other parsing offsets. In case of VLAN frame, the user should configure the offsets exactly as for non VLAN frame.

The user can modify the values for the parsing.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

8–15	—	Reserved
16–31	VLAN	VLAN tag (type=0x8100)

31.8.5 Time Stamp Unit Parsing Offset Values (PTPn_TSPOV)

The Time Stamp Unit Parsing Offset Values (PTPn_TSPOV) is shown in Figure 31-6.

In order to detect a PTP frame, the TSU should parse several fields in the Ethernet frame. TSU offset values register (PTPn_TSPOV) is used to determine the offset of each field in the Ethernet frame. The user can change the fields offset in case the structure of the frame has been changed or manipulated.

31.8.6 Time Stamp Unit Mode Register (PTPn_TSMR)

The Time Stamp Unit Mode Register (PTPn_TSMR) is shown in Figure 31-7.

The PTPn_TSMR register is used to determine the modes of operation of the TSU.

The TSU can operate in both in-band or out-of-band methods.

In addition, PTPn_TSMR EN bits enable the TSU operation.

31.8.7 Timer PTP Event Register (PTPn_TMR_PEVENT)/ Timer PTP Mask Register (PTPn_TMR_PEMASK)

The Time Stamp Unit Event Register (PTPn_TMR_PEVENT) and Time Stamp Mask Register are shown in Figure 31-8.

The PTPn_TMR_PEVENT is used as the TSU event register. The PTPn_TMR_PEVENT reports events recognized on the Ethernet channel and generates interrupts. After event recognition, the TSU sets the corresponding PTPn_TMR_PEVENT bit. The PTPn_TMR_PEVENT bits are cleared by writing ones; writing zeros does not affect bit values. All unmasked bits must be cleared before the CPU clears the internal interrupt request.

Interrupts generated by the TSU event register (PTPn_TMR_PEVENT) can be masked in the TSU mask register (PTPn_TMR_PEMASK), which has the same bit format as PTPn_TMR_PEVENT. If a PTPn_TMR_PEMASK bit = 1, the corresponding interrupt in the event register is enabled. If the bit is 0, the interrupt is masked.

31.8.8 Time Stamp Unit Receiver Time High (TMR_UCn_RXTS_H)/Time Stamp Unit Receiver Time Low (TMR_UCn_RXTS_L)/Time Stamp Unit Transmitter Time High (TMR_UCn_TXTS_H)/Time Stamp Unit Transmitter Time Low (TMR_UCn_TXTS_L)

The TMR_UCn_TXTS_L/TMR_UCn_TXTS_H and TMR_UCn_RXTS_L/TMR_UCn_RXTS_H registers are shown in Figure 31-9.

The TMR_UCn_TXTS_L/TMR_UCn_TXTS_H registers are used to capture the time stamp of a recognized PTP frame on the transmitter lines. The TSU (Time Stamp Unit) samples the IEEE1588 RTC (Real Time Clock) 64-bit counter, immediately after SFD (Start Frame Delimiter) indication. The sampled

value becomes valid only after one of the frame events. In this case, the CPU reads the value in order to calculate the synchronizations commands.

TMR_UCn_RXTS_L/TMR_UCn_RXTS_H has the same purpose on the receiver lines.

31.9 IEEE1588 Timer Mode Registers

31.9.1 Timer Control Register (TMR_CTRL)

The Timer Control register defines control fields relevant to the IEEE1588 timer. TMR_CTRL is a register writable by the user to reset, configure, and initialize the QUICC Engine IEEE1588 timer clock. Only one of these registers is active for the entire QUICC Engine. Figure 31-10 describes the definition for the TMR_CTRL register.

2	—	Reserved
3	FS	Fiper start indication 0 fiper countdown start is enabled through timer enable 1 fiper countdown start is enabled through timer enable and alarm indication. Note: Once set, FS will remain at 1 until cleared by software.
4–5	—	Reserved
6–15	TCLK_PERIOD	IEEE1588 timer reference clock period. The timer clock counter will increment by TCLK_PERIOD every time the accumulator register overflows. This clock period must be larger than the clock period of the timer reference clock. For applications where user does not want the clock period to be added, they can program this field to 1 to count the clock ticks. This field defaulted to 1 to count overflow ticks.
16–19	—	Reserved
22	ETEP2	External trigger 1 edge polarity 0 time stamp on the rising edge of the external trigger 1 time stamp on the falling edge of the external trigger
23	ETEP1	External trigger 2 edge polarity 0 time stamp on the rising edge of the external trigger 1 time stamp on the falling edge of the external trigger

Table 31-12. TMR_CTRL Field Descriptions (continued)

Bits	Name	Description
24	COPH	Generated clock output phase. 0 non-inverted divided clock is output 1 inverted divided clock is output
25	CIPH	External oscillator input clock phase. 0 non-inverted frequency tuned timer input clock 1 inverted frequency tuned timer input clock
26	TMSR	Timer soft reset. When enabled, it resets all the timer registers and state machines. 0 normal operation 1 places entire timer in reset except control and config registers
27	DBG	Enable debug mode. When set, it allows write to the read only timer registers.
28	BYP	Bypass drift compensated clock 0 64-bit clock counter is incremented on the accumulator overflow 1 64-bit clock counter is directly driven from the external oscillator, ignoring accumulator overflow
29	TE	IEEE1588 timer enable. If not enabled, all the timer registers and state machines are disabled. 0 timer not enabled 1 timer enabled and resumes normal operation
30–31	CKSEL	IEEE1588 Timer reference clock source select. 00 External high precision timer reference clock 01 system clock 10 transmit clock 11 RTC clock oscillator (NA for QUICC Engine)

31.9.2 Timer Event Register (TMR_TEVENT)/Timer Event Mask Register (TMR_TEMASK)

The IEEE1588 timer implementation requires several interrupt event signals. The QUICC Engine needs to add a new interrupt output line for the timer independent of the existing Tx, Rx and Error interrupts. The IEEE1588 timer interrupt does not require any interrupt coalescing. Software may poll this register at any time to check for pending interrupts. If an event occurs and its corresponding enable bit is set in the event mask register (EMASK), the event also causes a hardware interrupt at the PIC. A bit in the timer event register is cleared by writing a 1 to that bit position.

Figure 31-11shows the TMR_EVENT register.

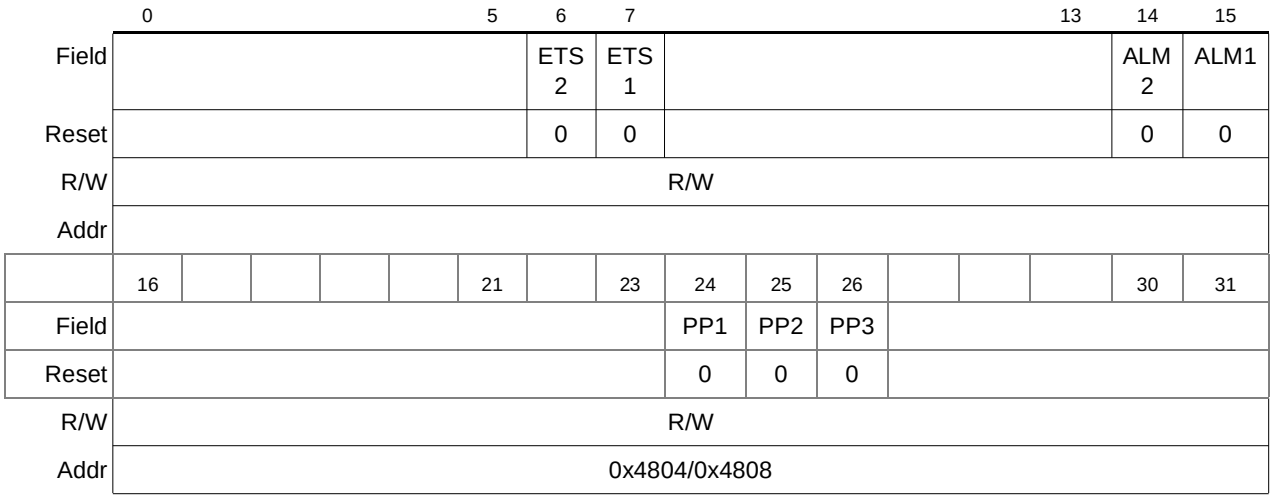

Figure 31-11. Event Register (TMR_TEVENT) / Mask Register (TMR_TEMASK)

Table 31-13 describes the fields.

31.9.3 Timer Counter Register (TMR_CNT_L/TMR_CNT_H)

The TMR_CNT_L/ TMR_CNT_H registers are shown in Figure 31-12.

The timer register (TMR_CNT_L/TMR_CNT_H) represents accurate time in terms clock ticks or in nano-seconds. This is a read/write register. Writes to these registers will override the previous time.

	0															15

Figure 31-12. TMR_CNT_L/TMR_CNT_H Register

Table 31-14 describes the fields.

Table 31-14. TMR_CNT_L/TMR_CNT_H Field Descriptions

Bits	Name	Description
0–31	TMR_CNT	H/L Value of the current time counter. Current time is calculated by adding TMROFF_H/L with the TMR_CNT_H/L counter. This register can be written through the register writes. Writes to the TMR_CNT_L register copies the written value into the shadow TMR_CNT_L register. Writes to the TMR_CNT_H register copies the values written into the shadow TMR_CNT_H register. Contents of the shadow registers are copied into the TMR_CNT_L and TMR_CNT_H registers following a write into the TMR_CNT_H register. Writes to these registers have precedence over the timer increment. The user must write to TMR_CNT_L register first. Reads from the TMR_CNT_L register copies the entire 64-bit clock time of the read enable into the TMR_CNT_H/L shadow registers. Read instruction from the TMR_CNT_H register reads the value stored in the TMR_CNT_H shadow register. The user must read the TMR_CNT_L register first to get correct 64-bit TMR_CNT_H/L counter values.

31.9.4 Timer Addend register (TMR_ADD)

The Timer drift compensation Addend register (TMR_ADD) is used to hold the timer frequency compensation value (FreqCompensationValue). The nominal frequency of the clock counter is determined by the FreqDivRatio and the clock frequency (FreqClock). This register is programmed with 2^{32}/FreqDivRatio. Frequency division ratio (FreqDivRatio) is the ratio between the frequency of the oscillator (TimerOsc) and the desired clock frequency (NominalFreq). FreqDivRatio is a design constant chosen to be greater than 1.0001. The ADDEND value is added to the 32-bit accumulator register at every rising edge of the oscillator clock (TimerOsc). The clock counter is incremented at every carry pulse of the accumulator. Only one of this register is required for the entire group of eTSEC. Figure 31-13 shows the TMR_ADD register.

Table 31-15 describes the TMR_ADD fields.

Table 31-15. TMR_ADD Field Descriptions

Bits	Name	Description
0–31	ADDEND	Timer drift compensation addend register value. It is programmed with a value of 2^32/FreqDivRatio. For example: FreqOsc = 50 MHz FreqClock = 40 MHz FreqDivRatio = 1.25 RTCAD = ceil(2^32/1.25) = 0xCCCC_CCCD

31.9.5 Timer Accumulator register (TMR_ACC)

The Timer Accumulator register accumulates the value of the addend register into it. An overflow pulse of the accumulator is used to increment the timer clock by TMR_CTRL[TCLK_PERIOD]. This register is read only.

Figure 31-14 shows the TMR_ACC register.

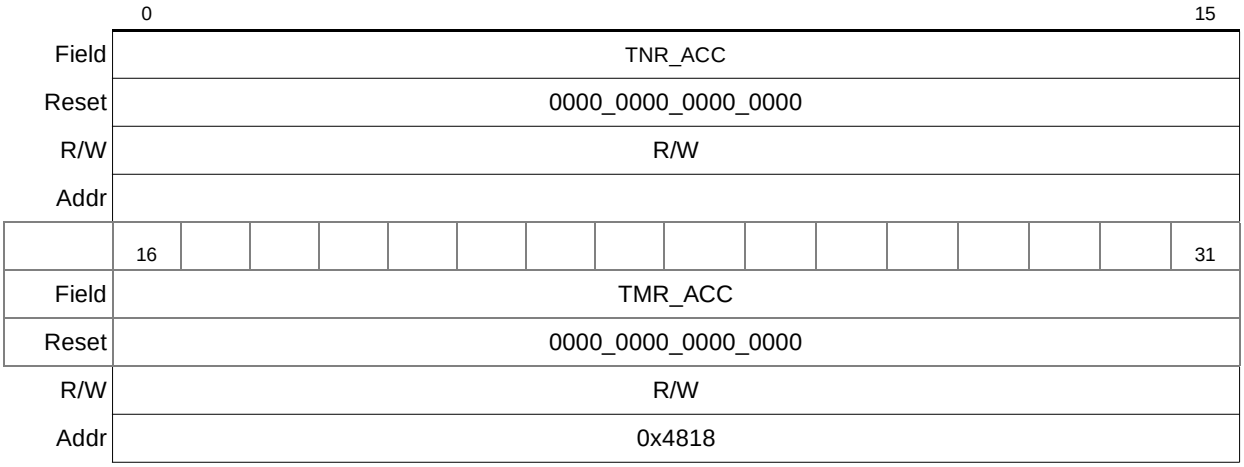

Figure 31-14. TMR_ACC Register

Table 31-16 describes the TMR_ACC fields.

Table 31-16. TMR_ACC Field Descriptions

Bits	Name	Description
0–31	TMR_ACC	32-bit timer accumulator register

31.9.6 Timer Prescale Register (TMR_PRSC)

The Timer prescale register is used to adjust output clock frequency. Figure 31-15 shows the TMR_PRSC register.

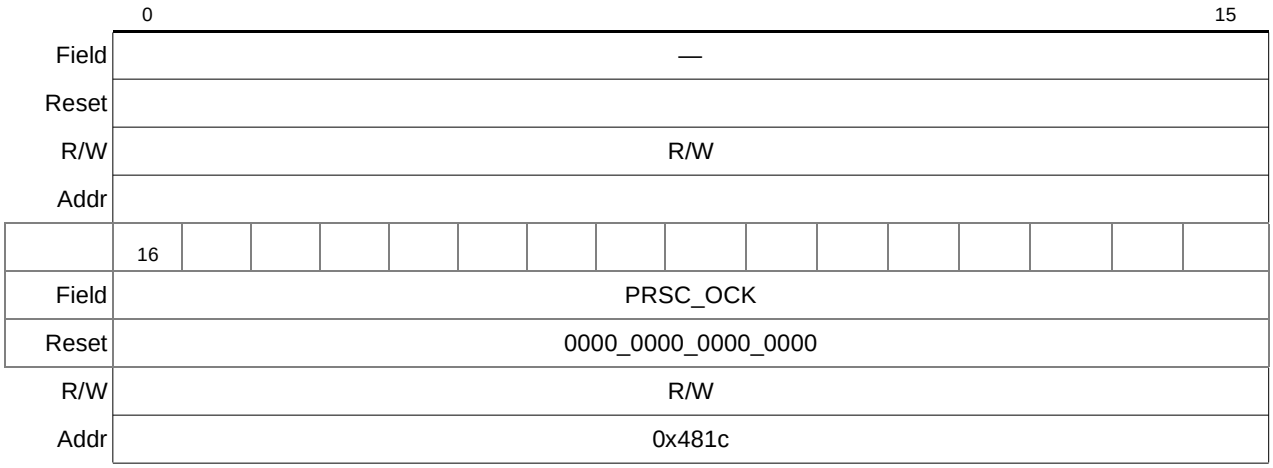

Figure 31-15. Prescale Register (TMR_PRSC)

Table 31-17 describes the TMR_PRSC fields.

Table 31-17. Prescale Register (TMR_PRSC)

Bits	Name	Description
0-15	—	RESERVED
16-31	PRSC_OCK	Output clock division/prescale factor. Output clock is generated by dividing the timer input clock by this number. Setting the prescaler value to “1” will generate an output clock in the same frequency as the system timer register.

31.9.7 Timer Offset Register (TMROFF_L/TMROFF_H)

The TMROFF register is shown in Figure 31-16.

The timer offset register is used to provide current time by adding its value to the clock counter.

Table 31-18 describes the fields.

Table 31-18. TMROFF_L/TMROFF_H Field Descriptions

Bits	Name	Description
0–31	TMROFF	The TMROFF, which is determined by the S/W calculations, updates the real time counter with its value. The update is executed when the H/W detects write transaction to the offset high register.

31.9.8 Alarm Time Register (TMR_ALARMn_L/TMR_ALARMn_H)

The TMR_ALARMn_L/TMR_ALARMn_H register is shown in Figure 31-17.

The Alarm Time comparator register (TMR_ALARMn_H/L) holds alarm time for comparison with the current time counter.

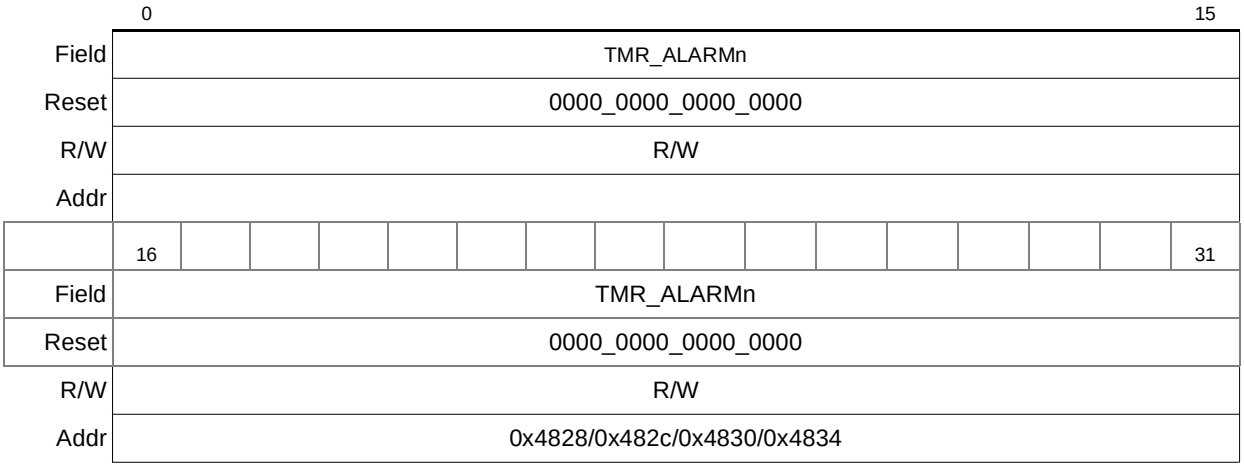

Figure 31-17. TMR_ALARMn Register Structure

Table 31-19 describes the TMR_ALARMn fields.

Table 31-19. TMR_ALARMn Bit Setting

Bits	Name	Description
0–31	TMR_ALARMn	The IEEE1588 RTC interrupt is generated when the value of the RTC counter (TMR_CNT_L/TMR_CNT_H) is greater than or equal to TMR_ALARMn[TMR_ALARM]. This value should be configured before enabling the timer. In FS mode, the alarm trigger is used as an indication to the fiper to start down counting. Only alarm 1 supports this mode. In FS mode, the alarm polarity bit should be configured to 0 (rising edge).

31.9.9 Timer Fixed Interval Period Register (TMR_FIPERn)

The Timer Fixed Interval Period pulse generator register is used to generate periodic pulses. This register is reset with 0xFFFF_FFFF to prevent any false pulse upon initialization. The down count register loads the value programmed in the fixed period interval (FIPER). The FIPER register must be programmed before the timer is enabled. In FS mode the FIPER should be programmed before the alarm value which triggers the start of the down counting. At every tick of the FreqOsc, the counter decrements by the value of TMR_CTRL[TCLK_PERIOD]. It generates a pulse when the down counter value reaches zero. It reloads the down counter in the cycle following a pulse. The user is responsible for loading these registers with desired period intervals. There are three FIPER registers.

Figure 31-18 shows the TMR_FIPER register.

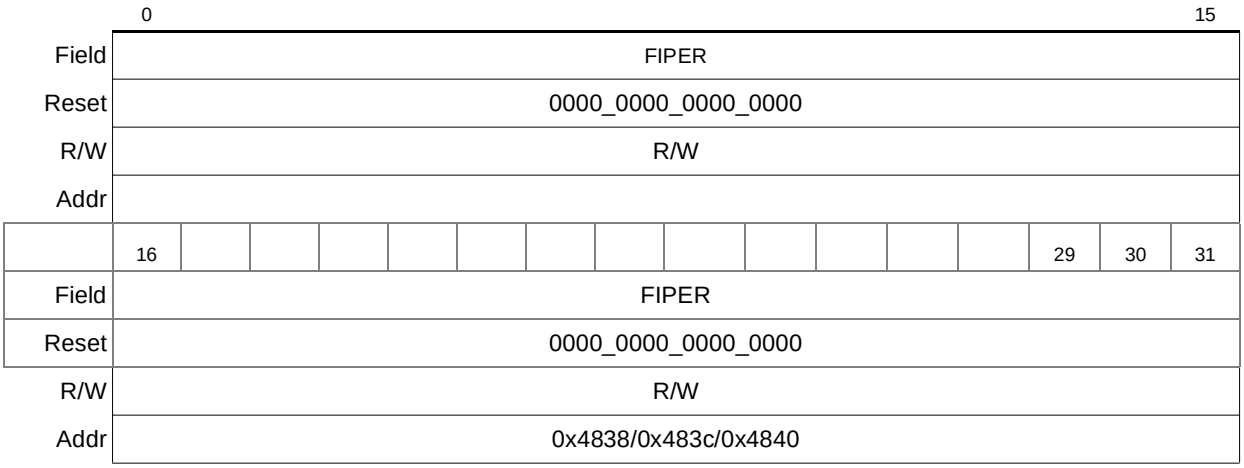

Figure 31-18. TMR_FIPERn Register

Table 31-20 describes the TMR_FIPERn fields.

Table 31-20. TMR_FIPERn Field Descriptions

Bits	Name	Description
0–31	FIPER	Fixed interval pulse period register. Note: In case the PPS signals should be phased aligned to the prescale output clock, the alarm value should be configured to **3 clock periods less** than the targeted value. In order to keep tracking the prescale output clock, each time before enabling the fiper, the user must reset the fiper by writing a new value to the register. The ratio between the prescale register value and the fiper value should be devisable by the clk period. **FIPER_VALUE = (prescale_value * tclk_per * N) - tclk_per** For example: prescale = 9 clock period = 10 fiper can get the following values: 80, 170, 260 .....

31.9.10 External Trigger Stamp Register (TMR_ETTSn_L/TMR_ETTSn_H)

The general purpose External Trigger Stamp register (TMR_ETTSn_H/L) holds the time at the programmable edge of the external trigger. There will be only two of these registers.

Figure 31-19 shows the TMR_ETTSn_H/L register.

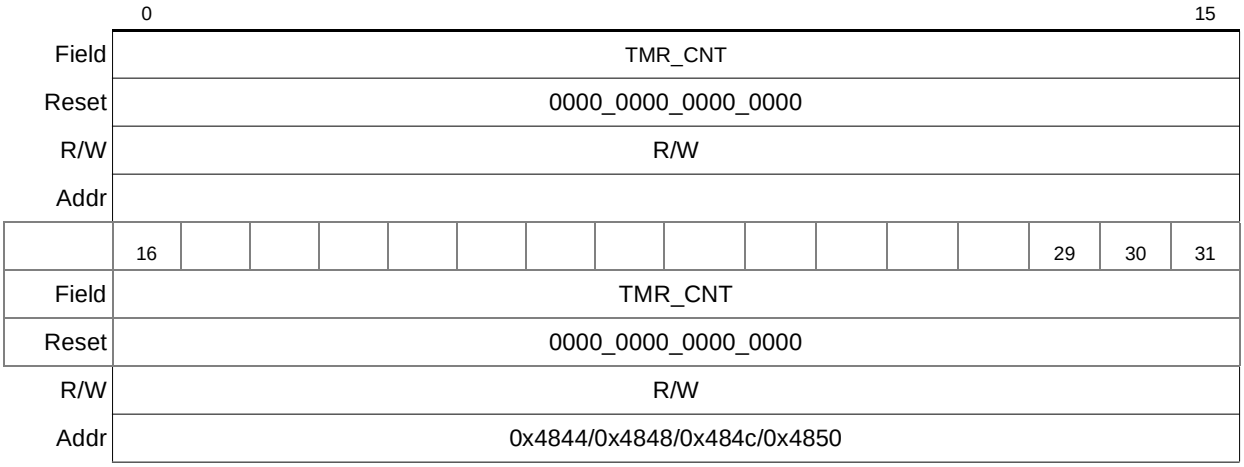

Figure 31-19. TMR_ETTSn_L/TMR_ETTSn_H Register

Table 31-21 describes the fields.

Table 31-21. TMR_ETTSn_L/TMR_ETTSn_H Field Descriptions

Bits	Name	Description
0–31	ETTS	Time stamp field at the programmable edge of the external trigger.

31.10 Time Stamp Unit

The TSU (Time Stamp Unit) logic implementation supports two different ways of operation. In-band and out-of-band methods. As mentioned in the preceding sections, the hardware assumption is that this is running on an Ethernet system.

In case of in-band mode, the timestamp reporting to the software is done in-band with the frame data. The user is responsible to set a dedicated PTP bit in Tx buffer descriptor when a PTP frame is transmitted. On the receiver side, the Ethernet mac sets the PTP bit in the Rx buffer descriptor following the TSU PTP recognition.

In case of out-of-band method, the reporting is done using dedicated registers per interface. The SW will read the transmitter’s timestamps after the “last” indication and the receiver’s timestamps if PTP bit was set in the RxBD. If there is sufficient time to guarantee that SW will be able to read time stamp register between PTP frames, then the out-of-band method is sufficient.

The TSU logic supports MII/RMII/GMII/RGMII interfaces.

In order to snapshot a precise time stamp, one of the hardware roles is to observe the MII ports, detect an SFD, and then capture the exact time.

Figure 31-20 shows the timestamp point of a PTP frame.

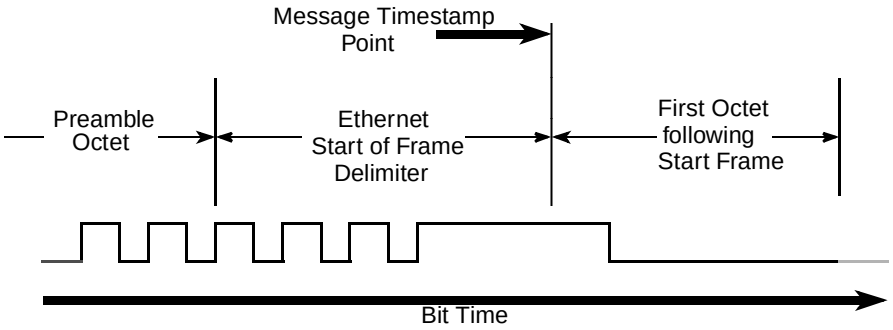

Figure 31-20. Message Timestamp Point

In addition, the TSU detects a PTP (Precise time protocol) frame of specific type and generates an indication to the CPU and to the MAC.

In the Version 1 specification, there are five types of PTP frame:

- Sync message
- Follow_Up message
- Delay_req message
- Delay_resp message
- Management message

Those five messages are divided into two groups:

- PTP event
- PTP general

The PTP event group consists of Sync and Delay_req messages. These messages should be timestamped and can cause an interrupt generation. The PTP general group consists of the rest of the frames, those frames transfer timestamps and determine general system parameters.

In order to detect a PTP frame, Table 31-22 summarizes the parsing fields and values:

Table 31-22. Parsing Values

Layer name	octet number	field name	value
IP	12-13	IP datagram	0x0800
UDP	23	Protocol: UDP	0x11
PTP event	36-37	Destination port number	0x13F
PTP general	36-37	Destination port number	0x140
Sync	74	control	0x0
Delay_req	74	control	0x1
Follow_up	74	control	0x2

Table 31-22. Parsing Values (continued)

Layer name	octet number	field name	value
Delay_resp	74	control	0x3
Management	74	control	0x4

In addition, the frames' lengths are determined in the following, Table 31-23.

Table 31-23. PTP frames length

message	frame length (octets)
Sync	171
Delay_req	171
Follow_up	97
Delay_resp	105
Management	105 + parameter_length/2

31.10.1 PTP Event Interrupts

In the case of out-of-band mode, the user can use the TSU (Time stamp unit) interrupts as a trigger to read the timestamps registers.The SW should clear the event register and read the timestamp before the next PTP frame detection. If a new PTP frame arrives and the relevant bit in the event register still set, an overrun indication will be asserted.

31.11 IEEE1588 Timer (Real Time Clock)

In a distributed control system containing multiple clocks, individual clocks tend to drift apart due to instabilities inherent in source oscillators and environmental conditions such as temperature, air circulation, mechanical stresses, vibration, aging etc. Hence, some kind of correction is necessary to synchronize individual clocks to maintain the notion of global time, which is accurate to some requisite clock resolution.

In order to achieve this goal, the IEEE1588 RTC supports the following:

- The nominal increment is chosen according to the nominal oscillator frequency.
- The drift is compensated by slightly increasing or decreasing the increment

Figure 31-21 illustrates the block diagram of the IEEE1588 RTC.

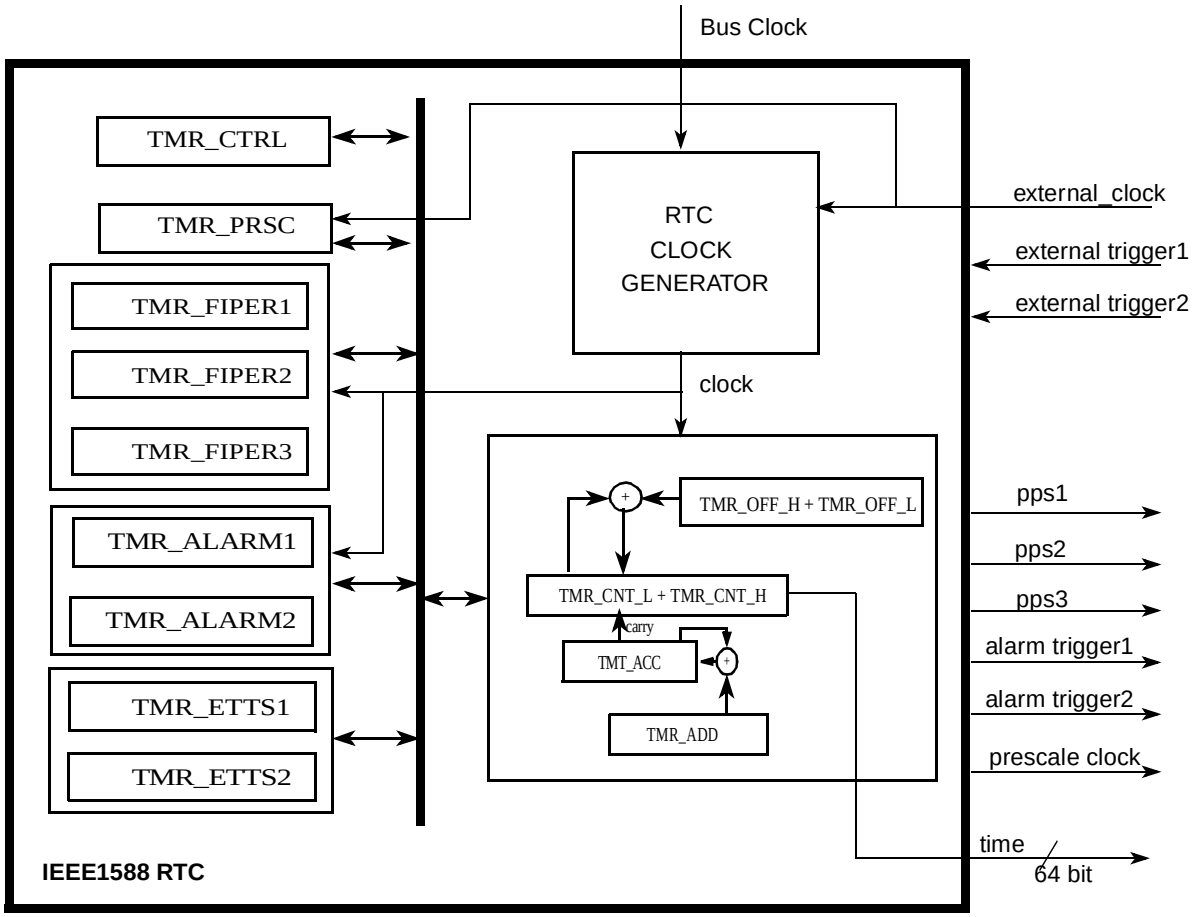

Figure 31-21. IEEE1588 RTC Block Diagram

All of the constituents of the frequency compensated clock operate at the frequency of input oscillator or sys_clk. The frequency compensation value contained in addend register is added to accumulator once every 1/sys_clk or 1/external_osc. The clock counter is incremented whenever the accumulator asserts an overflow pulse signal. Therefore the nominal frequency at which the clock counter is incremented is the frequency that the user had determined by updating the addend with a frequency compensation value.

The update of the frequency compensation value can be done every cycle of clock synchronization by sync and delay messages.

Table 31-24 shows examples of possible IEEE1588 RTC parameters. The results have been calculated according to the this equation:

frequency_compensation_value = 2^32/frequency_ratio.

Table 31-24. Values Example

Frequency sys_clk	Frequency Counter	Frequency Ratio	Frequency Compensation value
200MHz	150MHz	1.33	0xC07B3013
200MHz	190MHz	1.05	0xF3CF3CF3
200MHz	70MHz	2.86	0x5982AF70

In addition to the frequency compensation, the RTC enables updating of the offset of the timer counter. The offset value is derived from the timestamps transferred on PTP frames.

The S/W uses the offset register in order to add the correction value. The timer counter adds the value of the offset register if a write transaction to the relevant address is detected. The values in the offset register and in the addend register are represented in 2's complement.

The standard demands sub-micro resolution. The IEEE1588 RTC contains a 64-bit timer register and a 32-bit addend register. If the system clock reaches 200 MHz, by configuring the addend to 0xFFFF_FFFF, the counter will tick every 5 ns.

IEEE1588 RTC supports the following features:

- Two alarm output triggers, asserted if the timer value reaches the alarm register
- Three pulses per second output signals, generated by configuring the fiper registers
- Two input triggers in order to capture timestamps in a dedicated register
- Divided output clock, by configuring the prescale register

31.11.1 RTC Clock Sources

The IEEE1588 RTC enables three sources of input clock: the system clock, an external oscillator and Ethernet physical interface clock.

All the clocks should meet the performances and requirements of the standard.

The system clock could be up to 250MHz and might be sourced from the Baud Rate Generator in order to allow the user to generate a divided clock for the IEEE1588 timer.

31.11.2 Prescale Output Clock and Pulse per second Phase Alignment

In order to generate pulse per second signals that are phase aligned to the output prescale clock, as shown in Figure 31-22, the user should do the following:

1. Use the start fiper mode (TMR_CTRL[FS]) in the control register

2. The ratio between the prescale clock divider value and the fiper value should be devisable by the clock period, see Section 31.9.9, "Timer Fixed Interval Period Register (TMR_FIPERn)."

3. Configure the ALARM_1 register to a value which is less by 3 clock periods of the required FIPER enabling time.

4. Note that each time when writing a new value to the ALARM_1 when TMR_CTRL[FS] is set, the user should also write to the FIPERx register with the required PPS interval value.

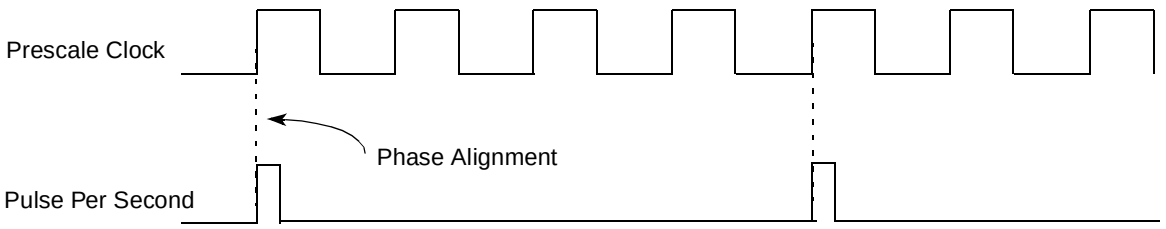

Figure 31-22. PPS and Prescale Clock Phase Alignment

31.11.3 External Signals Description

Table 31-25 describes the IEEE1588 Real Time Clock external signals:

Table 31-25. 1588 RTC External Signals

Signal Name	I/O	Description	Parallel Port Signal Pins	
			Primary Option	Secondary Option
PTP_PPS1	Output	Pulse per second output signal generated by configuring the FIPER1 register. Each time the FIPER1 value is expired one RTC clock period pulse is generated	CE_PC21	CE_PE20
PTP_PPS2	Output	Pulse per second output signal generated by configuring the FIPER2 register. Each time the FIPER2 value is expired one RTC clock period pulse is generated	CE_PC17	CE_PD19
PTP_PPS3	Output	Pulse per second output signal generated by configuring the FIPER3 register. Each time the FIPER3 value is expired one RTC clock period pulse is generated	CE_PC5	CE_PF29
PTP_ALARM1	Output	Alarm output triggers, set if the timer value reaches the alarm1 register	CE_PC0	CE_PE14
PTP_ALARM2	Output	Alarm output triggers, set if the timer value reaches the alarm2 register	CE_PC23	CE_PE6
PTP_REF_CLK	Output	Divided output clock, by configuring the TMR_PRSC register	CE_PC12	CE_PE26
PTP_CLK	Input	External oscillator Real Time Clock	CE_PC30	
PTP_EXT_TRIG1	Input	Input trigger to capture timestamps. The captured timestamp is stored in TMR_ETSS1L/TMR_ETSS1H	CE_PB4	CE_PC14
PTP_EXT_TRIG2	Input	Input trigger to capture timestamps. The captured timestamp is stored in TMR_ETSS2L/TMR_ETSS2H	CE_PC11	CE_PC27

31.12 PTP Frame Reception

The following describes the main actions performed for each operation mode when a PTP frame was received.

31.12.1 In-Band Mode

To use in-band mode, configure the UCC as follows:

- UCC in Ethernet Mode (GUMR[MODE])
- Set IEEE1588 mode in UPSMR[PTPE]
- Set MACFG[SRP] - Soft Rx Preamble mode

In order to work in in-band mode, the PTP should set the in-band mode in the TSMR register.

In this mode the received timestamps are transferred as part of the data payload.

The receive TSU (time stamp unit) is monitoring the received Ethernet frame on the physical line. When SFD is detected, the IEEE1588 Rx TSU locks the Real Time Value of the IEEE1588 clock and then notifies the Ethernet MAC that SFD is detected and the timestamp associated with it is ready.

The Ethernet MAC stores the 64-bit timestamp in memory as part of the frame, at the first eight bytes of each Ethernet frame, regardless of PTP indication.

When the Rx TSU parse unit is detecting a PTP frame, it will notify the Ethernet MAC that a PTP frame has been detected and the Ethernet controller will set RxBD[RPTP]

When the Software detects that a PTP frame has arrived, by getting an interrupt or by polling the RxBD[RPTP], it will search for the PTP frame type and read the timestamp located in the first eight bytes of each frame in memory if needed.

In case the PTP frame is marked with CRC, Overrun, or Non-octet receive errors, the interrupt in the TMR_PEVENT will not be set and the software should drop this frame regardless of the indication in the RxBD[RPTP].

31.12.2 Out-of-Band Mode

In order to work in out-of-band mode the UCC should be configured as followed:

- UCC in Ethernet Mode (GUMR[MODE])
- Set IEEE1588 mode in UPSMR[PTPE]

The receive TSU (time stamp unit) is monitoring the received Ethernet frame on the physical line. When SFD is detected, the IEEE1588 Rx TSU locks the Real Time Value of the IEEE1588 clock.

If the Rx TSU parse unit has detected a PTP frame, it will notify the Ethernet MAC that a PTP frame has been detected, and the Ethernet controller will set RxBD[RPTP]. In addition, the Rx TSU will set the corresponding bit in the event register and generate an interrupt to the CPU.

When the Software detects that a PTP frame has arrived by getting an interrupt or by polling the RxBD[RPTP] it will read the dedicated timestamp register (TMR_UCx_RXTS_H/L) through the host interface.

In case the PTP frame is marked with CRC, Overrun, or Non-octet receive errors, the interrupt in the TMR_PEVENT will not be set and the software should drop this frame regardless of the indication in the RxBD[RPTP].

31.13 PTP Frame Transmission

The following describes the main actions performed for each operation mode when a PTP frame is transmitted.

31.13.1 In-Band Mode

If the Software transmits a PTP frame, it should set the appropriate bit in the buffer descriptor TxBD[TPTP]. The Ethernet MAC is responsible to indicate to the Tx TSU that a PTP frame is transmitted.

The transmit TSU (time stamp unit) is monitoring the transmitted Ethernet frame on the physical line. When SFD is detected, the IEEE1588 Tx TSU locks the Real Time Value of the IEEE1588 clock. If the Tx TSU gets a PTP frame indication, it sets the corresponding bit in the event register and generates interrupt to the CPU.

The SW should access the dedicated timestamp register (TMR_UCx_TXTS_H/L) through the host interface after an interrupt generation or when the “last” bit in the TxBD is set (TxBD[last]).

31.13.2 Out-of-Band Mode

Same as in-band operation.

31.14 Initialization Sequence

TSU mode registers:

Set the PTP_TSMR[opmode] to in-band or out-of-band mode

Program the TMR_PEMASK register

Write 0xFFFF_FFFF to TMR_PEVENT to clear the PTP Event register

UCC mode register:

Set the GUMR[MODE] to Ethernet Mode

Select Ethernet PHY interface

- Select nibble or octal interface in MCCFG2[IFM] and UPSMR
- Set the UPSMR[PTPE] to one (enables IEEE1588 support)

Note: In RMII mode PTP_TSMR[opmode] must be configured first

Set MACCFG2[SRP] only when working in in-band mode

RTC mode registers:

Initialize the TMR_ALARMn registers to 0xFFFF_FFFF

Program the IEEE1588 timer clock period in TMR_CTRL[tclk_period]

Select the timer clock source in the TMR_CTRL[clksel]

Program the TMR_TEMASK register

Write 0xFFFF_FFFF to TMR_TEVENT to clear the RTC Event register

Program the TMR_ADD according to the needed drift compensation needed value

Enable Sequence:

Enable the RTC by setting TMR_CTRL[TE]

Enable the PTP by setting PTP_TSMR[En]

Enable the UCC by setting GUMR[ENR]

Enable the UCC by setting GUMR[ENT]

Chapter 32
ATM Controller AAL0, AAL1, and AAL5

32.1 Introduction

The ATM controller provides the ATM and AAL layers of the ATM protocol using the universal test and operations physical layer (PHY) interface for ATM (UTOPIA level II) for both master and slave modes. It performs segmentation and reassembly (SAR) functions of AAL5, AAL1 circuit emulation service (CES), AAL2, and AAL0, and most of the common parts of the convergence sublayer (CP-CS) of these protocols.

For each virtual channel (VC), the controller's ATM pace control (APC) unit generates a cell transmission rate to implement constant bit rate (CBR), variable bit rate (VBR), unspecified bit rate (UBR) or UBR+ traffic. To regulate VBR traffic, the APC unit performs a continuous-state leaky bucket algorithm. The APC unit also uses up to eight priority levels to prioritize real-time ATM channels, such as CBR and real-time VBR, over non-real-time ATM channels such as VBR and UBR.

The QUICC Engine block supports a special mode for ATM/TDM Interworking(IW). The QUICC Engine block performs automatic data forwarding between ATM channels and the MCC's TDM channels without core intervention.

The QUICC Engine block ATM SAR controller applications are as follows:

- ATM line card controllers
- ATM-to-WAN Interworking (frame relay, T1/E1 circuit emulation)
- Residential broadband network interface units (NIU) (ATM-to-Ethernet)
- High-performance ATM network interface cards (NIC)
- Bridges and routers with ATM interface

32.1.1 Features

The ATM controller has the following features:

- Full duplex segmentation and reassembly at OC12 rate.
- UTOPIA level II master and slave modes 8/16 bit
- AAL5, AAL1, AAL2, AAL0 protocols
- Up to 253 active VCs internally, and up to 64K VCs using external memory
- TM 4.1 CBR, VBR, UBR, UBR+ traffic types
- VBR type 1 and 2 traffic using leaky buckets (GCRA)
- GBR Guaranteed Bit Rate
- Hierarchical Frame Based scheduling
- Hierarchical Cell Based scheduling

- Unassign cells screening option
- Internal rate transmit mode
- Special mode for ATM-to-TDM or ATM-to-ATM data forwarding
- CLP and congestion indication marking
- User-defined cells up to 65 bytes
- Separate TxBD and RxBD tables for each virtual channel (VC)
- Special mode of global free buffer pools for dynamic and efficient memory allocation with early packet discard (EPD) support
- Interrupt report per channel using four priority interrupt queues
- Compliant with ATMF UNI 4.1 and ITU specification
- AAL5 cell format
  - — Reassembly
    - – Reassemble PDU directly to external memory
    - – CRC32 check
    - – CLP and congestion report
    - – CPCS_UU, CPI, and length check
    - – Abort message report
  - — Segmentation
    - – Segment PDU directly from external memory
    - – Performs PDU padding
    - – CRC32 generation
    - – Automatic last cell marking
    - – Automatic CPCS_UU, CPI, and length insertion
    - – Abort message option
- AAL1 cell format
  - — Reassembly
    - – Reassemble PDU directly to external memory
    - – Support for partially filled cells (configured on a per-VC basis)
    - – Sequence number check
    - – Sequence number protection (CRC-3 and parity) check
  - — Segmentation
    - – Segment PDU directly from external memory
    - – Partially filled cells support (configured on a per-VC basis)
    - – Sequence number generation
    - – Sequence number protection (CRC-3 and even parity) generation
  - — Structured AAL1 cell format
    - – Automatic synchronization using the structured pointer during reassembly

  - Structured pointer generation during segmentation
  - Unstructured AAL1 cell format
    - Clock recovery using external SRTS (synchronous residual time stamp) logic during reassembly
    - SRTS generation using external logic during segmentation
- AAL0 format
  - Receive
    - Whole cell is put in memory
    - Only cell payload is saved in memory
    - CRC10 pass/fail indication
  - Transmit
    - Reads a whole cell from memory
    - CRC10 insertion option
- AAL1 circuit emulation service
  - Refer to Chapter 35, “ATM AAL1 Circuit Emulation Service.
- AAL2 format
  - Refer to Chapter 41, “E2AAL2 Microcode”
- Support for user-defined cells
  - Support cells up to 65 bytes
  - Extra header insert/load on a per-frame basis
  - Extra header size has byte resolution
  - Asymmetric cell size for send and receive
  - HEC octet insertion option
- PHY
  - UTOPIA level II supports 8/16 bits 25/50 MHz
    - Supports UTOPIA master and slave modes
    - Supports cell-level handshake
    - Supports multiple-PHY polling mode
- ATM pace control (APC) unit
  - Peak cell rate pacing on a per-VC basis
  - Peak-and-sustain cell rate pacing using GCRA on a per-VC basis
  - Peak-and-minimum cell rate pacing on a per-VC basis
  - Up to eight priority levels
  - Fully managed by QUICC Engine block with no host intervention
  - Scalable APC mode
  - APC Flux mode
  - UBR+ prioritized mode

- Receive address look-up mechanism
  - Three modes of address look-up are supported
    - Address compression (including dynamic changes)
    - Mini-CAM look-up
    - Address look-up according to the UDC Extended Address Mode (UEAD)
- OAM (operations and maintenance) cells
  - OAM filtering according to PTI field and reserved VCI field
  - Raw cell queues for transmission and reception
  - CRC-10 generation/check
  - Performance monitoring support
    - Support up to 64 bidirectional block tests simultaneously
    - Automatic FMC and BRC cell generation and termination
    - User transmit $cell_{0+1}$ count
    - User transmit $cell_0$ count
    - PM cells time stamp insertion
    - Block error detection code ($BEDC_{0+1}$) generation/check
    - Total receive $cell_{0+1}$ count
    - Total receive $cell_0$ count
  - Specifying channel code for F5 OAM cells
- ATM layer statistic gathering on a per PHY basis.
  - UTOPIA receiver error cells count (Rx parity error or short/long cells error)
  - Miss inserted cell count
- Memory management
  - RxBD table per VC with option of global free buffer pool for AAL5
  - TxBD table per VC
- UPC
  - Programmable bundling of multiple VCCs to the same UPC, or per connection UPC
  - Up to 1023 Dual leaky buckets
  - Each bucket perform ATM forum's TM4.1 virtual Scheduling GCRA
  - GFR mode as described in ATM forum's TM4.1
  - Detection of cells that violates the traffic agreement.
    - Violating cells can be dropped
    - Violating cells can be tagged
  - Multiple Statistics Counters for cells and frames

32.1.2 ATM Controller—Modes of Operation

The ATM Controller main modes of operations are:

- ATM SAR AAL5, AAL1, AAL2, AAL0 protocols
- ATM pace control (APC) unit
  - TM 4.1 CBR, VBR, UBR, UBR+ traffic types
  - Scalable APC mode
  - APC Flux mode
  - UBR+ prioritized mode
  - GCRA Scheduler mode
  - Hierarchical Frame based scheduling
  - Hierarchical Cell Based scheduling
  - GBR -Guaranteed bit rate
- User-defined cells (UDC)
- Performance Monitoring
- Transmit Internal Rate Mode
- Three modes of address look-up are supported
  - Address compression
  - Mini-CAM Address look-up
  - Address look-up according to the UDC Extended Address Mode (UEAD)
- Receive Raw Cell Queue
- OAM Support
  - Virtual Path (F4) Flow
  - Virtual Channel (F5) Flow
- ATM-to-TDM Interworking
- CAS Support
- UPC
- Operation in a 82xx compatible mode and in Multi-Threading mode for high performance/ bandwidth requirements.

32.2 ATM Controller—Functional Description

The following sections provide an overview of the transmitter and receiver portions of the ATM controller. It assumes all the required programming of the Utopia interface and Virtual FIFO are done and memory has been allocated for the Virtual FIFO.

32.2.1 Transmitter Overview

Before the transmitter is enabled, the host must initialize the QUICC Engine block and create the transmit data structure, described in Section 32.3, “ATM Controller—Memory Map.” When data is ready for

transmission, the host arranges the BD table and writes the pointer of the first BD in the transmit connection table (TCT). The host issues an ATM TRANSMIT command, which inserts the current channel to the ATM pace control (APC) unit. The APC unit controls the ATM traffic of the transmitter. It reads the traffic parameters of each channel and divides the total bandwidth among them. The APC unit can pace the peak cell rate, peak-and-sustain cell rate (GCRA traffic) or peak-and-minimum cell rate traffic. The APC implements up to eight priority levels for servicing real-time channels before non-real-time channels.

For DSLAM application in multi PHY systems, in addition to the 82XX APC, which potentially consumes considerable amount of internal memory, especially when the channels rates are spread over a wide range of bandwidth, there is a new traffic shaper which has a smaller memory footprint and which is optimized for such applications. This is a Generic Cell Rate Algorithm (GCRA) scheduler. Number of channels per PHY is limited to 64.

The transmitter ATM cell is 53–65 bytes and includes 4 bytes of ATM cell header, a 1-byte HEC, and 48 bytes of payload. The HEC is a constant taken from UDSR*x*[0–15] when using UTOPIA 16 and from UDSR*x*[8–15] when using UTOPIA 8; User-defined cells (UDC mode) include an extra header of 1–12 bytes with an optional HEC octet. Cell transfers use the UTOPIA level II, cell-level handshake.

Transmission starts when the APC schedules a channel. According to the channel code, the ATM controller reads the channel's parameters which resides in the TCT and acts according to the setting in this entry. Each channel could be configured to work in different AAL type, different mode of operation and different scheduling scheme.

In auto-VC-off mode, the APC automatically deactivates the current channel when no buffer is ready to transmit. In this case, a new ATM TRANSMIT command is needed for transmission of the VC to resume.

Unlike the 82XX family the device doesn't transmit Idle cells and operation is in what is called in the 82XX user's manual "internal rate mode"

32.2.1.1 AAL5 Transmitter Overview

The transmitter reads 48 bytes from the external buffer, adds the cell header, and sends the cell through the UTOPIA interface. The transmitter adds any padding needed and appends the AAL5 trailer in the last cell of the AAL5 frame. The trailer consists of CPCS-UU+CPI, data length, and CRC-32 as defined in ITU I.363. The CPCS-UU+CPI (2-byte entry) can be specified by the user or optionally cleared by the transmitter; see Section 32.3.4.2, "Transmit Connection Table (TCT)." The transmitter identifies the last cell of the AAL5 message by setting the last (L) indication bit in the PTI field of the cell header. An interrupt may be generated to indicate the end of the frame.

When the transmission of the current frame ends and no additional valid buffers are in the BD table, the transmit process ends. The transmitter keeps polling the BD table every time this channel is scheduled to transmit. Note that a buffer-not-ready indication during frame transmission aborts the frame transfer.

32.2.1.2 AAL1 Transmitter Overview

The QUICC Engine block supports both structured and unstructured AAL1 formats. For the unstructured format, the transmitter reads 47 bytes from the external buffer and inserts them into the AAL1 user data field. The AAL1 PDU header, which consists of the sequence number (SN) and the sequence number protection (SNP) (CRC-3 and parity bit), is generated and inserted into the cell. The QUICC Engine block

supports synchronous residual time stamp (SRTS) generation using external PLL. If this mode is enabled, the QUICC Engine block reads the SRTS code from the external logic and inserts it into four outgoing cells.

For the structured format, the transmitter reads 47 or 46 bytes from the external buffer and inserts them into the AAL1 user data field. The QUICC Engine block generates the AAL1 PDU header and inserts it into the cell. The header consists of the SN, SNP, and the structured pointer.

The QUICC Engine block supports partially filled cells configured on a per-VC basis. In this mode (TCT[PFM] = 1), only valid octets are copied from the buffer to the ATM cell; the rest of the cell is filled with padding octets.

32.2.1.2.1 AAL1 CES Transmitter Overview

Refer to CES chapter, Section 35.2, “AAL1 CES Transmitter Overview.”

32.2.1.3 AAL0 Transmitter Overview

No specific adaptation layer is provided for AAL0. The ATM controller reads a whole cell from an external buffer, which always contains exactly one AAL0 cell. The ATM controller optionally generates CRC10 on the cell payload and places it at the end of the payload (CRC10 field). AAL0 mode can be used to send OAM cells or AAL3/4 raw cells.

32.2.1.4 AAL2 Transmitter Overview

Refer to AAL2 chapter, Section 32.2.1, “Transmitter Overview.”

32.2.2 Receiver Overview

Before the receiver is enabled, the host must initialize the QUICC Engine block and create the receive data structures described in Section 32.3, “ATM Controller—Memory Map.” Data structures varies according to the AAL type and mode of operation. The host arranges a BD table for each ATM channel. Buffers for each connection can be statically allocated (that is, each BD in the BD table is associated with a fixed buffer location) or in the case of AAL5, can be fetched by the QUICC Engine block from a global free buffer pool. See Section 32.3.9, “ATM Controller Buffer Descriptors (BDs).”

The receiver ATM cell size is 53–65 bytes. The cell includes: 4 bytes ATM cell header, 1 byte HEC, which is ignored, and 48 bytes payload. User-defined cells (UDC mode) include an extra header of 1–12 bytes with an optional HEC octet. Cell transfers use the UTOPIA level II, cell-level handshake.

Reception starts when the PHY asserts the receive cell available signal (RxCLAV) to indicate that the PHY has a complete cell in its receive FIFO. The receiver reads a complete cell from the UTOPIA interface and translates the header address (VP/VC) to a channel code by performing an address look-up. If no matches are found, the cell is discarded and the user-network interface (UNI) statistics tables are updated. The receiver uses the channel code to read the channel parameters from the receive connection table (RCT).

32.2.2.1 AAL5 Receiver Overview

The receiver copies the 48-byte cell payload to the external buffer and calculates CRC-32 on the entire CPCS-PDU. When the last AAL5 cell arrives, the receiver checks the length, CRC-32, and CPCS-UU+CPI fields and sets the corresponding RxBD status bits. An interrupt may be generated to one of the four interrupt queues. The receiver copies the last cell to memory including the padding and the AAL5 trailer. The CPCS-UU+CPI (16-bit entry) may be read directly from the AAL5 trailer.

The ATM controller monitors the CLP and CNG state of the incoming cells. When the message is closed, these events set RxBD[CLP] and RxBD[CNG].

When no buffer is ready to receive cells (busy state), the receiver switches to hunt state and drops all cells associated with the current frame (partial packet discard). The receiver tries to open new buffers for cell reception only after the last cell of the discarded AAL5 frame arrives.

32.2.2.2 AAL1 Receiver Overview

The ATM controller supports both AAL1 structured and unstructured formats. For the unstructured format, 47 octets are copied to the current receive buffer. The AAL1 PDU header, which consists of the sequence number (SN) and the sequence number protection (SNP) (CRC-3 and parity bit), is checked. The QUICC Engine block supports SRTS clock recovery using an external PLL. In this mode, the QUICC Engine block tracks the SRTS from the four incoming cells and writes the SRTS code to external logic. See Section 32.2.22.4.1, “SRTS Generation and Clock Recovery Using External Logic.”

In the unstructured format, when the receive process begins, the receiver hunts for the first cell with a valid sequence number (SN field). When one arrives, the receiver leaves the hunt state and starts receiving. If an SN mismatch is detected, the receiver closes the RxBD, sets the sequence number error flag (RxBD[SNE]), and switches to hunt state, where it stays until a cell with a valid SN field is received.

For the structured format, 47 or 46 octets are copied to the current receive buffer. The AAL1 PDU header, which consists of SN and SNP, is checked and the PDU status is written to the BD.

In the structured format, when the receive process begins, the receiver hunts for the first cell with a valid structured pointer to gain synchronization. When one arrives, the receiver leaves the hunt state and starts receiving. Then the receiver opens a new buffer. The structured pointer points to the first octet of the structured block, which then becomes the first byte of the new buffer. If an SN mismatch is detected, the ATM receiver closes the current RxBD, sets RxBD[SNE], and returns to the hunt state. The receiver then waits for a cell with a valid structured pointer to regain synchronization.

The QUICC Engine block supports partially filled cells configured on a per-VC basis. In this mode (RCT[PFM] = 1), the ATM controller copies only the valid octets from the cell user data field to the buffer.

32.2.2.2.1 AAL1 CES Receiver Overview

Refer to Section 35.3, “AAL1 CES Receiver Overview.”

32.2.2.3 AAL0 Receiver Overview

For AAL0, no specific adaptation layer processing is done. The ATM controller copies the whole cell to an external buffer. Each buffer contains exactly one AAL0 cell. The ATM controller calculates and checks

the CRC10 of the cell payload and sets RxBD[CRE] if a CRC error occurs. AAL0 mode can be useful for receiving OAM cells or AAL3/4 raw cells. There are several options for storing the cell content in the data buffer. In OAM cells the data buffer contains on top of the cell content also time stamp information and the PHY ID on which this OAM cell has been received.

32.2.2.4 AAL2 Receiver Overview

Refer to Section 41.4, "AAL2 Receiver."

32.2.3 ATM Multi-Threading

The Multi-threading mode of operation is introduced in the QUICC Engine block in order to support higher ATM bit rates, up to OC-12 rates. This mode enables parallel processing of ATM traffic thus getting better bus/QUICC Engine block utilization. Operation is kept very similar to the legacy PQ family with some modification to enable parallel processing. This mode is enabled per UCC by configuring the '**ATM_lvl_MT_en**' in the UCC parameter table. (See Table 32-25).

Figure 32-1 illustrates a possible Multi-threading setup. It demonstrates the multi thread structures for UCC Tx or UCC Rx when working in ATM mode. The term Distributor relates to the module which distribute cell handling to the threads. The distributor is directly connected to the serial device (UCC) and its request ID is identical to the UCC Tx or UCC Rx hardware request ID. The threads are processes which performs most of the cell processing work. Each thread has its own ID. Each thread contains information of a single ATM cell belonging to a specific Rx/Tx Channel Code. Operation of the threads is done in parallel. The Terminator is the process which is responsible to keep the correct order of arrival/transmission of the cells to and from the virtual FIFO of the device. Both the receiver and transmitter has its own Terminator SNUM which is allocated statically by the application.

The threads processes are resources available for the QUICC Engine block. These resources could be assigned in a static allocation for each serial device (UCC Rx/UCC Tx) or they could be allocated dynamically to a device upon heavy traffic load conditions. It is recommended that at least one static thread is assigned for each of the UCCs Tx or Rx distributors. Any combination of static/dynamic threads per UCC Tx/Rx is configurable.

Each transmitter/receiver pair requires an internal memory parameters page which in the legacy PQII consists of 0x100 bytes. The page contains very similar information as on the PQ family. The parameters names and programming model functionality is identical to this of the 82XX family. The changes in this new architecture apply to the arrangement of parameters within the page. It has been redefined to enable further expansion and better memory efficiency in future protocols and features. In the minimum configuration it could map to the legacy 82XX model with slight modifications. The distributor process has the traditional 0x100 bytes page and each thread has a 0x80 byte page associated with it. Structure of the page is described in section Section 32.3.1, "Parameter RAM Page Organization."

When the Tx/Rx UCC hardware request is asserted, the distributor module is activated. It performs some activities: scheduling on the transmitter and address look-up on the receiver and identifies the Channel Code of the requestor. Then it triggers operation of a thread for further processing. Threads are allocated dynamically or statically to the distributor. If all threads are busy the procedure in stalled. The objective is to have each thread process a different ATM channel, and by that achieving parallel processing. Identical

channel are processed by the same thread. For getting the best performance out of the device multi-threaded operation should be configured only under some conditions:

- If the UPC (Utopia POS Controller) operates in single PHY mode and the number of ATM channels is relatively large and parallelism is achievable.
- In case of using the UPC in multi-PHY mode and a single UCC, it depends on the number of PHYs which are active on the Utopia i/f. Higher number of PHYs increase the efficiency of multi-threading. The user should explore the option of having two or more UCCs handling the same Utopia bus and working in Non multi-threaded operation.

For detailed information about the thread page parameters see Section 32.3.3, “Multi-Threading Structures.”

The minimum amount of processes required for a UCC to work in Multi-threaded mode is the following: Distributor for Rx and Tx (which are hardware-assigned for each UCC), at least one thread for transmitter, at least one thread for receiver, and two threads for terminators which are assigned statically. The user can configure up to 32 threads per one ATM multi thread group, which could serve multiple UCCs. All of these threads use the same ‘common multi thread’ parameters, and can be allocated dynamically according to the system load. See Table 32-20 for the ‘Multi-thread_Common_Base’ parameter. If more than 32 threads are required, the user can allocate additional ATM multi thread group which uses a separate ‘common multi thread’ parameters, in a new UCC page. There is no relationship between these different Multi thread groups, meaning that there will be no dynamic sharing between the threads from one multi thread group to the other.

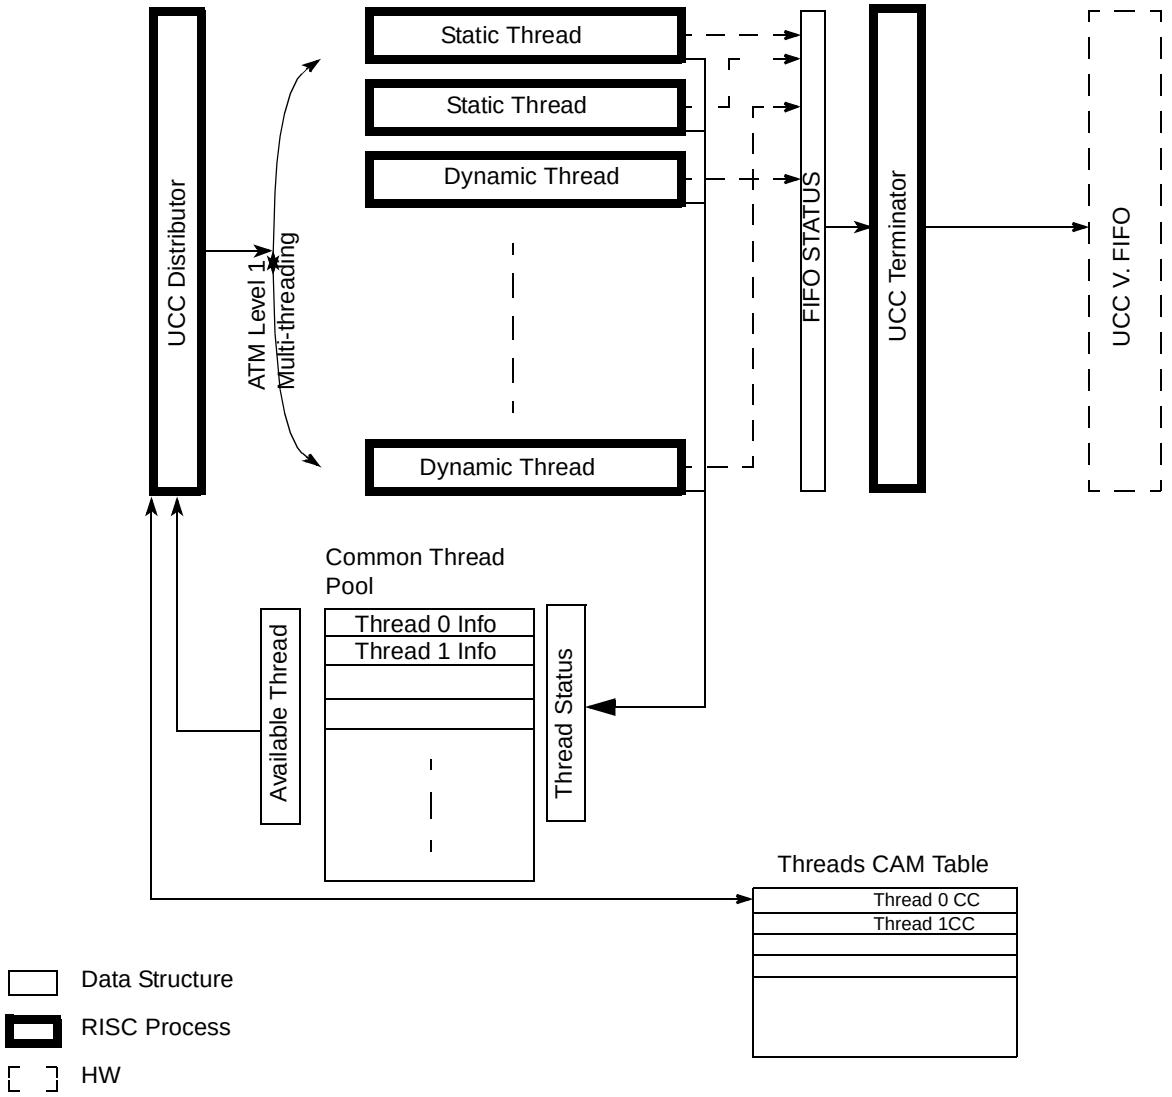

Figure 32-1. ATM UCC Multi-Threading Concept

In MSP HTCT mode it is not enough to use the HTCT-Channel Code as the only input for the multi thread distributor decision process, since in systems where there is only one HTCT the multi thread will not be useful. Therefore in addition to the HTCT CC there is also the FIFO ID index in the Distributor Tx CAM structure. In this case each CAM entry is of 4 bytes length. See Figure 32-2. Still in a system where there is only 1 HTCT and under it only one FIFO, then the multi thread is not useful for the Tx side.Potential problem- in the HTCT we keep information needed from next thread steps HTCT[FFS_TMP] and HTCT[EFDT_CUR] - this temporary parameters now should be stored in the thread page since the same HTCT could be used in several threads.

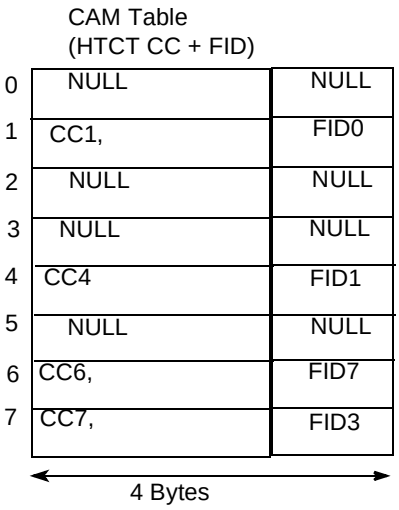

Figure 32-2. MSP HTCT distributor structures

In the same way for MSP Tx FIFO mode the multi thread algorithm can use the UCC no., PHY number and the FDT ID in order to perform the distributor process. In this case each CAM entry is still of 2 bytes length. See Figure 32-3.

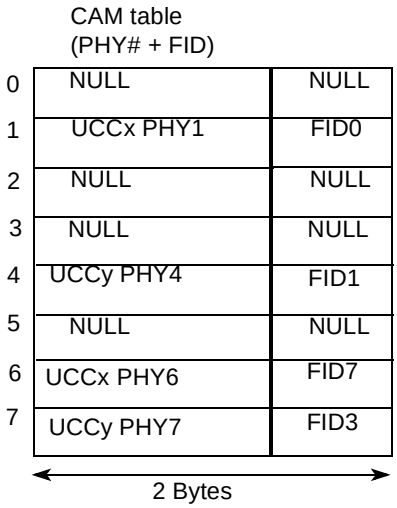

Figure 32-3. MSP FIFO Distributor Structures

When the thread is selected, the distributor puts all the relevant cell information in this thread page and triggers the thread.

When the Thread is called, it fetches the cell information from its page, and performs most of the ATM cell processing procedures. Once processing is finished the Terminator is invoked.

The Terminator process is responsible for keeping the sequence of events in the correct order with respect to time and location in the virtual FIFO, since the threads can change the order of the cells.

32.2.4 Performance Monitoring

The ATM controller supports performance monitoring testing according to ITU I.610. When performance monitoring is enabled, the ATM controller automatically generates and terminates FMCs (forward monitoring cells) and BRCs (backward reporting cells). See Section 32.2.19, "Performance Monitoring."

32.2.5 ATM Pace Control (APC) Unit

The ATM pace control (APC) unit schedules the ATM channels for transmitting. While performing this task, the APC unit uses the following parameters:

- Frequency (bandwidth) of each ATM channel
- ATM traffic pacing—Peak cell rate (PCR), sustain cell rate (SCR), and minimum rate (MCR)
- Priority level—Real-time channels (CBR or VBR-RT) are scheduled at high-priority levels; non-real-time channels (VBR-NRT, UBR) are scheduled at low-priority levels. Up to eight priority levels are available. In GBR mode a channel can resides on two priority levels. One has the parameters of the CBR level rate and one has the UBR level rate.

32.2.5.1 APC Modes and ATM Service Types

The ATM Forum (http://www.atmforum.com) defines the service types described in Table 32-1.

Table 32-1. ATM Service Types

Service Type	Cell Rate Pacing	Real-Time/ Non-Real-Time	Relative Priority
CBR	PCR	RT	1 (highest)
VBR-RT	PCR, SCR (peak-and-sustain)	RT	2
VBR-NRT	PCR, SCR (peak-and-sustain)	NRT	3
UBR+	PCR, MCR (peak-and-minimum)	NRT	4
UBR	PCR	NRT	5 (lowest)

For information about cell rate pacing, see Section 32.2.6, "ATM Traffic Type." For information about prioritization, see Section 32.2.11, "Determining the Priority of an ATM Channel."

32.2.5.2 APC Unit Scheduling Mechanism

The APC unit consists of an APC data structure in the multi-user RAM for each PHY and a special scheduling algorithm performed by the QUICC Engine block. Each PHY's APC data structure includes three elements: an APC parameter table, an APC priority table, and cell transmission scheduling tables for each priority level. (See Section 32.3.6, "APC Data Structure.")

Each PHY's APC parameter table holds parameters that define the priority table location, the number of priority levels, and other APC parameters. The priority table holds pointers that define the location and size of each priority level's scheduling table. Up to eight priority levels are available per PHY.

Each scheduling table is divided into time slots, as shown in Figure 32-4. The user determines the number of ATM cells to be sent each time slot (cells per slot). After a channel is sent, it is removed from the current time slot and advanced to a future time slot according to the channel's assigned traffic rate (specified in time slots). The PCR parameter in the TCT, or the SCR or MCR parameters in the TCT extension (TCTE) determine the channel's actual rate.

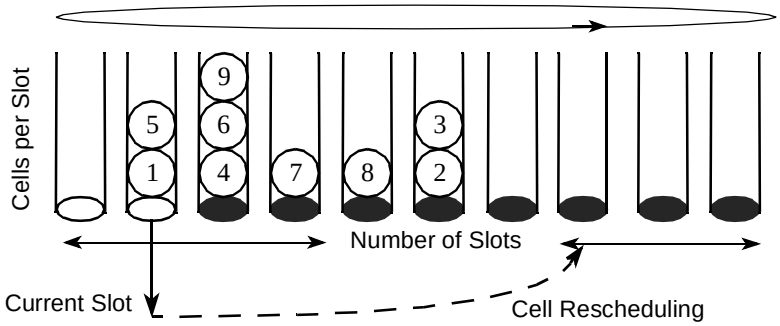

Figure 32-4. APC Scheduling Table Mechanism

Each 2-byte time-slot entry points to one ATM channel. Additional channels scheduled to transmit in the same slot are linked to each other using the APC linked-channel field in the TCT. The linked list is not limited; however, if the number of channels for the current slot exceeds the cells per slot parameter (CPS), the extra channels are sent in subsequent time slots. (The rescheduling of extra channels is based on the original slot to maintain each channel's pace.)

Note that a channel can appear only once in the scheduling table at a given time, because each channel has only one APC linked-channel field.

Figure 32-5 depicts a schematic view of the ATM scheduling per PHY. Up to eight priority levels are available, each has a the ATM channels assigned which are scheduled according to their contract. Each channels has it's parameters stored in a data structure named TCT- Transmit Connection Table and TCTE- Transmit Connection Table Extension.

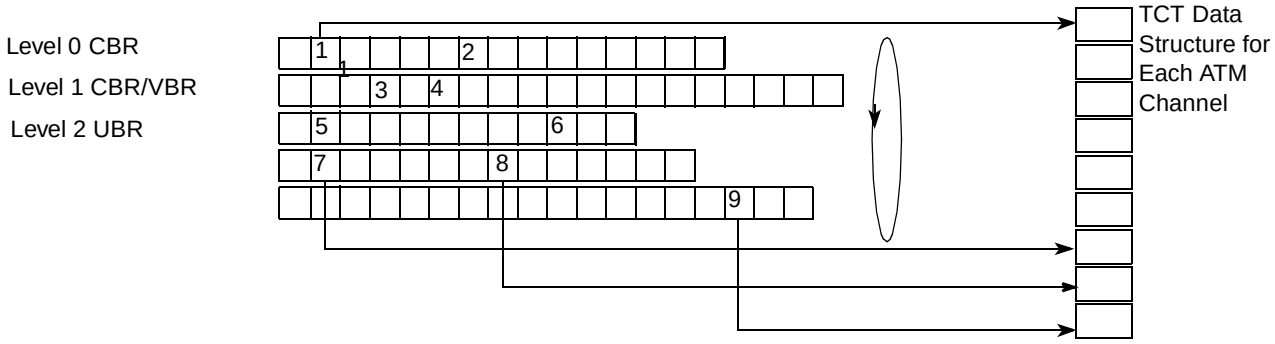

Figure 32-5. ATM Scheduling

32.2.5.3 Determining the Scheduling Table Size

The following sections describe how to determine the number of cells sent per time slot and the total number of slots needed in a scheduling table.

32.2.5.3.1 Determining the Cells Per Slot (CPS) in a Scheduling Table

The number of cells sent per time slot is determined by the channel with the maximum bit rate; see equation A. The maximum bit rate is achieved when a channel is rescheduled to the next slot. For example, if the line rate is 155.52 Mbps and there are eight cells per slot, equation A yields a maximum VC rate of 19.44 Mbps.

(A) $$\text{Max bit rate} = \frac{\text{line rate}}{\text{cells per slot}}$$

Note that a channel can appear only once per time slot; thus, 19.44 Mbps = 155.52Mbps/8.

The cells per slot parameter (CPS) affects the cell delay variation (CDV). Because the APC unit does not put cells in a definite order within each time slot (LIFO—last-in/first-out implementation), as CPS increases, the CDV increases. However as CPS decreases, the size of the scheduling table in the multi-user RAM increases and more QUICC Engine bandwidth is required.

32.2.5.3.2 Determining the Number of Slots in a Scheduling Table

The number of time slots in a scheduling table is determined by the channel with the minimum bit rate; see equation B. The minimum bit rate is achieved when the channel reschedules only once in a whole table scan. (The maximum schedule advance allowed is equal to number_of_slots – 1.) For example, if the line rate is 155.52 Mbps, the minimum bit rate is 32 kbps and the CPS is 4, then, according to equation B, the number of slots should be 1,216.

NOTE

The following APC configuration is not recommended for values outside the following ranges (PCR = peak cell rate, PCRF = peak cell rate fraction, NOS = number of slots):

PCR = 1 and PCRF = 0

PCR = NOS - 1 and PCRF = 0

(B) $$\text{Min bit rate} = \frac{\text{line rate}}{(\text{number\_of\_slots} - 1) \times \text{cells per slot}}$$

For the above example, 32 kbps = 155.52 Mbps/((1216-1) × 4).

Use equations (A) and (B) to obtain the maximum and minimum bit rates of a scheduling table. For example, given a line rate = 155.52 Mbps, number_of_slots = 1025, and CPS = 8:

$$\text{Max bit rate} = (155.52 \text{ Mbps})/8 = 19.44 \text{ Mbps}$$

$$\text{Min bit rate} = (155.52 \text{ Mbps})/(1024 \times 8) = 18.98 \text{ kbps.}$$

NOTE

In some of the operating modes of the ATM there is an automatic activation of channels into the APC. This operation requires having a minimal size of the APC table which is be 6 slots.

32.2.5.3.3 Determining the Time Slot Scheduling Rate of a Channel

The time slot scheduling rate of each ATM channel is defined by equation C. The resulting number of APC slots is written in either TCT[PCR], TCTE[SCR] or TCTE[MCR], depending on the traffic type.

$$\text{(C)} \qquad \text{Rate [slots]} = \frac{\text{line rate [bps]}}{\text{VC rate [bps]} \times \text{cells per slot}}$$

32.2.6 ATM Traffic Type

The APC uses the cell rate pacing parameters (PCR, SCR, and MCR) to generate CBR, VBR, UBR+, and UBR traffic. The user determines the kind of traffic that is generated per VC by writing to TCT[ATT] (ATM traffic type); see Section 32.3.4.2, "Transmit Connection Table (TCT)."

32.2.6.1 Peak Cell Rate Traffic Type

When the peak cell rate traffic type is selected, the APC schedules channels to transmit according to the PCR and PCR_FRACTION traffic parameters. Other traffic parameters do not apply to this traffic type.

32.2.6.2 Determining the PCR Traffic Type Parameters

Suppose a VC uses 15.66 Mbps of the total 155.52 Mbps and CPS = 8. Equation C yields:

$$\text{PCR [slots]} = (155.52\ \text{Mbps})/(15.66\ \text{Mbps} \times 8) = 1.241$$

The resulting number of slots is written into TCT[PCR] and TCT[PCR_FRACTION]. Because PCR_FRACTION is in units of 1/256 slots, the fraction must be converted as follows:

$$1.241 = 1+0.241 \times 256/256 = 1+ 61.79/256 \sim 1 + 62/256$$

PCR = 1 PCR_FRACTION = 62

32.2.6.3 Peak and Sustain Traffic Type (VBR)

Variable bit rate (VBR) traffic can burst at the peak cell rate as long as the long-term average rate does not exceed the sustainable cell rate. To support VBR channels, the APC implements the GCRA (generic cell rate algorithm) using three parameters—the peak cell rate (PCR), the sustained cell rate (SCR), and burst tolerance (BT), as shown in Figure 32-6. (The GCRA is also known as the leaky bucket algorithm.)

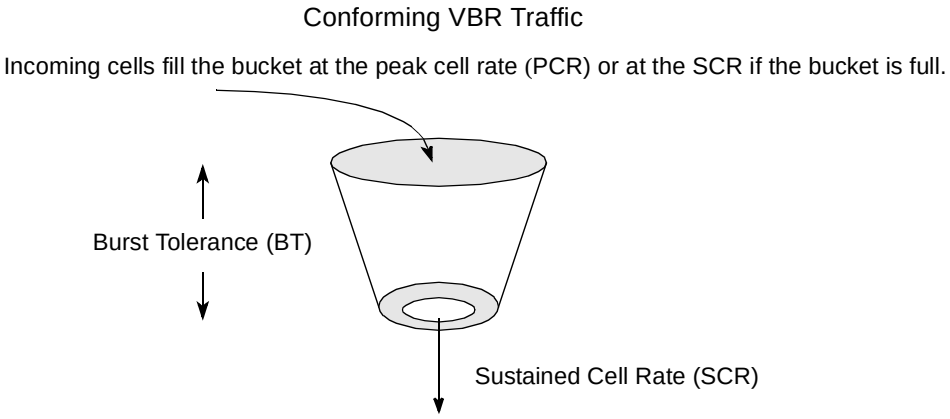

Figure 32-6. VBR Pacing Using the GCRA (Leaky Bucket Algorithm)

When a VBR channel is activated, it bursts at the peak cell rate (PCR) until reaching its initial burst tolerance (BT), which is the buffer length the network allocated for this VC. When the burst limit is reached, the APC reduces the VC's scheduling rate to the sustained cell rate (SCR). The VC continues sending at SCR as long as TxBDs are ready. However, as each SCR time allotment elapses with no TxBD ready to send, the APC grants the VC a credit for bursting at the peak cell rate (PCR). (Gaining credit implies that the buffer at the switch is not full and can tolerate a burst transmission.) If a TxBD becomes ready, the APC schedules the VC to burst at the PCR as long as credit remains. When the burst credit ends (the network's UPC leaky bucket reaches its limit), the APC schedules the VC according to SCR.

32.2.6.3.1 Example for Using VBR Traffic Parameters

Suppose the traffic parameters of a VBR channel are PCR = 6 Mbps, SCR = 2 Mbps, MBS (maximum burst size) = 1000 cells, and CPS = 8.

Equation C (see Section 32.2.5.3.3, "Determining the Time Slot Scheduling Rate of a Channel") yields the APC parameters, PCR, PCR_FRACTION, SCR, and SCR_FRACTION, which the user writes to the channel's TCT.

$$\text{PCR [slots]} = (155.52 \text{ Mbps})/(6 \text{ Mbps} \times 8) = 3.24$$

$$3.24 = 3 + 0.24 \times 256/256 = 3 + 61.44/256 \sim 3 + 62/256$$

$$\text{PCR} = 3 \qquad \text{PCR\_FRACTION} = 62$$

$$\text{SCR [slots]} = (155.52 \text{ Mbps})/(2 \text{ Mbps} \times 8) = 9.72$$

$$9.72 = 9 + (0.72 \times 256/256) = 9 + 184.32/256 \sim 9 + 185/256$$

$$\text{SCR} = 9 \qquad \text{SCR\_FRACTION} = 185$$

Equation D yields the number of slots the user writes to the channel's TCT[BT].

(D) $$BT\ [slots] = (MBS[cells] - 2) \times (SCR[slots] - PCR[slots]) + SCR[slots]$$
$$= (1000 - 2) \times ((9+185/256) - (3+62/256)) + (9 +185/256)$$
$$= 6477$$

32.2.6.3.2 Handling the Cell Loss Priority (CLP)—VBR Type 1 and 2

The QUICC Engine block supports two ways to schedule VBR traffic based on the cell loss priority (CLP). When TCTE[VBR2] is cleared, CLP_{0+1} cells are scheduled by PCR or SCR according to the GCRA state. When TCTE[VBR2] is set, CLP_0 cells are still scheduled by PCR or SCR according to the GCRA state, but CLP_1 cells are always scheduled by PCR. See Section 32.3.4.2.6, “VBR Protocol-Specific TCTE.”

32.2.6.4 Peak and Minimum Cell Rate Traffic Type (UBR+)

To support UBR+ channels, the APC schedules transmission according to PCR and MCR. For each priority level, the APC maintains a parameter that monitors the traffic load measured as the time-slot delay between the service pointer (pointing to the current time slot waiting transmission) and a real-time slot pointer. If the transmission delay is greater than MDA (maximum delay allowed), the APC begins scheduling channels according to the MCR parameter. If the delay, however, drops below MDA, the APC again schedules channels according to the PCR. Note that in order to guarantee a minimum cell rate for UBR+ channels, there must be enough bandwidth to simultaneously send all possible channels at the MCR. See Section 32.3.4.2.7, “UBR+ Protocol-Specific TCTE***.”

32.2.7 Scalable-APC Mode

If an ATM system requires connections with very high variance in bit rates that spans orders of magnitude, the code offers a way to reduce the space required by the APC scheduling table without impacting the scheduling itself. A new APC Mode was defined (Scalable APC) to support Low bit rates connections that would normally require very large APC scheduling tables.

Activating the Scalable APC mode is done by setting the bit SCL_EN in the control slot of the APC, see Table 32-47. The Scalable mode parameters, although transparent to the application, are placed in the TCTE table of the selected ATM channel. If any connection requires a Scalable-APC mode, the TCTE bit in the APC control slot has to be set by the user (if channel number> 255) and so is the SCL_EN bit. It is the application responsibility to clear offsets 0x1C - 0x1F in the TCTE tables of all the connections which resides in the APC scheduling table for proper operation.

32.2.7.1 Scalable-APC Mechanism

In APC scalable mode the user can put in the TCT values of PCR, SCR, MCR and OOBR which are actually bigger than the APC scheduling table size without affecting the scheduling of those channels.

For example: OC-3 PHY (155.52Mbps). ATM 32Kbps CBR connection and CPS=2.

Non APC scalable Mode:

PCR = 155.52Mbps/(32Kbps*CPS) =2430 Slots.

Number of slot in Priority Table = 155Mbps/(32Kbps*CPS) + 1 = 2431 Slots which occupies 4.75 KBytes in DPR.

The value of the CPS is determined by the fastest channel in the system as described in the user's manual. So if the fastest channel doesn't require a small value of CPS it could also be a mean to reduce the APC table size.

APC scalable Mode:

The user may choose an APC table which is smaller from the previous one.

For example: APC table will consist of 300 slots i.e. a factor of around 1:8.

The system will behave in the following manner:

As a channel is being scheduled for transmission and the scalable mode is enabled the selected rate for rescheduling is examined and stored in a shadow location. If this value is higher than the NOS-1 (NOS-Number of APC slots) value it indicates we have to "scale" this channel so it is rescheduled to the furthermost point in the APC i.e. NOS-1 slots away from it's current slot. The shadow value is decremented by the NOS-1 value. From that point and on, each time this channel is being selected for transmission the shadow value is examined. As long as it's value is greater than the NOS-1 value it will be reschedule with this value, and the cell will not be transmitted. Once the shadow value is smaller than the NOS-1, the rescheduling will be according to the shadow value and on the next time a cell will be transmitted.

The values of the rates on the TCT are programmed as if the APC size is big and the accuracy of the APC is not affected by the change. If for example the SCR value is bigger than the APC size but the PCR is smaller, the scaling would be performed only on the SCR while the PCR will be rescheduled without scaling.

It is important to state that using this mode will have an impact on performance of the QUICC Engine block as channels will be scheduled in the APC without transmitting any data. Bus load will also be increase as there is a need to fetch and update the TCTE parameters even for CBR connections. It also could increase the delay variation when the APC is loaded with a high number of active channels.

32.2.8 APC Flux Compensation

For variable bit rate PHY (e.g. radio link), which can fall below the transmission bandwidth defined by the APC internal rate timers, the ATM APC does not use the remaining bandwidth for higher priority traffic only. It "slows down" overall and all ATM channels in all priority levels are affected alike. As a solution to this problem a mechanism called "APC Flux Compensation" was defined. This mechanism is also useful when there is a multi -level APC which one of the lower priority level is oversubscribed with many UBR channels of which many are in idle state meaning there is nothing to transmit in this channels. This situation could cause a delay in servicing the highest priority CBR traffic since checking all those channels is time consuming process which could cause starvation of the highest priority APC level. Using this mechanism causes the CBR high priority APC level to regain the transmission.

When this mode is enabled, by setting Scheduler_MODE[AFC] bit (see Table 32-45) a QUICC Engine Time-Stamp register, CETSR, is set up by programming the CETSCR register, see Section 20.3.9, "QUICC Engine Time-Stamp Control Register (CETSCR).". The user should set the value of the expected

delta time per APC slot, in the APC_SLOT_DUR_VAL field in the Scheduler Parameter Table, see Table 32-44. This value represents the time needed for transmitting Cell per slot (CPS) ATM Cells on the PHY according to CETSCR pre-scale value.

For example: For a variable bit rate PHY, with a maximum rate set to 50Mbps, with CPS=2 and with CETSCR register programmed to 1 uS. period (For CETSCR which is configured for different period the APC_SLOT_DUR_VAL is different)

APC_SLOT_DUR_VAL= (53 × 8 bit per cell/ Max_Rate) × CPS

=(424b/50Mbps) × 2 = 16.96 us.

The user should program the parameters as follow:

APC_SLOT_DUR_VAL_INT = 0x00000010

APC_SLOT_DUR_VAL_Frac = 0.96 × 2^16 = 0xF5C2.

Whenever the APC Tx flow starts, it captures the CETSR value and compares it to the previous time it got serviced. This value is recorded on each APC service. If the delta time between the current CETSR and the recorded time is bigger than the APC_SLOT_DUR_VAL, then the APC RPTRs of all APC Priorities Tables for this PHY, see Table 32-46, will be advanced by the integer value of: (CETSR - APC_CETSR_LAST_VAL)/(APC_SLOT_DUR_VAL). In case where there is a difference which is a fraction of the APC_SLOT_DUR_VAL it will be recorded by the QUICC Engine block and on each transmit operation the accumulated fraction will be examined and if the value crosses the value of APC_SLOT_DUR_VAL the CETSR value will be advanced by one more entry. In this way there is a continuous compensation for any time drift on the PHY.

In cases of a big timing jitter, advancing the RPTRs would be limited by the value of APC_CETSR_Max_ADV in the Scheduler Parameter Table, see Table 32-45. When the PHY is slowed down for a long period of time and has gained a large credit i.e. the RPTR should be advanced by a large number, and the APC scheduling table is not very loaded with channels, advancing the RPTR could be such that it is bigger than some of the channels PCR value. In such a case, this channel could burst in a rate which is higher than the contract rate of this channel when rescheduled by the APC. In order to prevent it from happening, after advancing RPTR to its correct location, the APC Flux mechanism reschedules such a channel to an APC slot which is bigger than the slot pointed by the new RPTR.

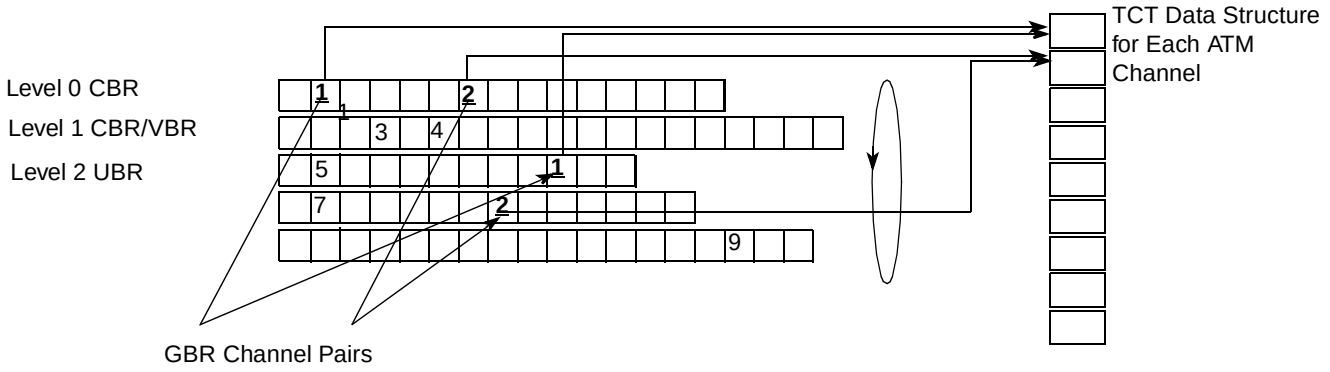
32.2.9 GBR Guaranteed Bit Rate

In systems where RT traffic and control traffic share the same bandwidth there is a need to multiplex these various type of traffic (data delay sensitive, data delay non sensitive and control/management flow) assuring each type gets proper priority and bandwidth. The goals set are:

- Guarantee minimum bit rate for control/management flow.
- Guarantee bit rate and latency for RT traffic.

In cases where there is an excess bandwidth available, distribute it to the rest of the flows following the general traffic priority rules, like delay sensitive data non delay sensitive data and control flow.

In the Guaranteed Bit Rate (GBR) mode the same channel can be scheduled in CBR & UBR priority levels concurrently, having different contracts on each priority and transmitting common data.



32.2.10 Prioritized UBR+ Mode

In systems with more than one APC priority level used by UBR+, the highest priority UBR+ level actually can take over all the capacity from the lower priority UBR+ levels, even if an MCR parameter is specified for lower priority levels. This is because usually the user use oversubscribing when he initialize the UBR+ PCR parameter.

This requires that guaranteed traffic (MCR) and non-guaranteed traffic of UBR+ VCs are required to always be in the same priority level, instead of having the guaranteed traffic (MCR) components of all UBR+ connections in highest priorities of the UBR+ levels, and then the non-guaranteed traffic would be scheduled at the lowest priority levels.

The prioritized UBR+ mechanism is a method for enabling the possibility to use UBR+ in different priority levels. This UBR+ channels get service according to two factors:

- The difference between the real-time pointer and service pointer for this level against the minimum delay allowed (MDA) threshold value set for this level.
- The priority level.

The user must configure the APC priority levels so that the low priority levels up to the last priority level contain UBR+ channels. See Figure 32-7, for an example APC with 6 priority levels, of which 4 are UBR+.

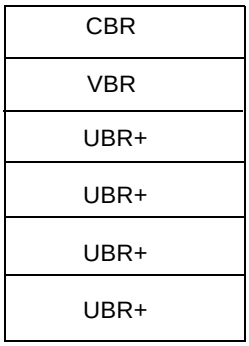


Figure 32-7. UBR+ Priority Level Example

The user must initialize the UBR+ priority decision table (see Figure 32-54) before enabling the UBR+ prioritized mode. This table is located at address Scheduler_Parameter_Table [AFP_LAST]+8. See Figure 32-8, for an example UBR+ priority decision table that contains four entries. The UBR+ prioritized mode is enabled by setting the PUBR+ bit in the Scheduler_Parameter_Table[Scheduler_MODE] entry.

NOTE

When there is only 1 UBR+ priority level, the UBR+ prioritized mode must be disabled.

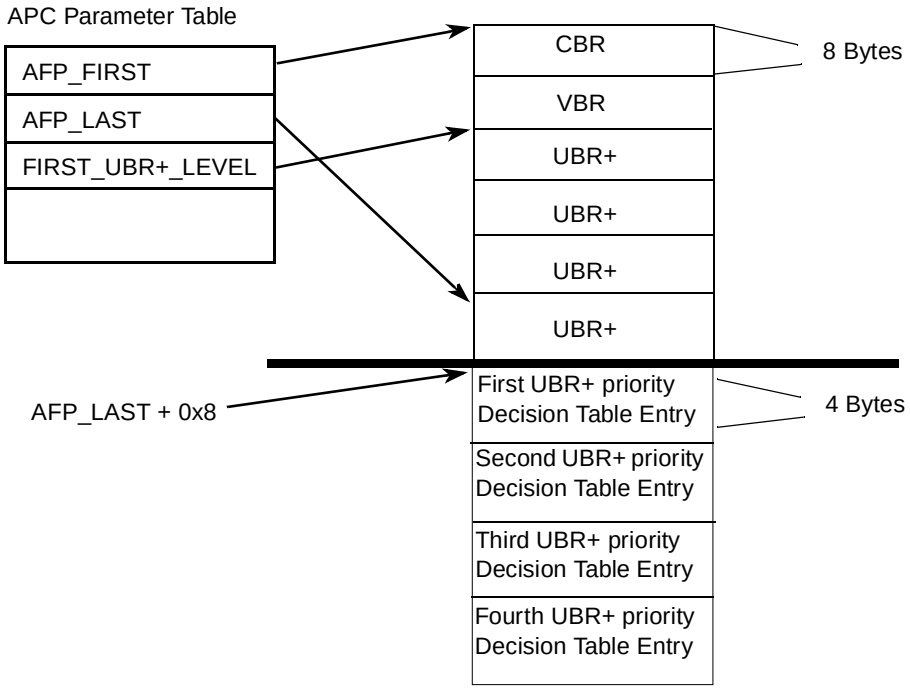

Figure 32-8. UBR+ Priority Table Example

32.2.11 Determining the Priority of an ATM Channel

The priority mechanism is implemented by adding priority table levels, which point to separate scheduling tables, see Section 32.3.6, "APC Data Structure." The APC flow control services the APC_LEVEL1 slots first. If there are no cells to send, the APC goes to the next priority level. The APC has up to eight priority levels with APC_LEVEL8 being the lowest. The user specifies the priority of an ATM channel when issuing the ATM TRANSMIT command; see Section 32.4.1, "ATM Commands."

The real-time channels, CBR and VBR-RT, should be inserted in APC_LEVEL1; non-real-time channels, VBR-NRT, and UBR should be inserted in lower priority levels.

32.2.12 GCRA Scheduler

The Generic Cell Rate Algorithm scheduler mechanism is a non-work conserving ATM scheduler, similar to the traditional APC. This CGRA scheduler method is ideal for systems with a large number of PHYs per UCC, the number of channels per PHY is relatively small (up to 64 channels or for a smaller memory

footprint 32 channels), and the variance between the channels rates is big. This is normally the case in DSLAM applications. The big advantages of the CGRA scheduler method compared to the traditional APC algorithm are the smaller internal RAM usage and the improvement in performance.

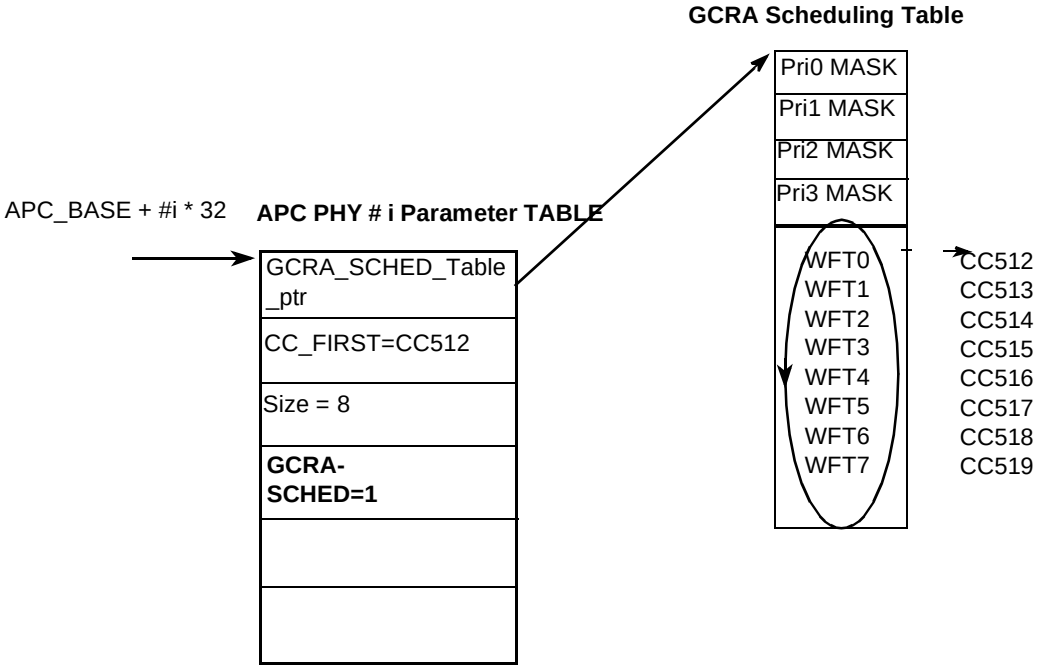

Figure 32-9. GCRA Scheduling structure

Figure 32-9 describes an example of GCRA scheduler. Each PHY which is programmed to work in GCRA scheduler mode, points to a GCRA scheduling table. This table contains the timing information (WFT) for a GCRA algorithm for each channel. The algorithm checks eligibility of all the channels to transmit. The channel which has the highest credit at a given time is selected for transmission. Once transmitting a cell the, GCRA is updated and the channel is rescheduled for transmission according to the parameters specified. Up to four priority levels are available for each PHY. Each priority has its own Priority MASK register, which identifies which channel out of the 64 available channels belongs to the priority level. The search in each priority is performed based on the bits which are set in the mask register. This MASK is also useful for polling mode. The QUICC Engine block clears this bit when there is nothing to transmit from the channel code (TCT[AVCOFF]=1), and the core set this bit, by issuing an ATM TRANSMIT COMMAND, when the next buffers are ready for transmission. In this way the QUICC Engine block is better utilized since channels with an empty queues are not taking part in the selection process.

The GCRA scheduler enables full utilization of the bandwidth in addition to the non work conserving GCRA. If no channel is eligible for transmission at a given time or in the case where the scheduler is empty there is another transmit queue which contains a list of channels for transmission. those are transmitted in a work conserving scheduling using round-robin algorithm for scheduling, This mode is useful for UBR channels. Transmission from this link is done without any comparison to the system time and without performing rescheduling to these channels.

For more information about the GCRA scheduler structures See Section 32.3.7, “GCRA Scheduler Structures”.

32.2.12.1 GCRA Scheduler Rate Programming

The values which are programmed in the TCT/TCTE are different then the standard APC and they have a meaning of timing. Time is measured by the QUICC Engine time stamp and a normalized time unit called “Increment”-INC is defined such that it reflect the time for transmitting a single cell at a specified rate. The formula for calculating the value of the INC parameter is described below:

$$\mathbf{INC = 424/(TSR\ Time\ Unit[Sec] \times Channel\ Rate[bps])}$$

NOTE

Programming of CETSCR time unit should be such that each tick is smaller than the cell transmission time of the fastest channel in the APC tables.

When programming a rate value in an ATM channel the values programmed are no longer specified in APC slot but in normalized time units so that PCR->1/PCR, SCR->1/SCR, OOBR-> 1/OOBR and MCR->1/MCR.

Example 32-1. GCRA Scheduler Programming:

Assuming the highest rate is CH #5, rate= 12Mbps and the lowest rate is CH #6, rate = 32Kbps. If using Time unit which is at the highest rate then value for CH #5 INC is 1, and the value for CH #6 INC is 12M/32K= 375. The Time stamp time unit should be programmed to:

Time Unit=424/12M=35.3 uS.

In case the Time Unit is 1usec., then we get:

$INC\ (CH5)=424/(1 \times 10^{-6} \times 12 \times 10^{6})=35.3 => PCR=0x23,\ PCR\ FRAC=0x55$

$INC\ (CH6)=424/(1 \times 10^{-6} \times 32 \times 10^{3})==>PCR=0x33B5\ PCR\ FRAC=0x80$

32.2.12.2 Dynamic Adding and Removing channels

Removing a channel from the GCRA scheduling table is done by setting the TCT[STPT] bit or by setting the TCT[AVCOFF] bit. In both cases, the QUICC Engine block is responsible to clear the corresponding bit in the Pri_MASK entry in the GCRA scheduler PHY Parameter Table. The host must not change this bit by itself.

To add a channel to the GCRA scheduling table, the user must issue an ATM TRANSMIT command, see Section 32.4.1, “ATM Commands.” This command actually sets the corresponding bit in the Pri_MASK field.

32.2.13 Hierarchical Scheduling

32.2.13.1 Frame Based Scheduling

In some applications the number of VCs is limited while there is still a need to maintain a few types of QOS for each VC. The standard definition of an ATM channel in the QUICC Engine block can support a single queue for transmission. It is not allowed to have several ATM channels having the same VPI/VCI, especially when running AAL5 traffic, since it could cause interleaving of data, and for this reason it is required to establish an hierarchy for transmission for each ATM channel. A channel is scheduled according to predefined contract using APC or GCRA scheduler. This channel can support up to eight queues for transmission, all queues have the same VPI/VCI. Selection is done by a WFQ algorithm. Once a queue is selected, the transmission from this queue continues until a complete frame is transmitted. See complete programming model in Section 32.3.8, “Hierarchical Scheduling.”

32.2.13.2 Hierarchical Cell Based Scheduling

The QUICC Engine block allows hierarchical scheduling where each queue in the second hierarchy has a different VPI/VCI. There is no potential interleaving problem between different AAL5 frames. The WFQ selection is performed a single ATM cell is transmitted. This functionality is described in Section 32.3.8, “Hierarchical Scheduling

32.2.14 VCI/VPI Address Lookup Mechanism

The QUICC Engine block supports three ways for address look up of incoming cells:

- Address compression see Section 32.2.14.1, “Address Compression”
- Mini-CAM address look-up see Section 32.2.14.2, “Mini-CAM Address Look-Up”
- Channel Code extracted from User Defined Cell header. see Section 32.2.16.1, “Channel Code Extracted from UEAD_OFFSET”

Writing to GMODE[ALM] (address-lookup-mechanism bits) in the parameter RAM selects the mode of operation. These three modes are described in the following sections.

32.2.14.1 Address Compression

The address compression mechanism uses two levels of address translation to help minimize the memory space needed to cover the available address range. The first level of translation (VP-level) uses a look-up table based on the Utopia bus ID, PHY address and the 12-bit virtual path (VP) identifier; the second level (VC-level) uses the 16-bit virtual channel identifier. If there is no match during address compression, the cell is considered a miss-inserted cell.

During the VP-level translation, VP_MASK in the ATM parameter RAM compresses an incoming cell’s Utopia ID, PHY address and VPI to create an index into the VP-level table. The VP-level table entry consists of another mask (VC_MASK) and a pointer to one of the VC-level tables (VCOFFSET). Note that the VP table is recommended to reside in the multi-user RAM.

In the VC-level translation, the VCI is compressed with the VC_MASK to generate a pointer to the VC-level table entry containing the received cell's channel code. The VC table should reside in external memory.

Figure 32-10 shows an example of address compression.

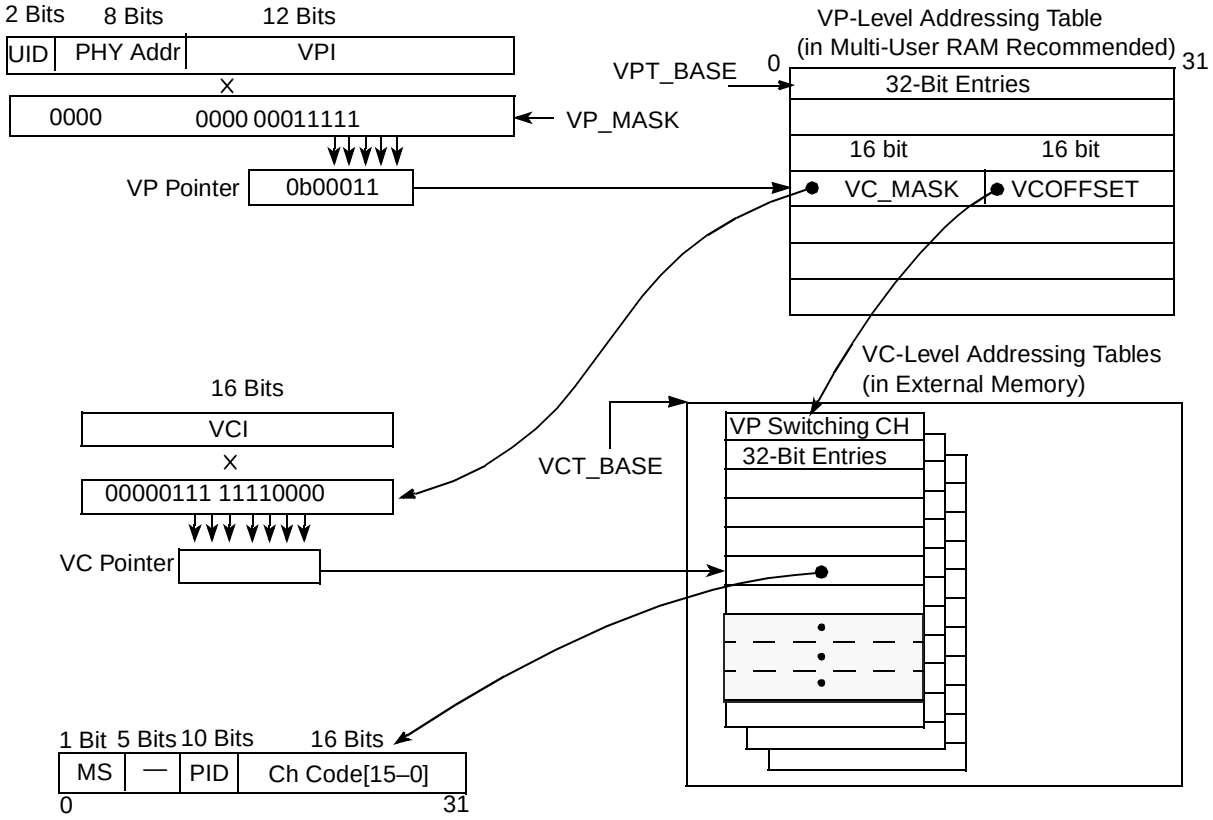

Figure 32-10. Address Compression Mechanism

Figure 32-10 shows VP_MASK selecting five VPI bits to index the VP-level table. The VP-level table entry contains the 16-bit mask (VC_MASK) and the VC-level table offset (VCOFFSET) for the next level of address mapping. The VC_MASK selects VCI bits 4–10, which is used with VCT_BASE and VCOFFSET to indicate the received cell's channel code. Address compression field descriptions are shown in Table 32-2.

Table 32-2. Field Descriptions for Address Compression

Bits	Name	Description
	UID	Utopia ID. Indicates the UTOPIA bus on which the ATM cell has been received.
	PHY Addr	In multiple PHY mode, this field contains the PHY address. PHY ID should be treated as follows: 5 LSBs represent the 5 address lines of the UTOPIA interface and 3 MSBs represent the device ID.
	GFC+VPI, VCI	The GFC, VPI, and VCI of the current channel.
0	MS	Match status. 0 Match was found. 1 Match was not found.

Table 32-2. Field Descriptions for Address Compression (continued)

Bits	Name	Description
1–5	—	Reserved, should be cleared.
6–15	PID	UPC ID. The bits are used to determine which UPC table is used for policing of this channel. 0 - UPC is disabled. 1-31 - UPC tables reside in the internal multi-user RAM starting from address INT_UPC_BASE. 32-1023 - UPC tables reside in external memory starting from address EXT_UPC_BASE.
16–31	Ch Code	Pointer to internal or external connection table.

32.2.14.1.1 VP-Level Address Compression Table (VPLT)

The size of the VP-level table depends on the number of mask bits in VP_MASK. This level mask can contain up to 22 bits. It contains the UTOPIA ID which is 2 bits, Phy address which has 8 bits assigned, and 12 bits for the GFC+VPI of the incoming ATM cells. For example, if only one PHY is available (PHY address = 0) and VPMASK = 0b11_1111_1111, VP pointer contains ten bits and the table is 4 Kbytes. Because each VPLT entry is 4 bytes, the address of an entry is VPT_BASE + VP pointer × 4.

Each VPLT entry has two parameters:

- VC_MASK—A 16-bit VC-level mask for masking the incoming cell's VCI
- VCOFFSET—A 16-bit VC-level table offset from VC_BASE that points to the appropriate VC-level table's (VCLT) starting address. The address of the VCLT is VC_BASE + VCOFFSET × 4.

  If the VCLTs are to be placed contiguously in memory, each table's VCOFFSET depends on the size of preceding tables. Each table's size depends on the number of ones in VC_MASK. Figure 32-11 gives the general formula for determining VCOFFSET.

General formula: $VCOFFSET_{(n+1)} = VCOFFSET_n + 2^{(\text{number of ones in VC\_MASKn})}$

Figure 32-11. General VCOFFSET Formula for Contiguous VCLTs

Table 32-3 shows example VCOFFSET calculations for a VP-level table with four entries.

Table 32-3. VCOFFSET Calculation Examples for Contiguous VCLTs

VP-Level Table Entry	VC_MASK	Number of Ones in VC_MASK	VC-Level Table Size	VCOFFSET
0	0x0237	6	2^6 = 64 entries	0
1	0x0230	3	2^3 = 8 entries	64
2	0xA007	5	2^5 = 32 entries	64 + 8 = 72
3	x	x	x	72 + 32 = 104

IMPORTANT: Since the offset field in each VPLT entry pointing to a VCLT table is only 16-bits, the maximum number of VC entries is limited to 64K VC's. In some configuration this might not be enough. For example: A multi PHY system with 128 PHYs where the number of the mask bit on the VP is 6 bits. This takes 7+6=13 bits for the VP level. There are 2^{13} VP level entries. Each entry should have its offset

to the VC level table. Since the VCT Base is common to all we have, on the average, a maximum of 2^3= 8 entries per VC table which might not be enough.

In order to solve this, there is an option to access the VC level with a different scale factor which span the memory and the tables could be bigger. Instead of accessing the table by:

VCLT = VC_BASE + VCOFFSET × 4, it uses a different scale factor (VCLT_SF) which is programmable. The address now is: VCLT = VC_BASE + VCOFFSET × $2^{(VCLT\_SF+2)}$. If the scale factor is not zero the offset calculation for each VCLT is different and has

The QUICC Engine block can check that all unallocated bits of the UID+ PHY + VPI are 0 by setting GMODE[CUAB] (check unallocated bits) in the parameter RAM. In case there are some un-allocated bit the QUICC Engine block will treat the incoming cell as a miss-inserted cell and discard the cell. Table 32-4 gives an example of VP-level table entry address calculation.

Table 32-4. VP-Level Table Entry Address Calculation Example

VPT_BASE	VP-Level Table Size	VP_MASK	UID+Phy+VPI	VP Pointer	VP Entry Address
0x0024_0000	64 entries	0x0237	0x0011	0x09	VP Base = 0x240000 0x09 x 4 = 0x000024 0x240024

Figure 32-12 shows the VP pointer address compression from Table 32-4.

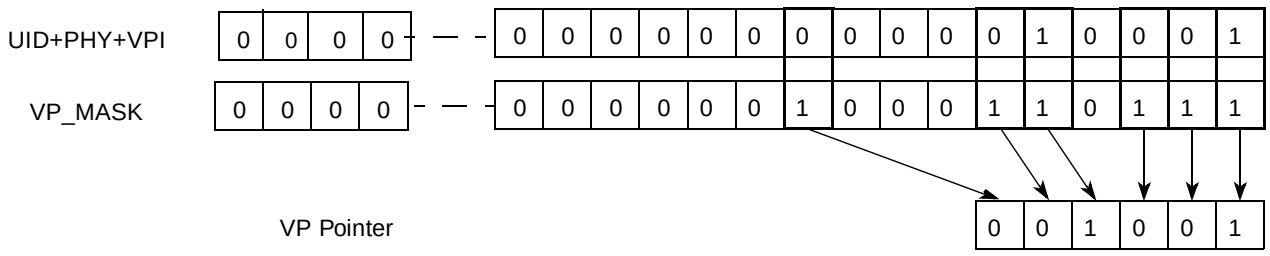

Figure 32-12. VP Pointer Address Compression

32.2.14.1.2 VC-Level Address Compression Tables (VCLTs)

Each VPLT entry points to a single VCLT. Like the VPLT, the size of each VCLT depends on VC_MASK. Because the VCLT contains word entries, if VC_MASK = 0b11_1111_1111, the table is 4 Kbytes. By default, the address of an entry in this table is VCT_BASE + VCOFFSET × 4 + VCpointer × 4, but it could be programmed to a different scale factor in order to span a bigger memory space when more VC are needed.

In the VC level the QUICC Engine block can check that all unallocated VCI bits are 0 by setting GMODE[CUAB] (check unallocated bits). If they are not, the cell is considered a miss-inserted cell. or alternatively, based on a mode in the UCC MODES, activate a **VP switching** flow where all incoming traffic is directed to a dedicated ATM VC. In this case the default ATM channel is located at the first VC-level table at offset 0x0.

An example of VC-level table entry address calculation is shown in Table 32-5. Note that VCOFFSET is assumed to be 0x100 for this example.

Table 32-5. VC-Level Table Entry Address Calculation Example

VCT_BASE	VCOffset	VC-Level Table Size	VC_MASK	VCI	VC Pointer	VC Entry Address
0x0084_0000	0x0100	32 entries	0x0037	0x0031	0x19	VC Base = 0x840000 0x100 x 4 = 0x000400 0x19 x 4 = 0x000064 0x840464

Figure 32-13 shows the VC pointer address compression from Table 32-5.

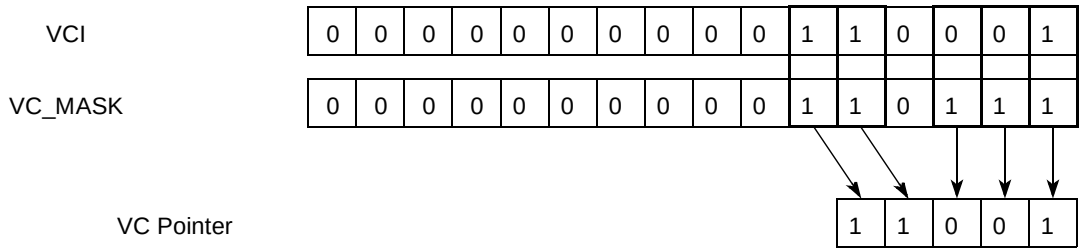

Figure 32-13. VC Pointer Address Compression

32.2.14.1.3 Dynamic Change of Address Compression Tables

It is possible to change the lookup table dynamically to get an updated mapping of ATM channels without the need to stop operation of the devices. See detailed description at Section 32.3.2.8, “Dynamic Address Compression Table change”.

32.2.14.2 Mini-CAM Address Look-Up

This mode of operation is suitable for systems where the number of VPI/VCI is relatively small. It is efficient due to the fact all the look-up is performed in internal MURAM and there is no access to external memory through DMA operations. The MURAM consumption is reduced significantly if the VPI/VCI are repetitive on the PHYs. The principal of this look-up is to have a match on a [GFC]VPI/VCI on a mini-CAM table located in the MURAM.

For each UCC there is a Mini CAM parameter table containing common parameters for this UCC. It replaces the Dynamic Address Look-up table. It contains a base address for the PHY table and for the array of mini-CAM tables for each PHY as indexed from the PHY table. Figure 32-14 illustrates the operation of this look-up

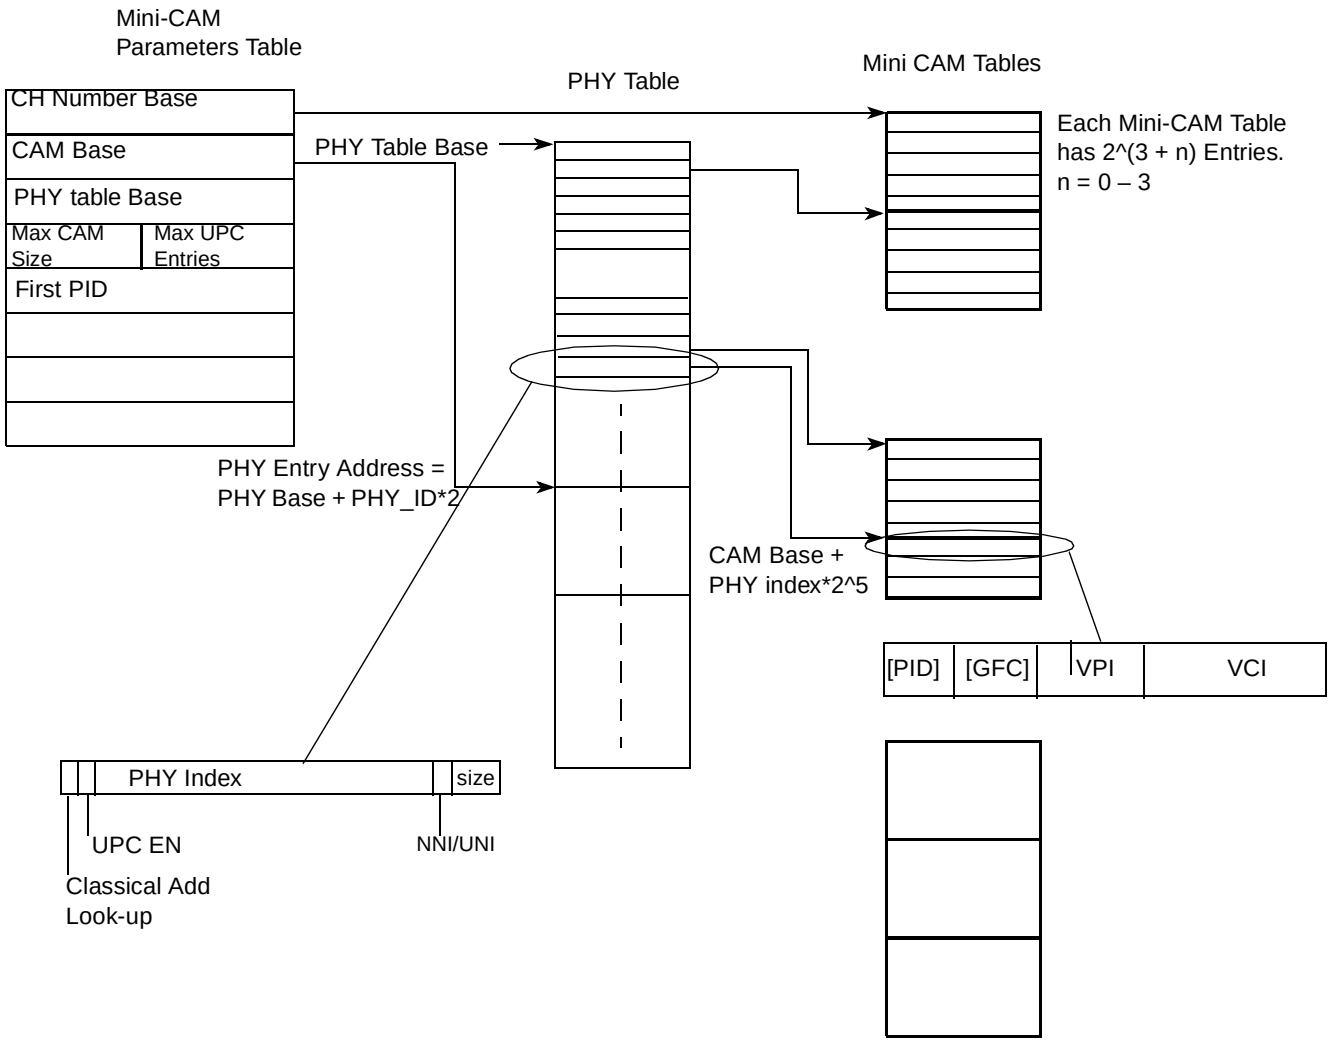

Figure 32-14. Mini-CAM Address Look-Up

The data structures used in this address look-up mode are described in the following paragraphs:

32.2.14.2.1 Mini CAM Parameter Table

When working in Mini CAM look-up this table replaces the dynamic address look-up table. It is described in details in Table 32-27. It contains the following fields:

Base_Channel# - This is the base channel number for calculations of the ATM channel code.

Mini-CAM_base - Base offset in the MURAM to the mini CAM tables

PHY_table_base - Base offset in the MURAM offset, to the PHY table

Max_MC_size - Number of entries in the largest mini CAM table in the system. Size of this table could be one of the following: 8,16,32,64. The value programmed in Max_MC_size is the power of 2 of the size so values are 3,4,5,6 respectively.

Max_UPC_Entries - If Policing is enabled in this PHY up to 15 PID (Policer ID) are available for each PHY. This value is maximum value of UPCs used for any of the PHYs. This value should be rounded to the next power of 2. The value programmed in Max_UPC_Entries is the power of 2 of the size (for example if the maximum number of UPCs used per PHY is 5 set this value to 3)

First_PID - The first Policer ID used in the system. Any of the UPCs used is calculated based on this number.

32.2.14.2.2 PHY Table

Each entry in the table is indexed by the PHY ID and consists of two bytes:

Bits 14-15 determines the number of entries in the mini-CAM table (0b00=8, 0b01=16, 0b10=32, 0b11=64) The size of the mini-CAM table should be set in such a way that it will contain all the required VC's and minimizes the size of the table. In this way MURAM usage is smaller and the performance is increased.

Bits 13 defines UNI/NNI mode (i.e. in NNI mode keep GFC and in UNI clear GFC for address check in lookup)

Bits 2-12 defines index into the Mini-CAM_base using 2^(5)*index as the mini-CAM address for this PHY.

Bit 1 UPC enabled for this PHY

Bit 0 - use classical lookup method and NOT the mini-CAM for this PHY. Use the Address look-up table as the table for the address compression parameters.

32.2.14.2.3 Mini-CAM Table

This is the Mini-CAM table for each PHY. It contains the actual GFC/VPI/VCI which are searched for this PHY. In cases where some PHYs uses identical GFC/VPI/VCI the index value in the PHY table entries for these PHY should be identical so that the mini-CAM tables are overlapping. The actual ATM channel number is different as it is based on the following calculation:

Channel# = Base_Channel# + PHY_ID * Max_MC_size + Mini-CAM index

If Policing is enabled the four MSB of each entry are used to identify a Policer ID to be used for this VPI/VCI. A zero in these bits indicate No Policer is enabled

PID# = First_PID + PHY_ID * Max_UPC_Entries + mini-CAM entry[PID]

32.2.14.2.4 Mini-CAM Lookup Process

Figure 32-15 is a schematic flow of the look-up process.

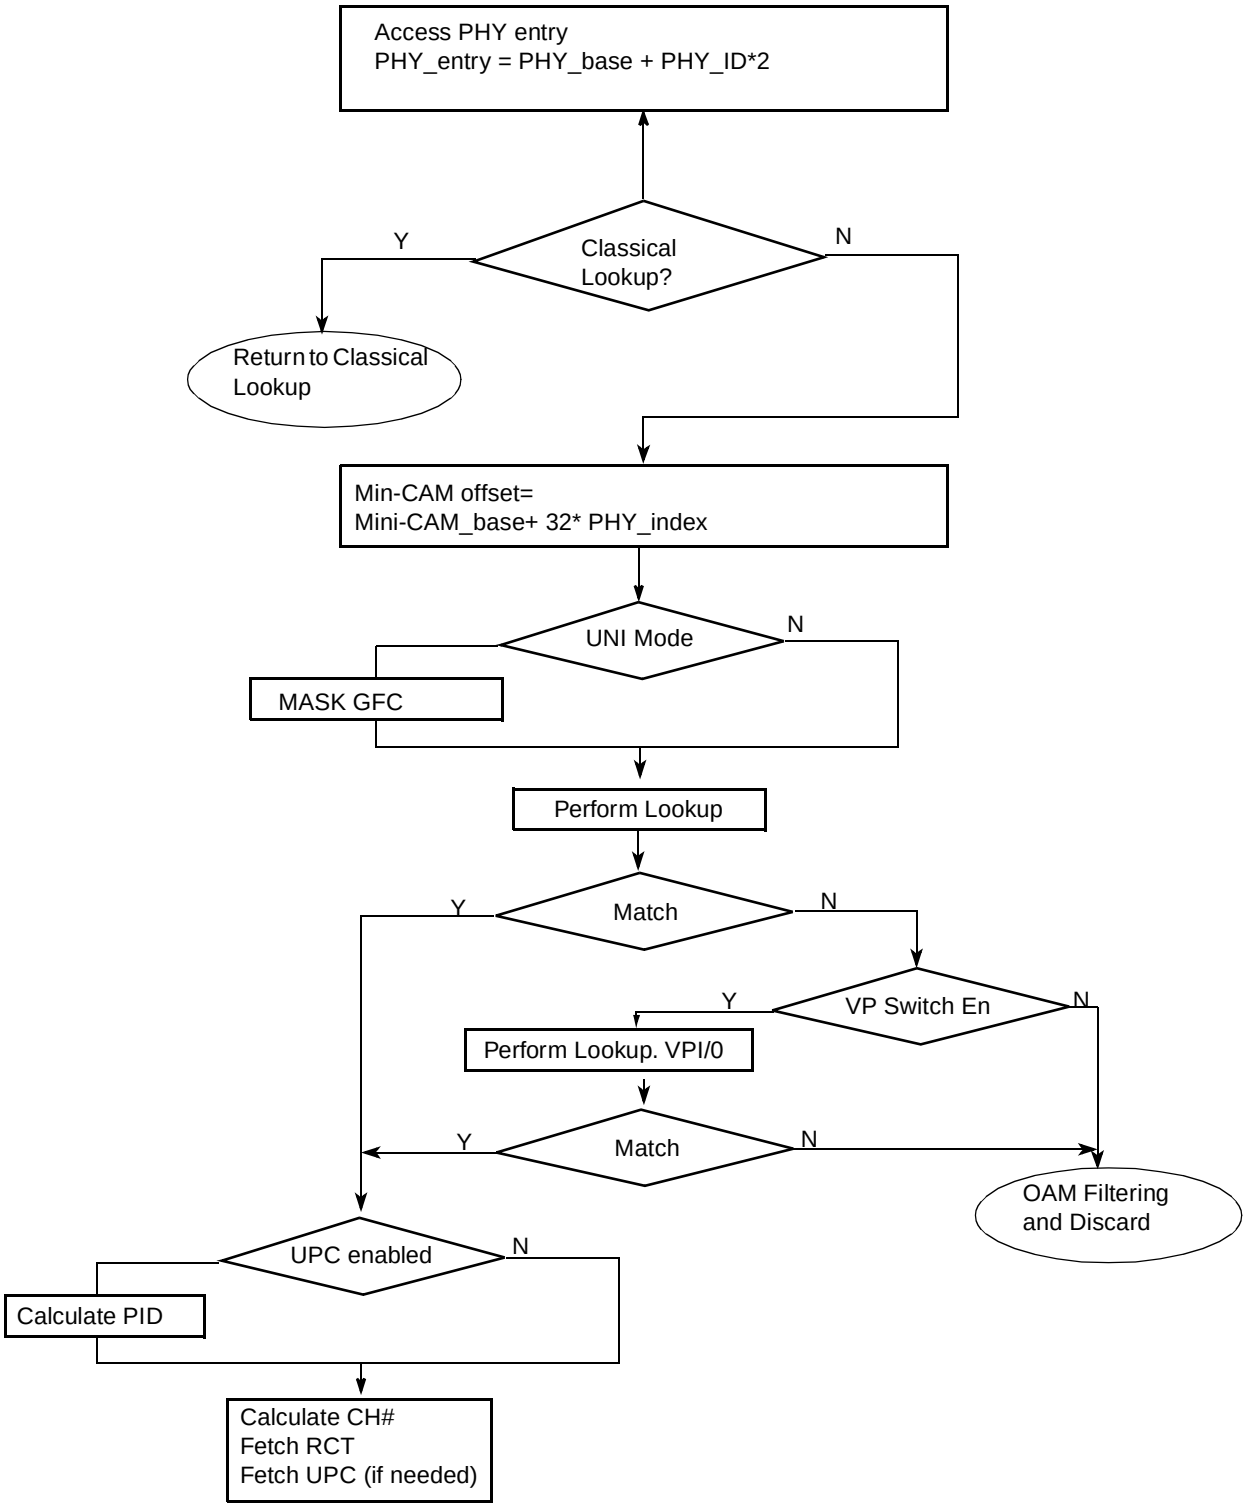

Figure 32-15. Mini-CAM Look-Up Flow

32.2.15 Miss-Inserted Cells

If the address lookup mechanism cannot find a match (MS=1), the cell is discarded and ATM layer statistics are updated, as described in Section 32.2.21, “ATM Layer Statistics.”

32.2.16 User-Defined Cells (UDC)

Typical ATM cells are 53 bytes long and consist of a 4-byte header, 1-byte HEC, and 48-byte payload. The QUICC Engine block also supports user-defined cells with up to 12 bytes of extra header fields for internal information for switching applications. This choice is made during initialization by writing to the UPSMR, see Section 33.6.5.1, “UPDCx in ATM Protocol.” As shown in Figure 32-16, the extra header size can vary between 1 to 12 bytes (byte resolution) and the HEC octet is optional.

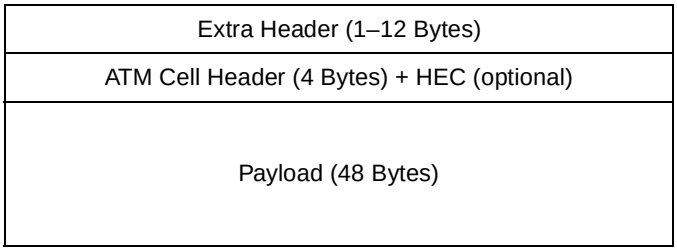

Figure 32-16. Format of User-Defined Cells

For AAL5 and AAL1 CES the extra header is taken from the Rx and Tx BDs. The transmitter reads the extra header from the UDC TxBD and adds it to each ATM cell associated with the current buffer. At the receive side, the extra header of the last cell in the current buffer is written to the UDC RxBD. For AAL0 the extra header is attached to the regular ATM cell in the buffer. The transmitter reads the extra header and the ATM cell from the buffer. The receiver writes the extra header and the regular ATM cell to the buffer.

32.2.16.1 Channel Code Extracted from UEAD_OFFSET

When working in User Defined Cells mode enabled, it is sometimes more efficient to disable the address look-up mechanism and to read the Channel Code (16 bits) directly from the Extra Header; this mode is enabled by programming GMODE[ALM]=10 (see section Section 32.3.2.5, “Global Mode Entry (GMODE)”). When using this mode, the UTOPIA port must set to User Define Cells (UDC) mode and include at least 2 bytes of Extra Header. CH_CODE_OFFSET entry in the parameter RAM specified the offset of the CH_CODE entry from the beginning of the Extra Header field. It should be an even address.

The CH_CODE entry can be located in 6 locations within the Extra Header. For each location CH_CODE_OFFSET should be set as shown in Table 32-6.

Table 32-6. CH_CODE Location In Extra Header

0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15	16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31
CHANNEL_CODE_OFFSET=2	CHANNEL_CODE_OFFSET=0
CHANNEL_CODE_OFFSET=6	CHANNEL_CODE_OFFSET=4
CHANNEL_CODE_OFFSET=10	CHANNEL_CODE_OFFSET=8

32.2.16.1.1 Channel Code Protection Mode

In “Read Channel code from Extra Header” mode, there is an optional protection mechanism, to prevent handling of cells with corrupted channel code. If enabled, in GMODE[ALM]=11 (see section Section 32.3.2.5, “Global Mode Entry (GMODE)”), the QUICC Engine block expects two occurrences of the same channel code appearing in the UDH (extra header) one after the other. The QUICC Engine block compares the two values, and processes the cell only if they are identical. Otherwise, the cell is treated as a miss-inserted cell—same treatment as in the case where MS=1 in the previous address lookup mechanisms. See section Section 32.2.15, “Miss-Inserted Cells.” Note that if the protection mode is enabled, the value of CHANNEL_CODE_OFFSET cannot exceed 8, since we need 4 bytes for the 2 occurrences of the channel code (max UDH size is 12 bytes). The CHANNEL_CODE_OFFSET points to the first occurrence of the channel code in the UDH (extra header).

32.2.17 Receive Raw Cell Queue

Each UCC has a raw cell queue designated for OAM handling. This queue is managed by a designated ATM Channel per UCC (RCT) which is called the raw cell queue. The user should program this channel to operate in AAL0 mode. This channel’s parameters are pointed by **OAM CH RCT PTR** which resides in parameter page of each UCC. For details see Table 32-18.

NOTE
On Backward Compatibility

Allocating AAL0 RCT for raw cell queue is no longer by allocating channel #1 as the channel for raw cell queue. Channel #1 shouldn’t be assigned in the system at all!

The receive raw cell queue is used for removing management cells from the regular cell flow to the host. When a management cell is sent to the receive raw cell queue, the QUICC Engine block sets RxBD[OAM]. The ALL0 BD specifies the channel code associated with the current OAM cell. Interrupt entry for ALL the OAM cells will contain the CC - Channel code #1 as the cause for the interrupt. The OAM buffer will contain the Time stamp value on which it has been received.

The following are optionally removed from the regular flow and sent to the raw cell queue:

- Segment F5 OAM (PTI = 0b100). To enable F5 segment filtering, set RCT[SEGF].
- End-to-end F5 OAM (PTI = 0b101). To enable F5 end-to-end filtering, set RCT[ENDF].
- RM cells (PTI = 0b110). They are sent to the raw cell queue.
- Reserved PTI value (PTI = 0b111). Always sent to the raw cell queue.
- VCI value: 3, 4, 6, 7–15. To enable VCI filtering set the associated bit in the VCIF entry in the parameter RAM.

Figure 32-17 shows a flowchart of the ATM cell flow.

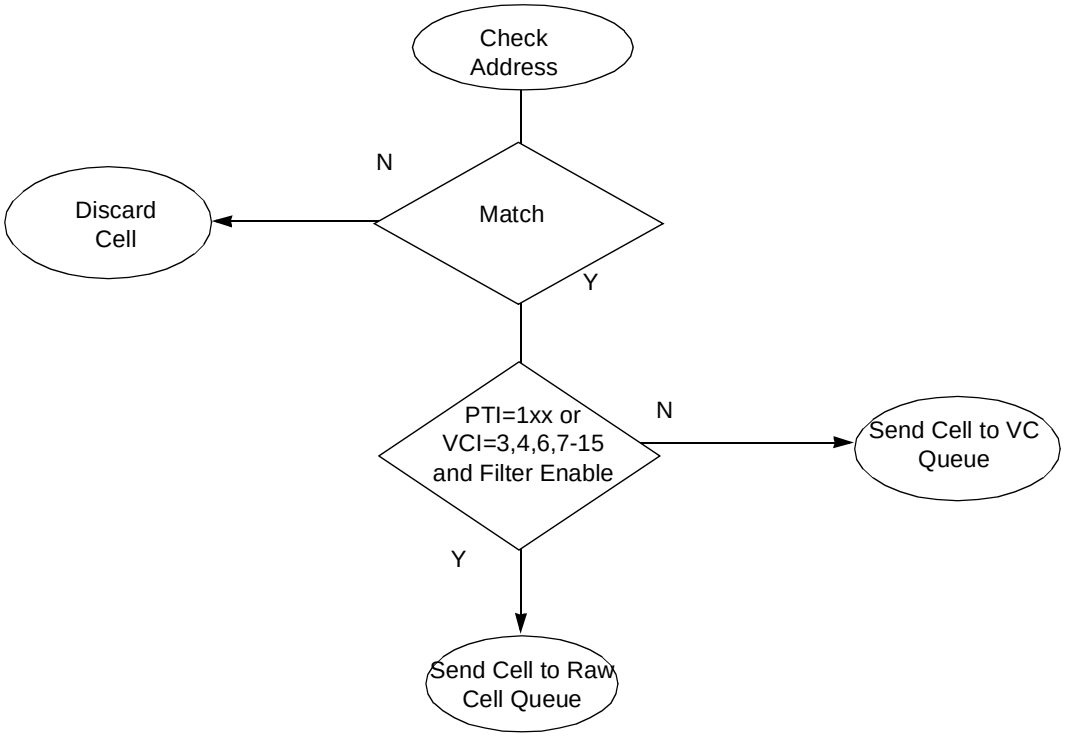

Figure 32-17. ATM Address Recognition Flowchart

NOTE

Even reserved VCI channels should appear in the CAM or address compression tables; otherwise, a cell on a reserved channel is considered miss-inserted.

32.2.18 OAM Support

This section describes the QUICC Engine block's support for ATM-layer (F4 out-of-band, and F5 in-band) operations and maintenance (OAM) of connections. Alarm surveillance, continuity checking, remote defect indication, and loopback cells are supported using OAM receive and transmit AAL0 cell queues. Using dedicated support, performance management block tests can be performed on up to 64 connections simultaneously. The QUICC Engine block automatically inserts forward monitoring cells (FMC) and generates backward-reporting cells (BRC) as recommended by ITU I.610.

32.2.18.1 ATM-Layer OAM Definitions

Table 32-7 lists pre-assigned header values at the user-network interface (UNI).

Table 32-7. Pre-Assigned Header Values at the UNI

Use	GFC	VPI	VCI	PTI	CLP
Segment OAM F4 flow cell	xxxx	aaaa_aaaa	0000_0000_0000_0011	0a0	a
End-to-end OAM F4 flow cell	xxxx	aaaa_aaaa	0000_0000_0000_0100	0a0	a
Segment OAM F5 flow cell	xxxx	aaaa_aaaa	aaaa_aaaa_aaaa_aaaa	100	a
End-to-end OAM F5 flow cell	xxxx	aaaa_aaaa	aaaa_aaaa_aaaa_aaaa	101	a

a = available for use by the appropriate ATM layer function

Table 32-8 lists pre-assigned header values at the network-node interface (NNI).

Table 32-8. Pre-Assigned Header Values at the NNI

Use	VPI	VCI	PTI	CLP
Segment OAM F4 flow cell	aaaa_aaaa_aaaa	0000_0000_0000_0011	0a0	a
End-to-end OAM F4 flow cell	aaaa_aaaa_aaaa	0000_0000_0000_0100	0a0	a
Segment OAM F5 flow cell	aaaa_aaaa_aaaa	aaaa_aaaa_aaaa_aaaa	100	a
End-to-end OAM F5 flow cell	aaaa_aaaa_aaaa	aaaa_aaaa_aaaa_aaaa	101	a

a= available for use by the appropriate ATM layer function

32.2.18.2 Virtual Path (F4) Flow Mechanism

The F4 flow is designated by pre-assigned virtual channel identifiers within the virtual path. The following two kinds of F4 flows can exist simultaneously:

- End-to-end (identified as VCI 4)—This flow is used for end-to-end VPC operations communications. Cells inserted into this flow can be removed only by the endpoints of the virtual path.
- Segment (identified as VCI 3)—This flow is used for communicating operations information within one VPC link or among multiple interconnected VPC links. The concatenation of VPC links is called a VPC segment. Cells inserted into this flow can be removed only by the segment endpoints, which must remove these cells to prevent confusion in adjacent segments.

32.2.18.3 Virtual Channel (F5) Flow Mechanism

The F5 flow is designated by pre-assigned payload type identifiers. The following two kinds of F5 flow can exist simultaneously:

- End-to-end (identified by PTI = 5)—This flow is used for end-to-end VCC operations communications. Cells inserted into this flow can be removed only by VC endpoints.
- Segment (identified by PTI = 4)—This flow is used for communicating operations information with the bound of one VCC link or multiple interconnected VCC links. A concatenation of VCC

links is called a VCC segment. Segment endpoints must remove these cells to prevent confusion in adjacent segments.

32.2.18.4 Receiving OAM F4 or F5 Cells

OAM F4/F5 flow cells are received using the raw cell queue, described in Section 32.2.17, "Receive Raw Cell Queue." An F4/F5 OAM cell which does not appear in the mini-CAM or address compression tables is considered a miss-inserted cell.

32.2.18.5 Transmitting OAM F4 or F5 Cells

OAM F4/F5 flow cells are sent using the usual AAL0 transmit flow. For OAM F4/F5 cell transmission, program channel one in the TCT to operate in AAL0 mode. Enable the CR10 (CRC-10 insertion) mode as described in Section 32.3.4.2.3, "AAL0 Protocol-Specific TCT." Prepare the OAM F4/F5 flow cell and insert it in an AAL0 TxBD. Finally, issue a ATM TRANSMIT command to send the OAM cell. For multiple PHYs, use several AAL0 channels—each PHY should have one transmit raw cell queue that is associated with its scheduling table.

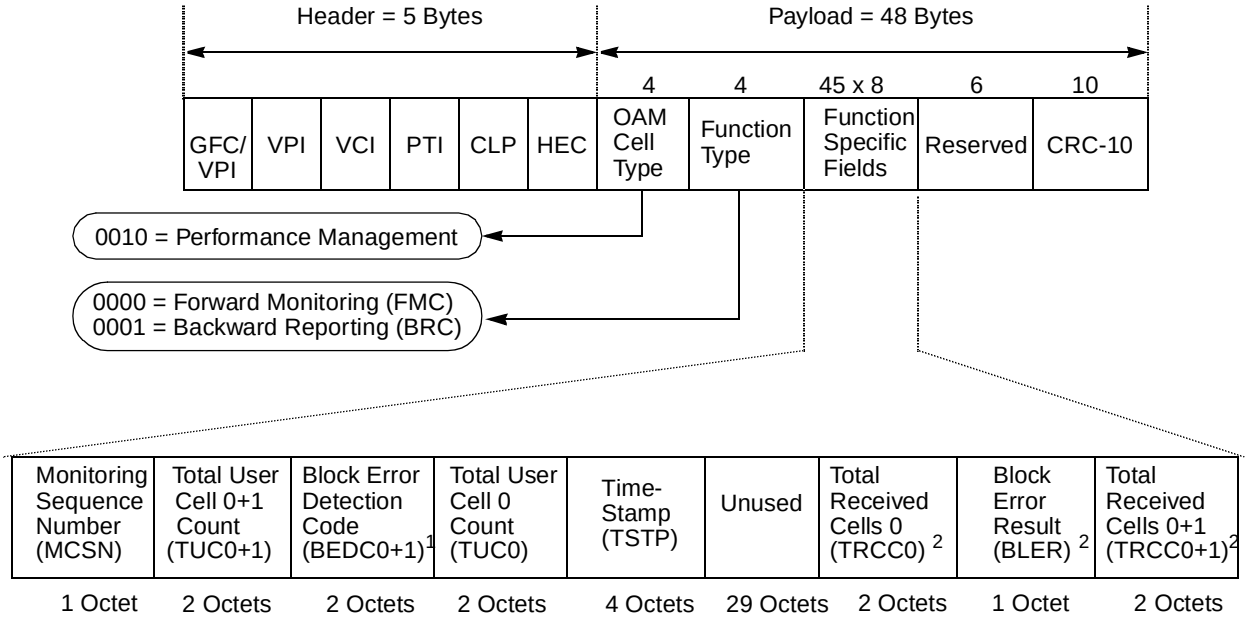
A series of OAM cells can be sent using one ATM TRANSMIT command by creating a table of AAL0 TxBDs. If the channel's TCT[AVCF] (auto VC off) is set, the transmitter automatically removes it from the APC (that is, it does not generate periodic transmit requests for this channel after all AAL0 BDs are processed).

32.2.19 Performance Monitoring

A connection's performance is monitored by inspecting blocks of cells (delimited by forward monitoring cells) sent between connection or segment endpoints. Each FMC contains statistics about the immediately preceding block of cells. When an endpoint receives an FMC, it adds the statistics generated locally across the same block to produce a backward reporting cell (BRC), which is then returned to the opposite endpoint.

The QUICC Engine block can run up to 64 bidirectional block tests simultaneously. When a bidirectional test is run, FMCs are generated for one direction and checked for the opposite.

Figure 32-18 shows the FMC and BRC cell structure.



1 $BEDC_{0+1}$ appears in FMCs only.

2 $TRCC_0$, BLER, and $TRCC_{0+1}$ appear in BRCs only.

Figure 32-18. Performance Monitoring Cell Structure (FMCs and BRCs)

Table 32-9 describes performance monitoring cell fields.

Table 32-9. Performance Monitoring Cell Fields

Field	Description	BRC	FMC
MCSN	Monitoring cell sequence number. The sequence number of the performance monitoring cell (modulo 256).	Yes	Yes
TUC_{0+1}	Total user cell 0+1 count. Counts all user cells (modulo 65,536) sent before the FMC was inserted.	Yes	Yes
TUC_0	Total user cell 0 count. Counts CLP = 0 user cells (modulo 65,536) sent before the FMC was inserted.	Yes	Yes
TSTP	Time stamp. Used to indicate when the cell was inserted.	Yes	Yes
$BEDC_{0+1}$	Block error detection code. Even parity over the payload of the block of user cells sent since the last FMC.	No	Yes
$TRCC_0$	Total received cell count 0. Counts CLP=0 user cells (modulo 65,536) received before the FMC was received.	Yes	No
BLER	Block error result. Counts error parity bits detected by the BEDC of the received FMC.	Yes	No
$TRCC_{0+1}$	Total received cell count 0+1. Counts all user cells (modulo 65,536) received before the FMC was received.	Yes	No

32.2.19.1 Running a Performance Block Test

For bidirectional PM block tests, FMCs are monitored at the receive side and generated at the transmit side. The following setup is required to run a bidirectional PM block test on an active VCC:

1. Assign one of the available 64 performance monitoring tables by writing to both RCT[PMT] and TCT[PMT] and initializing the one chosen. See Section 32.3.5, "OAM Performance Monitoring Tables."
2. For PM F5 segment termination set RCT[SEGF]; for PM F5 end-to-end termination set RCT[ENDF].
3. Finally, set the channel's RCT[PM] and TCT[PM] and the receive raw cell's RCT[PM].

For unidirectional PM block tests:

- For PM block monitoring only, set only the RCT fields above.
- For PM block generation only, set only the TCT fields above.

To run a block test on a VPC, assign all the VCCs of the tested VPC to the same performance monitoring table. Configure RCT[PMT] and TCT[PMT] to specify the performance monitoring table associated with each F4 channel.

32.2.19.2 PM Block Monitoring

PM block monitoring is done by the receiver. After initialization (see Section 32.2.19.1, "Running a Performance Block Test"), whenever a cell is received for a VCC or VPC, the TRCC counters are incremented and the BEDC is calculated. When an FMC is received, the QUICC Engine block adds the BRC fields into the cell payload ($TRCC_0$, $TRCC_{0+1}$, BLER) and transfers the cell to the receive raw cell queue. The user can monitor the BRC cell results and transfer the cell to the transmit raw cell queue.

Before the BRC is transferred to the transmit raw cell queue, the PM function type should be changed to backward reporting and additional checking should be done regarding the BLER field. If the sequence numbers (MCSN) of the last two FMCs are not sequential or the differences between the last two TUCs and the last two TRCCs are not equal, BLER should be set to all ones (see the ITU I.610 recommendation).

NOTE

TRCCs are free-running counters (modulo 65,536) that count user cells received. The total received cells of a particular block is the difference between TRCC values of two consecutive BRC cells. TRCC values are taken from a VC's performance monitoring table.

32.2.19.3 PM Block Generation

The transmitter generates the PM block. Each time the transmitted cell count parameter (TCC) in the performance monitoring table reaches zero, the QUICC Engine block inserts an FMC into the user cell stream. The QUICC Engine block copies the FMC header, SN-FMC, TUC_{0+1}, TUC_0, $BEDC_{0+1}$-Tx from the performance monitoring table and inserts them into the FMC payload. The TSTP value (FMC time stamp field) is taken from the QUICC Engine time stamp timer, see Section 20.3.9, "QUICC Engine Time-Stamp Control Register (CETSCR)."

The TUCs are free-running counters (modulo 65,536) that count transmitted user cells. The total transmitted cells of a particular block is the difference between TUC values of two consecutive FMCs. The BEDC (BIP-16, bit interleaved parity) calculation is done on the payload of all user cells of the current tested block. The performance monitoring block can range from 1 to 2K cells, as specified in the BLCKSIZE parameter in the performance monitoring table; see Section 32.3.5, "OAM Performance Monitoring Tables."

In Figure 32-19, the performance monitoring block size is 512 cells. For every 512 user cells sent, the ATM controller automatically inserts an FMC into the regular cell stream as defined in ITU I.610. When an FMC is received, the ATM controller adds the BRC fields to the cell payload and sends the cell to the raw cell queue. The user can monitor the BRC cell results and transfer the cell to the transmit raw cell queue.

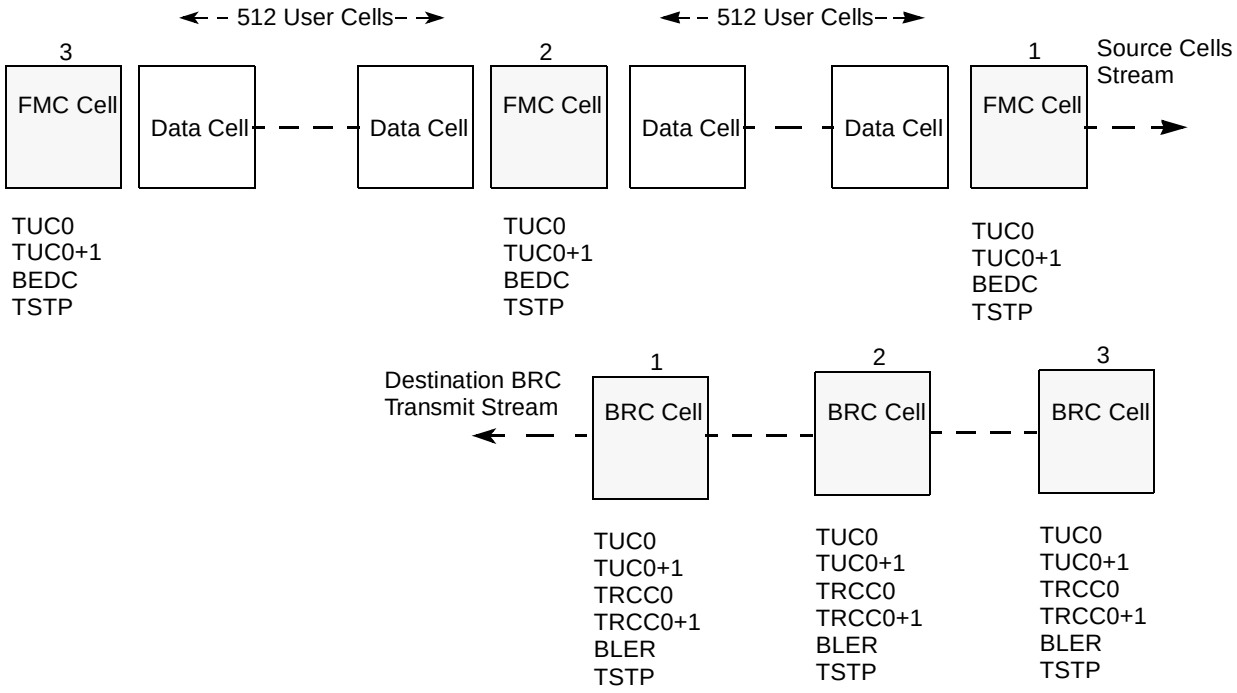


Figure 32-19. FMC, BRC Insertion

32.2.19.4 BRC Performance Calculations

BRC reception uses the regular AAL0 raw cell queue. On receiving two consecutive BRC cells, the management layer can calculate the following:

- The difference between two TUCs (Nt)
- The difference between two TRCCs (Nr)

Information about the connection can be gained by comparing Nt and Nr:

- If Nt > Nr, the difference indicates the number of lost cells of this block test.
- If Nt < Nr, the difference indicates the number of miss-inserted cells of this block test.
- When Nt = Nr, no cells are lost or miss-inserted.

32.2.20 UPC

The User Policer Controller (UPC) implements ATM forum's TM4.1 Virtual Scheduling algorithm. Providing a dual leaky bucket policing scheme, the UPC can detect cells that violates the traffic agreement (Non conformed cells) and optionally tag or discard them from the cell flow.

A Leaky Bucket parameter structure is defined either on a per connection (VCC) basis, per VPC basis, or per any arbitrary group of VCC's. Any address lookup resolution PID field output contains a pointer to a Dual Leaky bucket parameter structure (UPC parameter structure), see Table 32-5 and Table 32-4 for more description about the PID.

When policing has to be done for a group of VCC's (VCC's Bundle), then all the address lookup entries belonging to the same group have to point to the same UPC parameter structure. In this case the UPC controls the traffic stream generated by the unification of those VCC's.

Both leaky buckets independently perform the ATM Forum's TM4.1 **GCRA(I,L)** algorithm, where I and L express Bucket Increment and Bucket Limit respectively. In the UPC programming model, I is defined by **B1I** and **B2I** (Bucket 1 increment and Bucket 2 increment respectively), which is represented by an integer part, **B1II** (**B2II**), and a fraction part, **B1IF** (**B2IF**).

B1I (**B2I**) and **B1Lim** (**B2Lim**) represent the space between cells arrival times and the limits for leaky bucket 1 (2). Both have to be initialized by the user. The time units for both, the bucket increments and the bucket limits are identical to one-count time interval of the CETSCR - the QUICC Engine Time Stamp Control Register, see Section 20.3.9, "QUICC Engine Time-Stamp Control Register (CETSCR)."

The Theoretical arrival times for bucket 1 and bucket 2 (**B1T** and **B2T**) are internal variables which are maintained by the Leaky Bucket mechanism.

Each of the leaky buckets can be programmed to test GCRA conformance of CLP0, CLP1 or CLP0+1 cell streams, by setting the appropriate value to **LBF** (Leaky Bucket Filter) field (LBF1 for Leaky Bucket #1 and LBF2 for Leaky Bucket #2), see Table 32-10. Both LBF1 and LBF2 have to be initialized by the user.

Table 32-10. LBF - The Leaky Bucket Filter

Cell type monitored	LBF coding
Disable policing	000
GCRA CLP0 cell policing. CLP1 cells are bypassing this bucket	001
GCRA CLP1 Cell Policing. CLP0 cells are bypassing this bucket	010
GCRA CLP0+1 Policing. All cells are tested by this bucket	011
F-GCRA Policing. Can be applied only on bucket1, when using GFR mode. Only First cell of each packet with CLP=0 is tested for conformance. All the rest of the cells gets the same conformance result as first cell. If CLP=1 in the first cell the DM bit determines the action, which will preformed on the whole packet.	100
Reserved	101
Reserved	110

NOTE

OAM cells bypass the UPC (not checked by the UPC).

Only bucket1 can be programmed to test F-GCRA.

32.2.20.1 UPC Programming

Before enabling the UPC for any channel, the CETSCR must be initialized. The CETSR defines the time unit which is common to all leaky buckets and timestamps in the QUICC Engine block. Before a specific UPC is enabled, the following fields must be programmed:

- UPC Parameter Table fields (see Table)
- UPC Table fields (see Table 32-64. The CETSCR for the UPC is always CETSCR1.

The formula for the decimal representation of the bucket increment is:

```
A)       BI = CellSize/(BitRate x TimeUnit)
```

- BI is the decimal expression for the bucket increment.
- CellSize is the size of a cell on the physical media considered (in units of bits)
- TimeUnit is the time interval of one count of CETSR. Since CETSCR is global for all connections, TimeUnit has to be programed to be not bigger than the time required for one cell on the fastest connection.

After BI computation, it must be converted to hexadecimal fixed-point representation.

In the following example, the leaky bucket must be programmed for a connection with a rate of 16 Kbps, where the fastest connection in the system is 155 Mbps. We find the value of BI, assuming a cell size of 53 bytes:

```
B) TimeUnit <= 53x8/155Mbps = 2.735us
```

CETSCR is programmed to 2.7us. Substituting the value in (A) we get:

```
BI = (53x8)/(16kbps x 2.7us) = 9814.8148
```

Converting it to hexadecimal yields: BI = 0x2656.D09, which implies the following programming:

```
B1II[0:11] = 265, B1II[12:15] = 6, B1IF[0:11] = D09
```

The smallest data rate given by the substitution of BI = 64 K in (A), is 2400bps. The resolution is at least 0.02 %. The formula for the bucket limit is:

```
C) BLim = CDVT/TimeUnit
```

- BL is the decimal expression for the bucket's Limit.
- TimeUnit is the time interval of one count of CETSR. For details on TimeUnit, refer to the explanation of BI programming.

NOTE

The most significant bit of the BL value must be cleared.

Following the calculation in (C), the result is rounded to the closest integer and converted to a hexadecimal representation. The smallest value of L is 1 TimeUnit (2.7 us in the preceding example). The highest value is 190 min.

Example 32-2. Using PCR, CDVT

- Highest Frequency: 16 Mbps
- PCR = 1536 Kbps
- CDVT = 0.5 sec

```
TimeUnit <= 53x8/16Mbps = 26.5us.
```

This value of `TimeUnit` is larger than the highest possible value in CETSR, so we program CETSR to `TimeUnit` = 5us.

```
BI = (53x8)/(1536kbps x 5us) = 55.2083 -> BI= H37.355 -> BII=0037, BIF=355

BL = 0.5/5us = 100,000 -> BL=0x186A0
```

32.2.20.2 UPC Operation Modes

32.2.20.2.1 Cell Base UPC

When UPC Table[UPCM]=01, the UPC works in cell base mode. In this mode, the buckets can be configured to one of the GCRA mode. Cell which fails in the bucket1/2 test will be dropped or tagged according to DM1/2. Tagging is done by setting PNC bit in the RxBD. The host software can tag outgoing cells according to PNC.

32.2.20.2.2 Frame Awareness UPC

When UPC Table[UPCM]=10, the UPC use frame awareness mode. The buckets can be configured to one of the GCRA mode or to F-GCRA which is explained in Section , “GFR Frame-Eligibility (F-GCRA)”. Cell which fails in the bucket1/2 test will be tagged and might be dropped according to DM1/2. Tagging is done by setting PNC bit in the cell RxBD and also in the last BD of the frame. If a cell is dropped, all remaining cells of that frame are dropped, except the last cell. The last cell can be dropped only if it is also the first cell or if the first cell was dropped. When frame or part of it, is dropped, FDC (Frame Drop Counter) is updated. If AAL5 frame is partially dropped, crc error and length error will occur in the last RxBD of the frame.

32.2.20.2.3 GFR UPC

When UPC Table[UPCM]=11, the UPC works in GFR mode. In this mode, the following test are done on each cell:

1. Buckets test: **GCRA/F-GCRA**. Bucket1 and bucket2 are configured by UPC Table[LBF1] and UPC Table[LBF2]. A cell which fails in the bucket1/2 test will be tagged and might be dropped according to UPC Table[DM1/2]. Tagging is done by setting PNC in the cell BD and also in the last BD of the frame.

2. Maximum frame size (MFS). If the cell is not the last cell, the number of cells in frame until and include this cell, should be less than MFS. Cell which fails in this test will be dropped. If a cell is dropped, the PNC bit in the last BD of frame will be set.
3. CLP. The cell CLP should be the same as in the first cell. If it is not, the PNC bit in the last BD of the frame is set. If CLPDM=1 (CLP Drop Mode), the cell is dropped.

NOTE

There is no distinction between CLP0 to CLP1 change and CLP1 to CLP0 change.

If a cell is dropped, due to one of the three tests, all remaining cells of that frame are dropped, except the last cell. The last cell will be dropped only if it is also the first cell or if the first cell was dropped. When frame or part of it, is dropped, FDC (Frame Drop Counter) is updated. If frame is partially dropped, crc error and length error will occur in the last RxBD of the frame.

GFR Conformance

The UPC supports GFR conformance testing according to the ATM Forum TM4.1 section 4.5.5.1. A frame is conforming if all its cells are conforming. A cell is conforming if it meets the following conditions:

1. The cell conforms to GCRA(1/PCR, CDVT) were PCR is defined for the CLP0+1 cell stream.
2. Its CLP value is identical to the CLP of the first cell.
3. The cell either is the last cell of the frame or the number of cells in frame up to and including this cell is less than MFS (Maximum Frame Size).

The configuration for GFR conforming:

1. UPC Table(UPCM)=11 -> GFR mode.
2. Leaky bucket 2 (Leaky bucket 1 is disabled at this point, and could be used later for F-GCRA) is configured to do GCRA(1/PCR,CDVT) for CLP0+1 cells stream, and drop any non-conformed cell.
3. UPC Table (CLPDM) set to 1, meaning that change in CLP will cause frame discard (if the user does not want to drop cells because of CLP change, CLPDM should be clear).
4. UPC Table (UPCMFS) should be assigned to the appropriate value.

GFR Frame-Eligibility (F-GCRA)

A frame is said to be “eligible” if and only if it meet the following conditions (ATM Forum TM 4.1 section 4.5.5.2):

1. It is conformed (see GFR conformance).
2. It passes the F-GCRA test.

In F-GCRA test only the first cell of the frame is tested. It should meets the following conditions:

1. CLP=0.
2. GCRA(1/MCR,BT+CDVT).

If the first cell meets those condition, the frame is considered as passing the test. The F-GCRA has two versions which differ in the TAT update. In ATM Forum TM specifications Version 4.1 annexB.5, if the frame passes the F-GCRA test or it is not conformed, the TAT is updated upon each cell arrival. In ATM Forum TM specifications Version 4.1 Appendix VI.2 if the frame pass the F-GCRA test, the TAT is updated upon each cell arrival. The QUICC Engine block UPC implements the F-GCRA Appendix VI.2 version.

The UPC configuration for eligibility test:

1. Setting GFR conforming test configuration, as in previous section.
2. Configure leaky bucket 1 to do the F-GCRA(1/MCR,BT+CDVT) test.
3. Configure the UPC Table[DM] bit: if set then frame which fails the F-GCRA test will be dropped, and if cleared frame which fails the F-GCRA test will be tagged by setting PNC bit in its RxBD.

32.2.20.3 Examples of Dual Leaky Bucket Configurations

Some Leaky Bucket examples are shown in Table 32-11. The examples show Leaky Bucket programming for ATM Forum TM Specification 4.1 service Categories and ITU-T I.371 ATM Transfer Capabilities.

Table 32-11. Example to Dual Leaky Bucket Configurations

ATM Forum TM4.1 Service Categories	ITU-T I.371 ATM Transfer Capability	LBF1	LBF2
CBR.1	DBR Configuration 1	011	000
VBR.1	SBR Configuration 1	011	011
VBR.2	SBR Configuration 2	011	001
VBR.3	SBR Configuration 3	011	001
GFR.1	—	100	011
GFR.2	—	100	011
UBR.1	—	011	000
UBR.2	—	011	000

32.2.20.4 UPC Statistics

The UPC manages a set of 16-bit counters for statistics that reside in the UPC table. When one of these counters overflows, a maskable interrupt can be generated to the host:

- CLP0 and CLP1 count the incoming cells.
- Nonconforming CLP0 counter (NCCLP0) and nonconforming CLP1 counter (NCCLP1) count the cells not conformed by the UPC buckets. A failure in one of the buckets causes the cell to be counted as nonconforming. NCCLP0CLP1/NCCLP1 applies to cells that arrived with CLP1.
- FC counter counts the incoming frames that were not dropped, meaning frames that were not counted by the FDC. This counter is applied only in frame mode (UPC Table[UPCM] = 10/11).
- FDC is the frame drop counter. When the UPC drops a frame or part of a frame, the FDC is updated. This counter is applied only in frame mode (UPC Table[UPCM] = 10/11).

- CDC is the cell drop counter. When the UPC drops a cell, the CDC is updated. This counter is applied only in cell base mode (UPC Table[UPCM] = 01).

32.2.21 ATM Layer Statistics

ATM layer statistics can be used to identify problems, such as the line-bit error rate, that affect the UNI performance. Statistics are kept in three 16-bit wrap-around counters:

- UTOPIA error dropped cells count—Counts cells discarded due to UTOPIA errors: Rx parity errors and short or long cells.
- miss-inserted dropped cell count—Counts cells discarded due to address look-up failure.

Counters are implemented in the multi-user RAM for each PHY device. The counters of each PHY are located in the UNI statistics table, described in Section 32.3.12, "UNI Statistics Table."

32.2.22 ATM-to-TDM Interworking

The QUICC Engine block supports ATM and TDM Interworking. The MCC and the SI handle the TDM data processing. The ATM controller processes the ATM data.

Possible Interworking applications include the following:

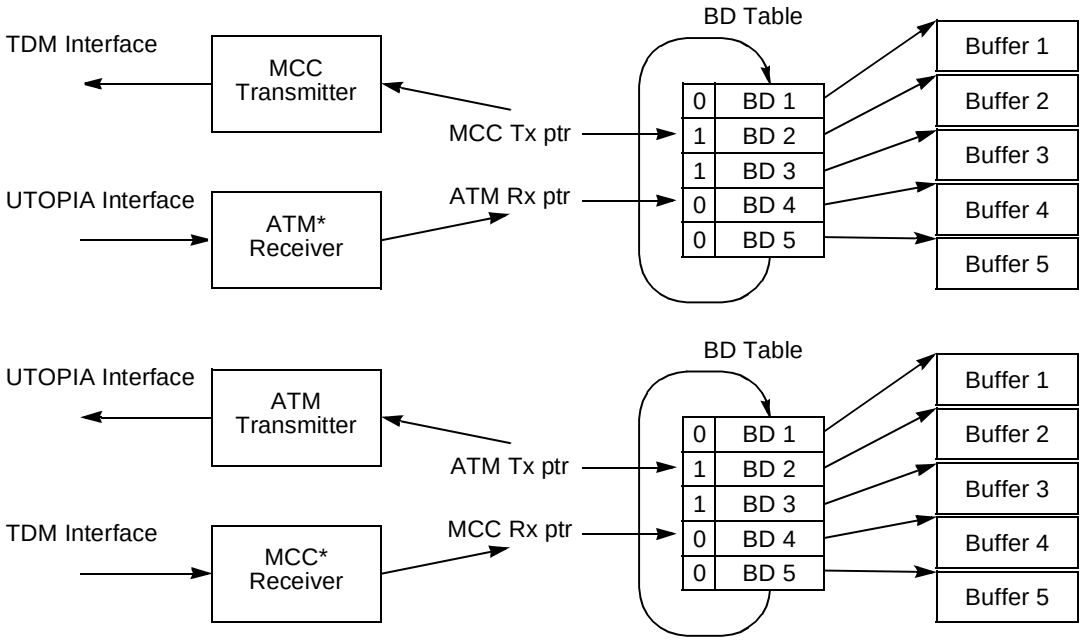
- Circuit emulation service (CES)
- Carrying voice over ATM
- Multiplexing several low speed services, such as voice and data, onto one ATM connection

Data forwarding between the ATM controller and an MCC can be done in two ways:

- Core intervention. When an MCC receive buffer is full and its RxBD is closed, the MCC interrupts the core. The core copies the MCC's receive buffer pointer to an ATM TxBD and sets the ready bit (TxBD[R]). Similarly, when an ATM receive buffer is full and its RxBD is closed, the core services the ATM controller's interrupt by copying the ATM receive buffer pointer to an MCC TxBD and setting TxBD[R]. This mode is useful when additional core processing is required.
- Automatic data forwarding. This mode enables automatic data forwarding between AAL1/AAL0 and transparent mode over a TDM interface.

32.2.22.1 Automatic Data Forwarding

The basic concept of automatic data forwarding is to program the ATM controller and the MCC to process the same BD table, as shown in Figure 32-20.



* The MCC and ATM receivers should be programmed to operate in opposite polarity E (empty) bit.

Figure 32-20. ATM-to-TDM Interworking

When going from TDM to ATM, the MCC receiver routes data from the TDM line to a specific BD table. The ATM controller transmitter is programmed to operate on the same table. When the MCC fills a receive buffer, the ATM controller sends it. The two controllers synchronize on the MCC's RxBD[E] and the ATM controller's TxBD[R].

When going from ATM to TDM, the ATM receiver reassembles data received from a particular channel to a specific BD table. The MCC transmitter is programmed to operate on the same table. When the ATM controller fills a receive buffer, the MCC controller sends it. The controllers synchronize on the ATM controller's RxBD[E] and the MCC's TxBD[R].

The MCC and ATM receivers must be programmed to operate in opposite E-bit polarity. That is, both receivers receive data into buffers whose RxBD[E] = 0 and set RxBD[E] when a buffer is full. For the ATM receiver, set RCT[INVE] of the AAL1- and AAL0-specific areas of the receive connection table, see Section 32.3.4.1, "Receive Connection Table (RCT)." For the MCC receiver, set CHAMR[EP], see Section 34.2.2.2.3, "Channel Mode Register (CHAMR)—Transparent Mode."

32.2.22.2 Using Interrupts in Automatic Data Forwarding

The core can program the MCC and ATM interrupt mechanism to trigger interrupts for events such as a buffer closing or transfer errors. The interrupt mechanism can be used to synchronize the start of the automatic bridging process. For example, to start the MCC transmitter after a specific buffer reaches the ATM receiver (the buffering is required to cope with the ATM network's CDV), set ATM RxBD[I]. When the receive buffer is full, the RxBD is closed, RxBD[E] is set (because it is operating in opposite E-bit polarity), and the core is interrupted. The core then starts the MCC transmitter.

32.2.22.3 Timing Issues

Use of the TDM interface assumes that all communicating entities are synchronized (that is, that they are using a synchronized serial clock). If the TDM interfaces are not synchronized, a slip can occur in the reassembly buffer. If a buffer-not-ready event occurs at the MCC transmitter, the user must restart the MCC transmit channel.

32.2.22.4 Clock Synchronization (SRTS and Adaptive FIFOs)

Clock synchronization methods, such as using a time stamp (SRTS) or adaptive FIFOs, prevent buffer slipping during reassembly. The SRTS method may be implemented using external logic. The QUICC Engine block can read the SRTS from external logic and insert it into AAL1 CES cells, and can track the SRTS from AAL1 CES cells and deliver it to external logic. See Section 32.2.22.4.1, “SRTS Generation and Clock Recovery Using External Logic.”

Alternatively, an adaptive FIFOs method can be implemented using the core to maintain the bridging buffer at a mid-level point. The difference between the MCC and ATM data pointers is a measure of buffer synchronization. The core calculates the difference between pointers at regular intervals and adapts the TDM clock accordingly to hold the difference constant.

32.2.22.4.1 SRTS Generation and Clock Recovery Using External Logic

The QUICC Engine block supports SRTS generation using external logic. If SRTS generation is enabled (TCT[SRT] = 1), the QUICC Engine block reads SRTS[0–3] from the external SRTS logic and inserts it into 4 cells whose SN fields equal 1, 3, 5, and 7, as shown in Figure 32-21.

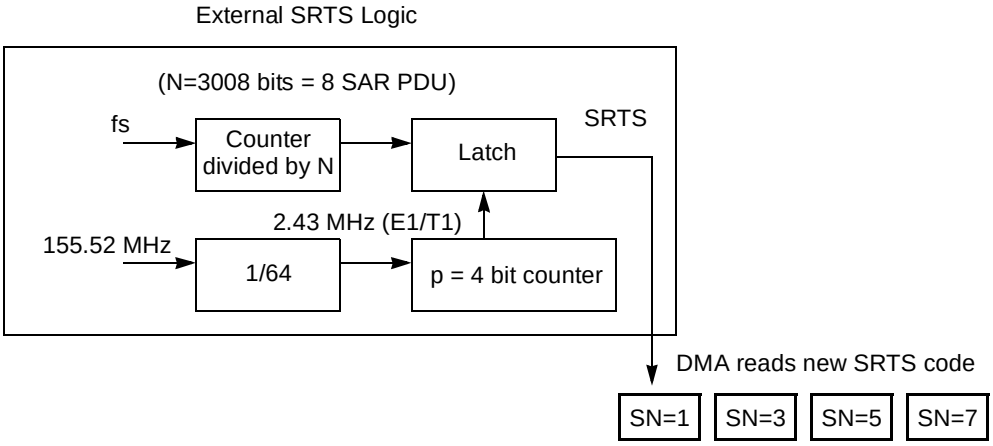


Figure 32-21. AAL1 CES SRTS Generation Using External Logic

For every eight cells, the external SRTS logic should supply a valid SRTS code. The QUICC Engine block reads the SRTS code from the bus selected in TCT[BDB] using a DMA read cycle of 1-byte data size. Each AAL1 CES channel can be programmed to select one of 16 addresses available for reading the SRTS result. The SRTS code should be placed on the least-significant nibble of that address (SRTS[0]=lsb, SRTS[3]=msb). The SRTS is synchronized with the sequence count cycle—SRTS[0] is inserted into the cell with SN = 7; SRTS[3] is inserted into the cell with SN = 1. For every eighth AAL1 CES SAR PDU,

the SRTS logic samples a new SRTS and stores it internally. The SRTS is a sample of a 4-bit counter with a 2.43-MHz reference clock (for E1/T1) synchronized with the network clock.

The QUICC Engine block supports clock recovery using an external SRTS PLL. If SRTS recovery is enabled (RCT[SRT]=1), the QUICC Engine block tracks the SRTS from four incoming cells whose SN field equals 1, 3, 5, and 7 and writes the result to external SRTS logic, as shown in Figure 32-22.

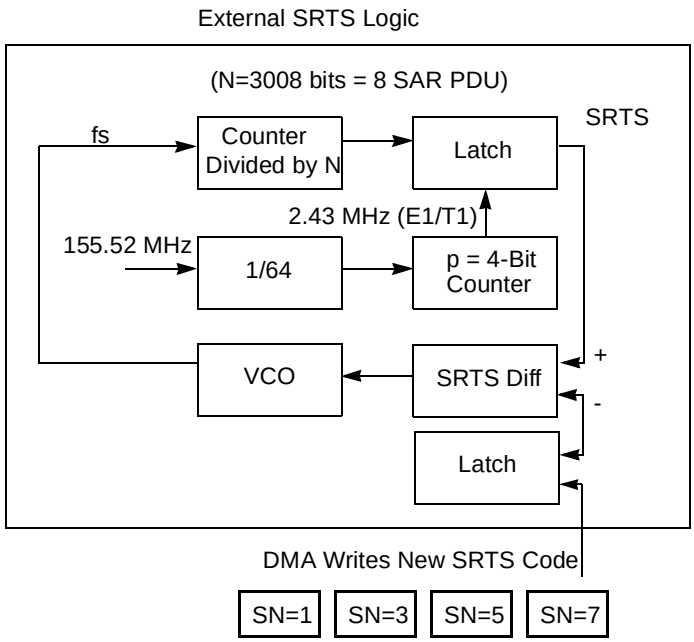

Figure 32-22. AAL1 CES SRTS Clock Recovery Using External Logic

On every eighth cell, the QUICC Engine block writes a new SRTS code to the external logic using the bus selected in RCT[BDB]. The QUICC Engine block writes the SRTS code using a DMA write cycle of 1-byte data size. Each AAL1 CES channel can be programmed to select one of 16 addresses available for writing the SRTS result. The SRTS code is written to the least-significant nibble of that address (SRTS[0]=lsb, SRTS[3]=msb). The SRTS is synchronized with the sequence count cycle—SRTS[3] is read from the cell with SN = 1 and SRTS[0] is read from the cell with SN = 7. The SRTS PLL makes periodic clock adjustments based on the difference between a locally generated SRTS and a remotely generated SRTS retrieved every eight received cells.

32.2.22.5 Mapping TDM Time Slots to VCs

Using the MCC and the SI, any TDM time-slot combination can be routed to a specific data buffer, see Section 34.2.5, “MCC Configuration Registers (MCCF) and Chapter 19, “System Interface.” The same data buffers should be used by the ATM controller to route receive and transmit data. For information about ATM buffers see Section 32.3.9, “ATM Controller Buffer Descriptors (BDs).”

32.2.22.6 CAS Support

For applications requiring channel-associated signaling (CAS), circuit emulation with CAS requires additional core processing. External framers perform the CAS manipulation through a serial or parallel interface.

When the MCC receives a multi-frame block, it generates an interrupt to the core. The core reads the CAS block from the external framer and places it at the end of the ATM data buffer after the structured multi-frame block. The core then passes the buffer pointer to the ATM controller, and the controller packs the data and CAS block into AAL1 CES cells. All AAL1 CES functions, such as generating PDU-headers and structured pointers, operate normally.

When the ATM controller receives a multi-frame block, it generates an interrupt to the core. The core reads the CAS block from the data buffer and writes it to the external framer. The core then moves the buffer pointer to the MCC. The buffer's data length should not include the CAS octets.

To optimize the process, the framer may interrupt the core only when the CAS information changes. (CAS information changes slowly.) The core can keep the CAS block in memory and connect to the framer only when the CAS changes. The core can use regular read and write cycles when connecting to the framer through a parallel interface.

The MCC and ATM controller should be synchronized with the framer's multi-frame block boundary. At the ATM side, the structured block size should equal the multi-frame block size plus the size of the CAS block so that the structured pointer, inserted by the ATM controller, points to the start of the structured data block. At the MCC side, the MCC must to be synchronized with the super frame sync signal. This synchronization can be achieved by external logic that triggers on the super frame sync signal and starts delivering the frame sync to the MCC. When loss of super frame synchronization occurs, this logic should reset and trigger again on the next super frame indication.

32.2.22.7 Trunk Condition

According to the Bellcore standard, the Interworking function (IWF) should be able to transmit special payload on both ATM and TDM channels to signal alarm conditions (Bellcore TR-NWT-000170). The core can be used to generate the trunk condition payload in special buffers (or existing buffers) for the ATM controller or MCC.

32.2.22.8 ATM-to-ATM Data Forwarding

A simple automatic data forwarding can be used to switch ATM AAL0 cells from one ATM port to another without core intervention. The ATM receiver and transmitter should be programed to process the same BD table. When the ATM receiver fills an AAL0 buffer, the ATM transmitter sends it. The ATM receiver and transmitter are synchronized using the same mechanism as described for ATM-to-TDM automatic forwarding; see Section 32.2.22.1, "Automatic Data Forwarding."

A more complex and feature reach method of ATM switching is available as MSP- Multi-Service Platform which is described in Chapter 39, "Enhanced MSP Microcode."

32.3 ATM Controller—Memory Map

The ATM memory structure, described in the following sections, includes the parameter RAM, the connection tables, OAM performance monitoring tables, the APC data structure, BD tables, the AAL1 CES sequence number protection table, the UNI statistics table and the UPC table.

32.3.1 Parameter RAM Page Organization

Figure 32-23 describes the organization of the parameter page for ATM mode. This structure of the page applies to the Distributor page as well as to the Thread page. The difference is the values programmed into different parameters page at initialization of the pages by the host. Each page is partitioned to sub pages starting at sub-page 0. Each sub-page contains parameters supporting different functionality. All the sub-pages have the same format which is depicted in the drawing. In addition to the sub-pages there is a single parameter - Local Page Parameter ptr which is a pointer to a table containing parameters associated with the current page. Detailed description will follow. Each of the sub-pages contains three fields which are actually pointers to data structures needed for supporting the functionality. First pointer is a pointer to a Configuration table which consists of all the fixed values parameters required by specific adaptation layers. The other two pointers are designated as a temporary storage used by the QUICC Engine block when processing a cell. On the distributor page one pointer is assigned for receiver temporary variables and the other is assigned for transmitter variables. In a thread page this two values are programmed to an identical values, which can act as receiver or transmitter variables depending on the thread functionality.

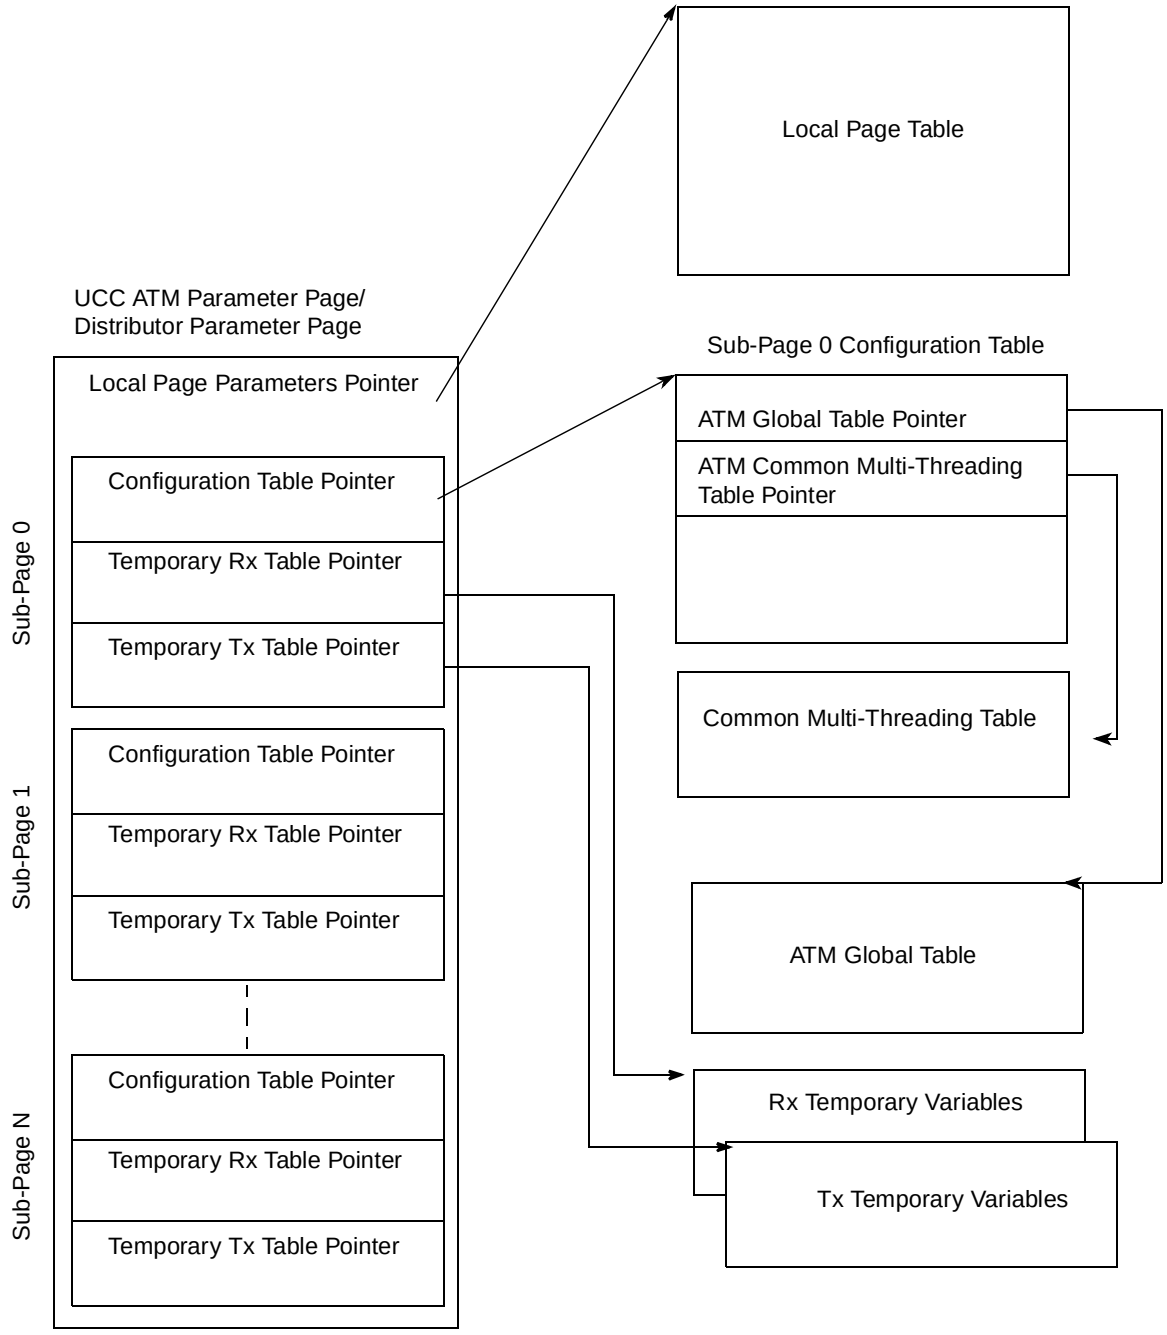

Figure 32-23. Parameter Page Organization

32.3.2 Parameter RAM

When configured for ATM mode, the UCC parameter page is mapped as shown in Table 32-12. When working in Non Multi-threading mode in the ATM level the UCC page is the only page used. When working in Multi-Thread mode the UCC page is called Distributor page. In this mode the Distributor page and the threads pages have the same structure. The host should initialize the distributor page with all the information required for operation of the UCC to which it is associated. The threads pages have to be

partially initialized while some of the parameters are assigned to the thread page dynamically during runtime.

32.3.2.1 Parameter RAM for Non Multi-Threading Operation

Table 32-12 describes the UCC page under Non Multi-Threading operation for the ATM level. There is a difference in memory allocation required for each of the modes. For details on parameter RAM on Multi-Threading mode see Section 32.3.2.2, "Parameter RAM for Multi-threading Operation."

Table 32-12. UCC Parameter RAM Page

Offset	Size	Field	Description	Mem Allocation
0x00	HW	**Local_page_ parameters_ptr**	Pointer to the table in the MURAM which contains parameters which are relevant and local to the current page. The address should be 8 bytes aligned.	Allocate 0x10 bytes. For content of the local parameter table see Table 32-13. **For PQ2 like operation, with 0x100 bytes page, should point to address of the UCC page+0x10.**
0x02	HW	**sub-page0_ Configuration_ Table_ptr**	This is a pointer to static configuration parameters table. Support for AAL0, AAL5, AAL2 and AAL1- CES. The address is 8 bytes aligned.	Allocate 0x60 bytes. see Table 32-18 for table content.The size of this table is 0x80 but last 0x20 bytes are for multi-threading operation and are not used. **For PQ2 like operation, with 0x100 bytes page, should point to address of the UCC page+0x20.**
0x04	HW	**sub-page0_Rx_ Tmp_Table_ptr**	Pointer to a table containing temporary Rx variables and parameters. Address is 8 bytes aligned.	Allocate 0x40bytes. All table entries should be cleared. **For PQ2 like operation, with 0x100 bytes page, should point to address of the UCC page+0x80.**
0x06	HW	**sub-page0_Tx_ Tmp_Table_ptr**	Pointer to a table containing temporary Tx variables and parameters. Address is 8 bytes aligned.	Allocate 0x40 bytes. Al entries in the table should be cleared. **For PQ2 like operation, with 0x100 bytes page, should point to address of the UCC page+0xC0.**
0x08	HW	**sub-page1_ Configuration_ Table_ptr**	**Initialize when E2AAL2, Policer or MSP are enabled.** This is a pointer to static configuration parameters table. Address is 8 bytes aligned.	Allocate 0x40 bytes. see Table for table content.
0x0a	HW	**sub-page1_Rx_ Tmp_Table_ptr**	**Initialize when E2AAL2, Policer or MSP are enabled.** Pointer to a table containing temporary Rx variables and parameters. Address is 8 bytes aligned.	Allocate 0x40 bytes. All entries in table should be cleared.

Table 32-12. UCC Parameter RAM Page (continued)

Offset	Size	Field	Description	Mem Allocation
0x0c	HW	**sub-page1_Tx_ Tmp_Table_ptr**	**Initialize when E2AAL2, Policer or MSP are enabled.** Pointer to a table containing temporary Tx variables and parameters. Address is 8 bytes aligned.	Allocate 0x40 bytes All entries in table should be cleared.

Figure 32-24 describes a possible arrangement for UCC Parameter Page which is 0x100 bytes. In this configuration all the sub-page0 parameters are contained in the thread page while sub-page1 parameters are located in a different location in the MURAM pointed by the Sub_page1_Rx/Tx_Tmp_Ptr's.

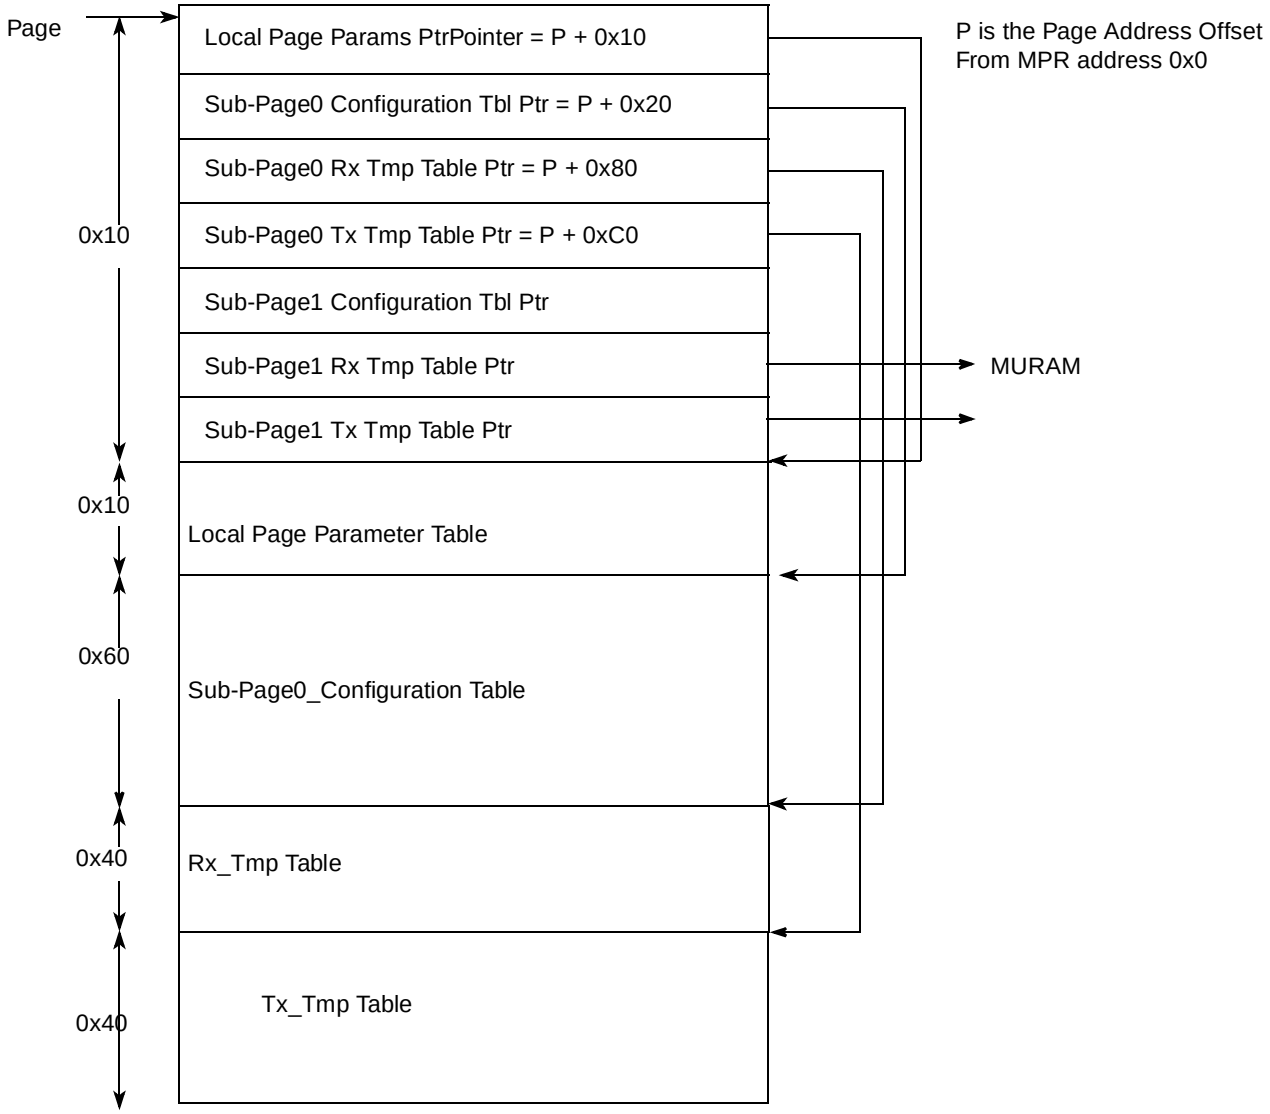

Figure 32-24. Possible Configuration for 0x100 Bytes UCC Page

Table 32-13 is pointed from distributor page see Table 32-12 [Local_page_parameters_ptr]. For Non-Multi-threading mode the size of this table is reduced to 0x10 bytes.

Table 32-13. UCC Local Page Parameter Table

Offset	Size	Field	Description	Non Multi-Threading Mem Allocation
0x00	HW	**INT_RCT_TMP_ptr**	Memory location to where an external RCT is dma'ed.	Allocate 0x40 bytes. 32 bytes aligned.
0x02	HW	**IMA_Temp**	Memory location where an the IMA cell is built	If IMA is enabled Allocate 0x80 bytes. 0x80 bytes aligned.
0x04	HW	**Rx TMP**	Memory location for receiver address look-up information.	Allocate 0x20 bytes.
0x06	HW	**RxQD_tmp** **AAL1_INT_RX_CRT**	Dual purpose. AAL2: Memory location to where an AAL2 RxQD is dma'ed CES: Memory location to where the CAS Rx Routing table is fetched	If AAL2 or CES is enabled allocate 0x20 bytes. 32 bytes aligned
0x08	HW	**PPRS_INT_PTR/ AAL1_INT_TX_CRT**	Dual purpose. 1. AAL2:Partial Packet Receive Storage internal pointer. Valid only if PPRS mode in enabled in the RCT. Allocates 64 bytes in RAM, needed for the QUICC Engine block in order to fetch the partial packet from PPRS external table. 2. CES: Memory location to where the CAS Tx Routing table is fetched	Allocate 0x40 bytes for temporary storage of partial packet or CAS routing table.
0x0A	HW	**Res**	Reserved- Should be cleared	
0x0C	W	**Res**	Reserved- Should be cleared	

32.3.2.2 Parameter RAM for Multi-threading Operation

Table 32-14 describes the UCC page under Multi-Threading operation. In this mode the UCC page is called Distributor page. There is a difference in memory allocation required for each of the modes. For details on parameter RAM on Non Multi-Threading mode see Section 32.3.2.1, "Parameter RAM for Non Multi-Threading Operation."

Table 32-14. Distributor Parameter RAM Page

Offset	Size	Field	Description	Multi-Threading Mem Allocation
0x00	HW	**Local_page_ parameters_ptr**	Pointer to the table in the MURAM which contains parameters which are relevant and local to the current page. The address should be 8 bytes aligned.	Allocate 0x10 bytes For content of the local parameter table see Table 32-15

Table 32-14. Distributor Parameter RAM Page (continued)

Offset	Size	Field	Description	Multi-Threading Mem Allocation
0x02	HW	**sub-page0_ Configuration_ Table_ptr**	This is a pointer to static configuration parameters table. Support for AAL0, AAL5, AAL2 and AAL1- CES. The address is 8 bytes aligned.	Allocate 0x80 bytes. See Table 32-18 for table content
0x04	HW	**sub-page0_Rx_ Tmp_Table_ptr**	Pointer to a table containing temporary Rx variables and parameters. Address is 8 bytes aligned.	Allocate 0x40bytes. All table entries should be cleared.
0x06	HW	**sub-page0_Tx_ Tmp_Table_ptr**	Pointer to a table containing temporary Tx variables and parameters. Address is 8 bytes aligned.	Allocate 0x40 bytes. Al entries in the table should be cleared.
0x08	HW	**sub-page1_ Configuration_ Table_ptr**	**Initialize when E2AAL2, Policer or MSP are enabled.** This is a pointer to static configuration parameters table. Support for E2AAL2, Policer and MSP. Address is 8 bytes aligned.	Allocate 0x40 bytes. see Table for table content.
0x0a	HW	**Reserved**	Reserved. Should be cleared.	No Allocation needed
0x0c	HW	**Reserved**	Reserved. Should be cleared.	No Allocation needed

Table 32-15 is pointed from distributor page see Table 32-14 [Local_page_parameters_ptr]. For Multi-Threading mode the table has to be fully initialized.

Table 32-15. Distributor Local Page Parameter Table

Offset	Size	Field	Description	Multi-Threading Mem Allocation
0x00	HW	**Reserved**	Reserved. Should be cleared.	No allocation is needed
0x02	HW	**Reserved**	Reserved. Should be cleared.	No allocation needed
0x04	HW	**Rx TMP**	Memory location for receiver address look-up information in multi-threading mode.	Allocate 0x20 bytes.
0x06	HW	**Reserved**	Reserved. Should be cleared.	No allocation needed
0x08-0x10	24 bytes	**Reserved**	Reserved. Should be cleared.	

Table 32-16 describes the Thread parameter table which has to be assigned and initialized for each of the

ATM threads available in the system.

Table 32-16. Thread Parameter RAM Page

Offset	Size	Field	Description	Memory allocation
0x00	HW	**Local_page_parameters_ptr**	Pointer to the table in the MURAM which contains parameters which are relevant and local to the current page. The address should be 8 bytes aligned.	Allocate 0x30 bytes. See Table 32-17 for initialization details.
0x02	HW	**sub-page0_Configuration_Table_ptr**	This is a pointer to static configuration parameters table. Support for AAL0, AAL5, AAL2 and AAL1- CES. The address is 8 bytes aligned.	This entry is passes to a thread page by the Distributor Dynamically. **Initialized to 0.**
0x04	HW	**sub-page0_Rx_Tmp_Table_ptr**	Pointer to a table containing temporary Rx variables and parameters. Address is 8 bytes aligned.	Allocate 0x40 bytes. Should be equal to the pointer in: sub-page0_Tx_Tmp_Table_ptr.
0x06	HW	**sub-page0_Tx_Tmp_Table_ptr**	Pointer to a table containing temporary Tx variables and parameters. Address is 8 bytes aligned.	The same 0x40 bytes allocated in sub-page0_Rx_Tmp_Table_ptr.
0x08	HW	**sub-page1_Configuration_Table_ptr**	This is a pointer to static configuration parameters table. Support for E2AAL2, Policer and MSP. Address is 8 bytes aligned.	This entry is passes to a thread page by the Distributor Dynamically. **Initialized to 0.**
0x0a	HW	**sub-page1_Rx_Tmp_Table_ptr**	Pointer to a table containing temporary Rx variables and parameters. Address is 8 bytes aligned.	Allocate 0x40 bytes. Should be equal to the sub-page1_Tx_Tmp_Table_ptr.
0x0c	HW	**sub-page1_Tx_Tmp_Table_ptr**	Pointer to a table containing temporary Tx variables and parameters. Address is 8 bytes aligned.	The same 0x40 bytes allocated in sub-page1_Rx_Tmp_Table_ptr.

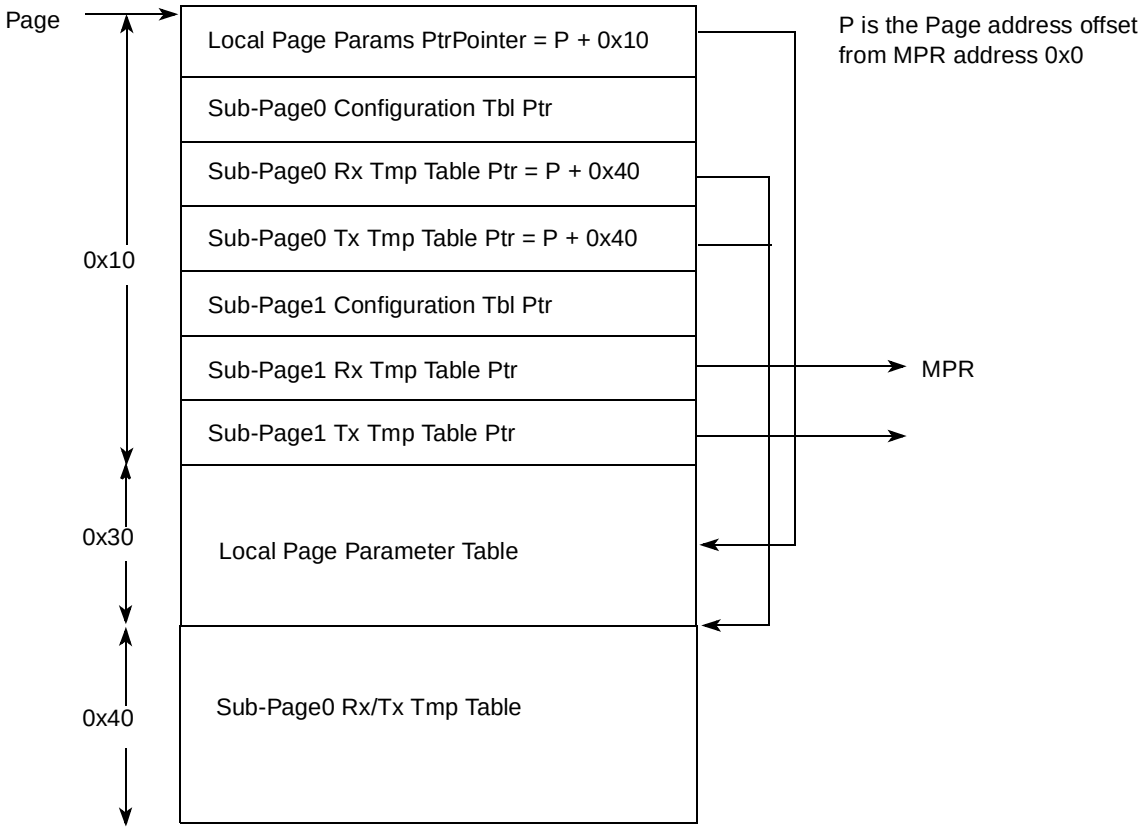

Figure 32-25. Possible Configuration for a Thread Page

Figure 32-25 describes a possible arrangement for a Thread Parameter Page which is 0x80 bytes. In this configuration all the sub-page0 parameters are contained in the thread page. There is no need for the Sub-Page Configuration table in the thread page. Sub-page1 Rx/Tx Tmp tables parameters are located in a different location in the MURAM pointed by the Sub_page1_Rx/Tx_Tmp_Ptr's.

Table 32-17. Thread Local Page Parameter Table

Offset	Size	Field	Description	Mem Allocation
0x00	HW	**INT_RCT_TMP_ptr**	Memory location to where an external RCT is dma'ed	Allocate 0x20 bytes. 32 bytes aligned
0x02	HW	**Res**	reserved should be cleared.	—
0x04	HW	**Res**	reserved should be cleared.	—
0x06	HW	**RxQD_tmp** **Rx_Des_Base_Int/** **AAL1_INT_RX_CRT**	Dual purpose. AAL2: Memory location to where an AAL2 RxQD is dma'ed CES: Memory location to where the CAS Rx Routing table is fetched	If AAL2 or CES is enabled allocate 0x20 bytes. 32 bytes aligned

Table 32-17. Thread Local Page Parameter Table (continued)

Offset	Size	Field	Description	Mem Allocation
0x08	HW	**PPRS_INT_PTR/ AAL1_INT_TX_CRT**	Dual purpose. 1. AAL2:Partial Packet Receive Storage internal pointer. Valid only if PPRS mode in enabled in the RCT. Allocates 64 bytes in RAM, needed for the QUICC Engine block in order to fetch the partial packet from PPRS external table. 2. CES: Memory location to where the CAS Tx Routing table is fetched	Allocate 0x40 bytes for temporary storage of partial packet or CAS routing table.
0x0A–0x2F	Res	**Reserved**	Reserved should be cleared	—

Table 32-18 contains all the fixed value parameters configured by the host for the ATM operation. This table is pointed from the distributor page and is passed to each thread dynamically upon assignment to a distributor. This sub-page contains parameters which are general to the ATM and IMA and parameters for AAL0, AAL5, AAL1 and AAL2. This table is pointed from distributor page Table 32-12 [sub-page0_Configuration_Table_ptr].

Table 32-18. Sub-page0 Configuration Table

Offset	Size	Field	Description	Mem Allocation
0x00	HW	**Global ATM Parameters Table ptr**	A pointer to a Common ATM parameters for all the UCCs see Table 32-19 for table content	Allocate 0x30 bytes. 32 bytes aligned
0x02	HW	**OAM CH RCT PTR**	A pointer to OAM RCT. This RCT is a designated channel for RAW cell queue On PQII family this was channel #1 of each UCC	Allocate 0x20 bytes. 32 bytes aligned.
0x04	HW	**IMAROOT**	Pointer to the IMA root parameter table.	If IMA enabled Allocate 0x80 bytes. 128 byte aligned
0x06	HW	**UCC_Modes**	Defines mode of operation for this UCC. See 32.3.2.6/32-72.	
0x08	W	**Reserved**	Reserved. Should be cleared.	
0x0c	HW	**GMODE**	Global mode. User-defined. See 32.3.2.5/32-70.	
0x0e	HW	**INT_TCTE_TMP_ptr**	A temporary area for fetching the external TCTE	Allocate 0x20 bytes.
0x10	HW	**ADD_COMP_LOOKUP_BASE**	This is a pointer to the Address compression lookup table described inTable 32-26.	points to a 12 bytes table (if address compression is enabled).

Table 32-18. Sub-page0 Configuration Table (continued)

Offset	Size	Field	Description	Mem Allocation
0x12	HW	**DYN_ADD_COMP_BASE /Mini-CAM Look-up table base**	If using the dynamic change of address compression table this is the pointer to the alternate table If using Mini CAM address look-up this entry points to the parameter table for this mode described in Table 32-27.	points to a 12 bytes table.
0x14	HW	**Receiver- Time-out request period**	This value determines a time-out period for request asserted to the QUICC Engine ATM receiver. It is measured in UTOPIA clocks count. If **UCC_Modes[NPL]** is set **or GMODE[ALM] =1x** program this value to zero	NA
0x16	HW	**VCI_FILTER**	VCI filtering enable bits. When cells with VCI = 3, 4, 6, 7-15 are received and the associated VCIF bit = 1 the cell is sent to the raw cell queue. VCIF[0–2, 5] should be zero. See 32.3.2.4/32-70.	
0x18	HW	**APCP_BASE**	APC parameter table base address. User-defined offset from multi-user RAM base.	Number of PHY's *32 bytes
0x1A	HW	**FBT_BASE**	Free buffer pool parameter table base. User-defined offset from multi-user RAM base.	Number of Buffer pools *32 bytes (Up to 4 pools)
0x1C	HW	**INTT_BASE**	Interrupt queue parameter table base. User-defined offset from multi-user RAM base.	Number of queues *32 (Up to 4 queues)
0x1E	HW	**UNI_STATT_BASE**	UNI statistics table base. User-defined offset from multi-user RAM base. Note that this must be set up according to 32.3.12/32-136.	Number of phy's * 4 bytes
0x20	HW	**UEAD_OFFSET/ CHANNEL_CODE_OFFSET**	User-defined cells mode only. Offset to the user-defined extended address (UEAD) in the UDC extra header. When GMODE[ALM]=1x this entry points to the offset in the UDC where the CC resides. It Must be an even address. See 32.3.2.3/32-69.	

Table 32-18. Sub-page0 Configuration Table (continued)

Offset	Size	Field	Description	Mem Allocation
0x22	HW	**IDLE_BASE**	Valid only when Serial ATM is enabled. Idle/unassign cell base address. Points to multi-user RAM area contains idle/unassign cell template (little-endian format). Should be 64-byte aligned. User-defined offset from multi-user RAM base. The ATM header should be 0x0000_0000 or 0x0100_0000 (CLP=1).	
0x24	HW	**IDLE_SIZE**	Valid only when Serial ATM is enabled. Idle/unassign cell size. 52 in regular mode; 68 in case of UDC of size 1-8 bytes, 76 in case of UDC of size 9-12 bytes.	
0x26	Byte	**BD_BASE_EXT (MSB)**	The MSB byte of the base address for the BDs.	
0x27	Byte	**Res**	Reserved Should be cleared	
0x28	W	**TCELL_TMP_BASE_EXT**	Used for AAL1 CES and AAL2. For AAL2 operation with count CU enabled. Temporary location base address for storing partially filled ATM AAL2 cells which are still awaiting the count to expire or the full payload. Points to a total of 64*last_AAL2_Ch# octets reserved in external memory for the partially filled cells. For AAL1 CES this is a temporary location for storing partially filled cells when there is no data available for transmission in the next BD. Bus location is identical to the bus on which the data resides (imposes same bus usage for all the AAL2 channels using this feature).	64bytes * number of AAL2 channels.
0x2C	HW	**RxQD_Base_Int**	Points to the base address of the internal RxQD table. The pointer should be 32-byte aligned. User-defined.	
0x2E	HW	**PMT_BASE**	Performance monitoring table base. User-defined offset from multi-user RAM base.	Number of Tables * 32 (Up to 64 tables)
0x30	W	**AAL1_Ext_STATS_BASE**	AAL1 External Statistics Table Base. Points to External memory. Should be 16-byte aligned (16 octets for each AAL1 channel).User-defined. See Section 35.16, “External AAL1 CES Statistics Tables.”	

Table 32-18. Sub-page0 Configuration Table (continued)

Offset	Size	Field	Description	Mem Allocation
0x34	HW	**AAL1_DUMMY_CELL_BASE**	ALL1 Dummy cell base address. Points to multi-user RAM area contains the AAL1 dummy cell template (little-endian format). Should be 64-byte aligned. User-defined.	
0x36	HW	**INT_RTCRT_BASE**	Internal receive/transmit CAS routing table extension base. User-defined. Should be 64-byte aligned. Each transmitter entry is accessed using: INT_RTCRT_BASE + cc * 64 and for a receiver INT_RTCRT_BASE + CC * 64 + 32.Note that because AAL1 CES does not need the TCT extension, the AAL1 CES microcode uses this Hword to point to a CAS routing table. Should be 32 byte aligned. User-defined.	
0x38	W	**EXT_RTCRT_BASE**	External receive/transmit CAS routing table extension base. User-defined. Should be 64-byte aligned. Each transmitter entry is accessed using: EXT_RTCRT_BASE + CC * 64 and for a receiver EXT_RTCRT_BASE + CC * 64 + 32.Note that because AAL1 CES does not need the TCT extension, the AAL1 CES microcode uses this word to point to a CAS routing table.	
0x3c	HW	**AAL1_SNPT_BASE**	AAL1 SNP protection look-up table base address. (AAL1 and CES only.) The 32-byte table resides in multi-user RAM. AAL1_SNPT_BASE must be halfword-aligned. User-defined offset from multi-user RAM base. See 32.3.11/32-136.	
0x3e	HW	**ADAPTIVE_THRESHOLDS_BASE (CATB)**	CES adaptive threshold tables base address. Points to the multi-user RAM area containing the CES slip control thresholds and the adaptive counter See Section 35.15, “Internal AAL1 CES Statistics Tables.” Should be 8-byte aligned (8 octets for each AAL1-MCC channel). User-defined and should match the CATB value programmed in the MCC parameter RAM; see Section 34.2.2.3, “MCC Parameters for AAL1 CES Usage.”	

Table 32-18. Sub-page0 Configuration Table (continued)

Offset	Size	Field	Description	Mem Allocation
0x40	W	**SRTS_BASE**	External SRTS logic base address. AAL1 and CES only. Should be 16-byte aligned. The four least-significant bits are taken from SRTS_DEV in the AAL1-specific area of the connection table entries.	
0x44	HW	**IN_CAS_BLOCK_BASE**	Incoming CAS Block Base (depicted in Figure 35-12). Points to multi-user RAM. Should be 32-byte aligned. User-defined.	
0x46	HW	**OUT_CAS_BLOCK_BASE**	Outgoing CAS Block Base (depicted in Figure 32-66). Points to multi-user RAM. Should be 32-byte aligned. User-defined.	
0x48	HW	**AAL1_Out_CAS_Status_Reg (OCASSR)**	Outgoing CAS Status Register. See Section 35.10, “Outgoing CAS Status Register (OCASSR).”	
0x4a	HW	**Res**	Reserved. Should be cleared	
0x4c	HW	**AAL1_Int_STATS_BASE**	AAL1 Internal Statistics Table Base. Points to multi-user RAM. Should be 16-byte aligned. User-defined. See Section 35.15, “Internal AAL1 CES Statistics Tables.”	
0x4e	HW	**EAAL2_PAD_TMP_BASE**	PAD template base address. Points to an internal memory area that contains the zero cell template. Should be 64-byte aligned. User-defined.	64 bytes
0x50	W	**RAS_Timer_Duration**	Contains the RAS_Timer duration in time units as defined by Time Stamp1 Register (CETSCR1) for the SSSAR sublayer. User-defined.	
0x54	W	**RxQD_Base_Ext**	Points to the base address of the external RxQD table. The actual address of the first RxQD in the table is RxQD_Base_Ext + 512*4. User-defined.	

Table 32-18. Sub-page0 Configuration Table (continued)

Offset	Size	Field	Description	Mem Allocation
0x58	W	**Rx_UDC_BASE**	Valid only for AAL2 VCs. Points to the base of the RX UDC header table that contains the UDC headers of the AAL2 VCs. The pointer to a VC UDC header is: RX_UDC_Base + 16*CH# (where CH# is the ATM channel number) Bus location is identical to the bus on which the data resides (imposes same bus usage for all channels)	
0x5c	W	**Tx_UDC_BASE**	Valid only for AAL2 VCs. Points to the base of the TX UDC header table that contains the UDC headers of the AAL2 VCs. The pointer to a VC UDC header is: TX_UDC_Base + 16*CH# (where CH# is the ATM channel number) Bus location is identical to the bus on which the data resides (imposes same bus usage for all channels)	
0x60	Byte	**Rx Terminator SNUM**	The SNUM which is used for the receiver terminator process. For available thread numbers see Table 20-15. Needed only for ATM level 1 MTH mode.	
0x61	Byte	**Tx Terminator SNUM**	The SNUM which is used for the transmitter terminator process. For available threads numbers see Table 20-15. Needed only for ATM level 1 MTH mode.	
0x62	HW	**Common MTH parameters Table Base**	**Valid in multi-Threading mode.** Pointer to the Common Multi thread page described in Table 32-20.	Points to a 0x20 byte table.
0x64	HW	**MTH_Terminator_Rx_Status_ptr**	**Valid in multi-Threading mode only.** All 66 bytes Rx terminator status should be cleared.	Allocates 0x42 bytes. This pointer should be 0x80 bytes aligned.
0x66	HW	**MTH_Terminator_Tx_Status_ptr**	**Valid in multi-Threading mode only.** All 66 bytes Tx terminator status should be cleared.	Allocates 0x42 bytes. This pointer should be 0x80 bytes aligned.
0x68	W	**ATM_Available_Rx_Thread_MASK**	32 bit indicating available threads for this receiver UCC. See Figure 32-26.	
0x6C	W	**ATM_Available_Tx_Thread_MASK**	32 bit indicating available threads for this transmitter UCC. See Figure 32-26.	

Note: The value of the time-out should be determined based on the application of the ATM traffic for this UCC. In order to optimize performance of the QUICC Engine block, the ATM traffic received is processed in pipe-line where each cell triggers completion of processing a previous cell. In cases where there is a period of idle on the line it potentially cause a stall in the pipe where last cell is not processed. The value of this time-out defines an allowed idle period on the UTOPIA bus for this UCC. If the timeout has expired, a request is asserted to the RISC in order to finish processing the last cell in the FIFO. The value determines a maximum latency allowed on the system in cases of a bursty traffic. A minimum value of this timer should be a cell time slot in the expected rtae.When setting a too low value this could cause over requesting of the QUICC Engine block thus causing no efficient work of the RISC. When setting a higher value it could cause a higher latency on a last cell in a burst. Setting this entry to zero disables this feature.

32.3.2.2.1 ATM_Available_Xx_Thread_Mask Description

Each bit in this register indicates availability of the relevant thread number to this distributor. Numbering of the threads is according to their location in the ATM Thread Table described in Section 32.2.3, “ATM Multi-Threading.” Setting a bit indicates the thread is available and clearing the bit indicates the thread is not available. When a user wants to designate a thread uniquely to a specific UCC the bit corresponding to this thread is set exclusively for this distributor. A thread which is available for operation under several UCC will have it’s bit set in each of the distributors pages of these UCCs. The thread number is also referred as Thread ID and are assigned in a consecutive manner. At least two threads should be assigned per UCC. One for receive and one for transmit operation.

Bit	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
	Th0	Th1	Th2	Th3	Th4	Th5	Th6	Th7	Th8	Th9	Th10	Th11	Th12	Th13	Th14	Th15
Bit	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
	Th16	Th17	Th18	Th19	Th20	Th21	Th22	Th23	Th24	Th25	Th26	Th27	Th28	Th29	Th30	Th31

Figure 32-26. ATM_Available_Xx_Thread_Mask

Table 32-19 shows the Global ATM parameters Table. It is pointed from Table 32-18 [Global ATM Parameters Table ptr].

Table 32-19. Global ATM Parameters Table

Offset	Size	Field	Description
0x00	HW	**INT_RCT_BASE**	Internal receive connection table base. User-defined offset from multi-user RAM base. Should be common value for all the ATM UCCs.
0x02	HW	**INT_TCT_BASE**	Internal transmit connection table base. User-defined offset from multi-user RAM base. Should be common value for all the ATM UCCs.
0x04	W	**EXT_RCT_BASE**	External receive connection table base. User-defined. Should be common value for all the ATM UCCs.
0x08	W	**EXT_TCT_BASE**	External transmit connection table base. User-defined. Should be common value for all the ATM UCCs.
0x0C	W	**EXT_TCTE_BASE**	External transmit connection table extension base. User-defined. Should be common value for all the ATM UCCs.
0x10	HW	**INT_TCTE_BASE**	Internal transmit connection table extension base. User-defined offset from multi-user RAM base. Should be common value for all the ATM UCCs.

Table 32-19. Global ATM Parameters Table (continued)

Offset	Size	Field	Description
0x12	HW	**COMM_INFO_CTL**	The information field associated with the last host command. User-defined. See 32.4.1/32-142.
0x14	HW	**COMM_INFO_CC**	
0x16	HW	**COMM_INFO_BT**	
0x18	W	COMM_SUS_TMP	Command. Reserved. Should be initialized to 0.
0x1C	HW	COMM_LK_TMP	Command. Reserved. Should be initialized to 0.
0x1E	HW	**ATM_AVCON_BASE**	ATM Auto VC ON Table Base. Valid for ATM switch mode, when the TCT[AVCF] is set and when the TCT[VCON] bit is cleared. The AVCON mechanism **must** be enabled on the receiver side, see for AAL2 mode the RxQD[AVCON] bit (Section 41.4.3, “AAL2 Switching”). This is a Pointer to a multi port RAM array, which contains one bit per TCT channel. see Figure 32-27. If the switched channel is scheduled using the GCRA scheduler, DRR APC the VCON bit is located at the GCRA scheduler, DRR APC structure and is not required in the array. Used in MSP in hierarchical APC mode .
0x20–0x30	16 Bytes	**Res**	Reserved. Should be cleared.

Figure 32-27 describes the ATM AVCON array. For better memory utilization it is recommended that the switched TCTs will be consecutive channels, to eliminate gaps in this table. The area dedicated for this table is equal to the integer “round up” number of switch TCTs (which participate in the AVCON/AVCF mechanism) divided by 8. This area should be initialized with zero.

The transmitter clears the corresponding TCT bit on event of deactivating a channel, and the receiver, when detecting that this bit is cleared, will activate the channel and set this bit.

Figure 32-27. ATM AVCON Array

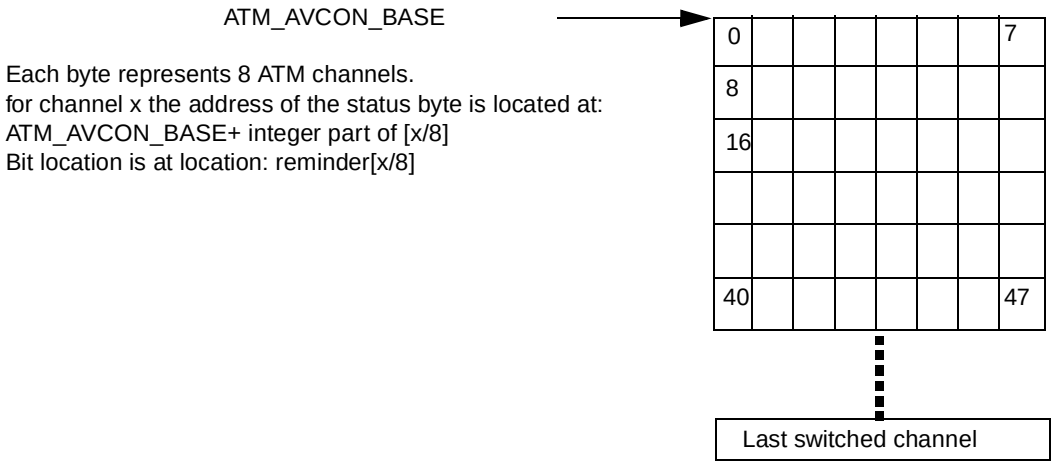

Table 32-20 contains the Common MTH Parameters. It is pointed from Table 32-18 [Common MTH parameters Table Base]. The table contains all the management parameters for the Multi-threaded

operation for the ATM. Several UCCs should point to this table since the threads are a common resource and are shared between the UCC's. In general when UCC_MODES(ATM_lvl_MT_en) is set, this table has to be initialized. If ATM level operates in Non-Multi-threaded operation this table has to be assigned and initialized as instructed in the table. If only ATM level is required in multi-threaded operation only the first 10 bytes should be initialized (Allocation is still for 0x20 bytes).

Table 32-20. Common MTH Parameters Table

Offset	Size	Field	Description	Mem allocation
0x00	HW	**ATM_Threads_Table_Base**	Points to a table in MURAM which contains the list of all available threads for this group as described in Table 32-30 ATM thread table.	Number of threads* 4 bytes.
0x02	HW	**ATM_Thread_CAM_BASE**	Offset to a table in MURAM which has 4 bytes per entry. Each entry in this table should be initialized to 0.	Number of threads* 4 bytes
0x04	W	**ATM_Thread_Empty_Status**	Thread Empty Status. This structure consist 1 bit per thread, which represents if the thread is empty or not. On initialization, the number of zeros in this parameter is equal to the number of threads. For example if there are 10 ATM threads, then initialize 0x003F-FFFF.	—
0x08	Byte	**ATM_THREAD_CAM_SIZE**	The size of the (ATM_thread_CAM table in bytes-1). equal to (Number of threads* 4 -1).	
0x09–20				

Table 32-21 consists all the fixed value parameters configured by the host for the additional functionality of the ATM operation. This table is pointed from the distributor page and is passed to each thread dynamically upon assignment to a distributor. This sub-page contains parameters which are needed for AAL2, policer and MSP operation.This table is pointed from Table 32-12 [sub-page1_Configuration_Table_ptr].

Table 32-21. Sub-page1 Configuration Table

Offset	Size	Field	Description
0x00	W	**TxQDExtBase**	E2AAL2 Mode: TxQD external RAM Base address. All external TxQDs are located as offsets from this field. Must be 32 bytes aligned. See Section 41.3.5.5, "SSSAR Tx Queue Descriptor."

Table 32-21. Sub-page1 Configuration Table (continued)

Offset	Size	Field	Description
0x04	W	**TxCIDStatsAddrBASE**	E2AAL2 Mode: External RAM TxCIDStatsAddr Table Base address, used when TCT[ExtStatsAddr] bit is set. Must be Word aligned. See Section 41.3.5.1, "AAL2 Transmit Connection Tables."
0x08	HW	**TxCIDStatsOffsetBASE**	E2AAL2 Mode: Internal RAM TxCIDStatsOffset Table Base address, used when TCT[ExtStatsAddr] bit is cleared. Must be HWord aligned. See Section 41.3.5.1, "AAL2 Transmit Connection Tables."
0x0A	HW	**Res**	Reserved. Should be cleared.
0x0C	W	**PPRS_EXT_BASE**	E2AAL2 Mode: Partial Packet Receive Storage External Base. When PPRS mode is enabled in the RCT, the user should allocate a table in external memory of 64 bytes multiplied by the number of RCT channels. Each channel store an incoming partial packet at an address which is PPRS_EXT_BASE + 64* Ch# Should be 64bytes aligned. IMPOTRANT: The bus selection for this area is determined by the LSB bit of this entry (overriding the alignment requirements) If the LSB= 0 it resides on the coherent system bus. If the LSB=1 it resides on the QUICC Engine secondary bus.
0x10	W	**EXT_UPC_BASE**	Standalone UPC Mode: External UPC Table base. User-defined. Should be aligned to 64 byte address.
0x14	HW	**INT_UPC_BASE**	Standalone UPC Mode: Internal UPC Table base. User-defined. Should be aligned to 16 byte address.
0x16	HW	**FS_BASE**	MSP Mode: FIFO Status Table Base Address in multi-user RAM. The FIFO Status table contains the FIFO Status Entries: One byte entry for each Hierarchical connection. The value of FS_BASE should be the same for all the UCCs.
0x18	HW	**QLTS_BASE**	MSP Mode: Queue Level Threshold Set table base address. User-defined offset from multi-user RAM base. The value of QLTS_BASE must be 16 byte aligned (three least significant bits are zero).
0x1A	HW	**FDTP_BASE**	MSP Mode: FIFO Descriptor Pointers Table Base. Should be aligned to 8 bytes. See Section 39.18.2, "FIFO Descriptor Pointers Table."
0x1C	HW	**FCP_BASE**	MSP Mode: Free Cell Pool Descriptor base address. User-defined offset from multi-user RAM base. If one free cell pool is used, 32 bytes need to be allocated in the DPR. If two free cell Pools are used 64 bytes need to be allocated.

Table 32-21. Sub-page1 Configuration Table (continued)

Offset	Size	Field	Description
0x1E	HW	**INS_CELL_TMP_PTR**	MSP Mode: Insert Cell Temporary pointer field. Used only for insert of cell command for FTCT/HTCT modes. Pointer to multi-user RAM 8 byte location (should be 8 bytes aligned), which are used by the QUICC Engine block to build the COV of the cell that would be written to the FIFO, for the “dummy” receive of the insert cell command.
0x20	HW	**MCE_BASE**	MSP Mode: Pointer for multi-cast event mask image table base address. Should be defined for the UCC where the MRCT resides.
0x22	HW	**FEPTR_BASE**	MSP Mode: Pointer to table per MRCT[MCGID], which is used to point to another table of WFTs pointers, for Multicast-FIFO with auto FE mechanism. Should be defined for the UCC where the MRCT resides.
0x24	W	**MSP_UPC_BASE**	MSP Mode: External memory Pointer to UPC parameter table Base address. Should be aligned to 32 bytes.
0x28	W	**EXT_INS_CELL_BASE**	MSP Mode: External Insert Cell BASE. Should be aligned to 8 bytes. See Section 39.15.3, “Insert Cell Mode.”
0x2C	HW	**INT_INS_CELL_BASE**	MSP Mode: Internal Insert Cell BASE. The user should always allocate at least one entry at INT_INS_CELL_BASE (associated with channel 0). Should be aligned to 8 bytes. See Section 39.15.3, “Insert Cell Mode.”
0x2E	Byte	**INS_CELL_Header_LOC**	MSP Mode: Insert Cell header Location. 0x0000 - Header is located in the Insert cell template (each table entry consist of 4bytes). 0x8000 - Header is located in the Insert Cell Table (each table entry consist of 8 bytes).
0x2F	Byte	**Res**	Reserved. Should be cleared
0x30	HW	**AAL2_THresholds_Tbl_Base**	E2AAL2 Mode: Pointer to an internal table where the queue management thresholds sets are stored. This is valid for AAL2 working in switched mode.
0x32–0x3F		**—**	Reserved. Should be cleared.

32.3.2.3 Determining UEAD_OFFSET (UEAD Mode Only)

The UEAD_OFFSET value described in Table 32-18 is based on the position of the user-defined extended address (UEAD) in the UDC extra header. Table 32-22 shows how to determine UEAD_OFFSET: first determine the half word-aligned location of the UEAD, and then read the corresponding UEAD_OFFSET value.

Offset	0 — 15	16 — 31
0x0	UEAD_OFFSET = 0x2	UEAD_OFFSET = 0x0
0x4	UEAD_OFFSET = 0x6	UEAD_OFFSET = 0x4
0x8	UEAD_OFFSET = 0xA	UEAD_OFFSET = 0x8

Table 32-22. UEAD_OFFSETs for Extended Addresses in the UDC Extra Header

32.3.2.4 VCI Filtering (VCIF)

VCI filtering enable bits are shown in Figure 32-28.

	0–2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	—	VC3	VC4	—	VC6	VC7	VC8	VC9	VC10	VC11	VC12	VC13	VC14	VC15

Figure 32-28. VCI Filtering Enable Bits

Table 32-23 describes the operation of the VCI filtering enable bits.

Table 32-23. VCI Filtering Enable Field Descriptions

Bits	Name	Description
0–2, 5	—	Clear these bits.
3, 4, 6, 7–15	VC*x*	VCI filtering enable 0 Do not send cells with this VCI to the raw cell queue. 1 Send cells with this VCI to the raw cell queue.

32.3.2.5 Global Mode Entry (GMODE)

Figure 32-29 shows the layout of the global mode entry (GMODE).

	0–1	2	3–5	6	7	8	9	10	11	12	13	14–15
Field	—	GBL	—	ALB	CTB	REM	MSP	IMA_EN	UEAD	CUAB	EVPT	ALM

Figure 32-29. Global Mode Entry (GMODE)

Table 32-24 describes GMODE fields.

Table 32-24. GMODE Field Descriptions

Bits	Name	Description
0–1	—	Reserved, should be cleared.
2	GBL	Global. Asserting GBL enables snooping of external connection tables and address look-up tables. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”
3–5	—	Reserved, should be cleared.

Table 32-24. GMODE Field Descriptions (continued)

Bits	Name	Description
6	ALB	Address look up bus for CAM or address compression tables 0 Reside on the coherent system bus. 1 Reside on the QUICC Engine secondary bus.
7	CTB	External connection tables bus 0 Reside on the coherent system bus. 1 Reside on the CE secondary bus.
8	REM[1]	Receive emergency mode 0 Enable REM operation. When the receive FIFO is full, the ATM transmitter stops sending data cells until the receiver emergency state is cleared (FIFO not full). The transmitter pace is maintained, although a small CDV may be introduced. This mode enables the receiver to receive bursts of cells above the steady state performance. 1 Disable REM operation. Note that to check system performance the user may want to set this bit.
9	MSP	MSP Mode. 0 MSP is disabled. 1 MSP is enabled at least on one of the PHYs.
10	IMA_EN	Enable the associated UCC in IMA mode. 0 Default. UCC Enabled in normal ATM mode 1 UCC enabled in IMA mode Note that individual PHYs of those IMA-mode enabled UCCs may still be set for non-IMA functionality via the IMAPHY register in the IMA root table. **Important**: IMA mode is operable in IMA NON MULTI-threaded mode only so that UCC_Modes[ATM_lvl_MT_en] should be cleared.
11	UEAD	User-defined cells extended address mode. See 32.2.16.1/32-33. 0 Disable UEAD mode. 1 Enable UEAD mode.
12	CUAB	Check unallocated bits 0 Do not check unallocated bits during address compression. 1 Check unallocated bits during address compression.
13	EVPT	External address compression VP table 0 VP table resides in multi-user RAM. 1 VP table reside in external memory.
14–15	ALM	Address look-up mechanism. See 32.2.14/32-25. 00 Reserved. Should not be used. 01 All PHYs Address compression mode. 10 All PHYs Channel code is in UDH (extra header), location programmed in CH_CODE_OFFSET. No address look-up is performed and no Protection mode. 11 All PHYs Channel code is in UDH. Protection Mode is enabled. Channel code appears twice in UDH, and cell is discarded if values are not identical. CH_CODE_OFFSET points to the first occurrence of the channel code. **Note:** In Case Ucc_Modes[MCAL] is set the Mini-Cam lookup is overriding this setting unless there is a PHY that does need one of these modes

[1] GMODE[REM] must be set to disable receive emergency mode. If receive emergency mode were enabled, it would result in IMA transmit protocol violations in cases of system overload, potentially avoiding protocol errors in the IMA receiver at the expense of generating IMA transmit protocol violations to the far end. Rather than causing erratic transmit operation, it is better to set GMODE[REM] and deal with the IMA receive protocol violations locally. Note further that the system should be designed such that overload problems never occur in the field; any errors due to overload should be eliminated during system design and debug.

NOTE

For better system performance and better bus utilization it is recommended to have the Look-up tables and the connection tables to reside on a different bus than the bus used for the data buffers or BD's. In this way the load of the buses and the DMA latency when accessing these data structures is decreased and performance increase.

32.3.2.6 UCC_Modes

UCC_Modes entry is a 16 bit register used to define mode of operation for the UCC. Each bit enables a certain feature and some could be changed dynamically and used as trigger for QUICC Engine block operation. Features are described in Table 32-25.

	0	1	2	3	4	5	6 7	8	9	10	11	12	13 15
Field	ATM_1v1_MT_en	IDLE_ModEn	TSR_Sel	—	—	DYN_ACEn	UID	VPSW_En	NPL	MCAL			—

Figure 32-30. UCC Modes Entry

Table 32-25. UCC_Modes Field Descriptions

Bits	Name	Description
0	**ATM_lvl_MT_en**	This bit specified operation in Multi-threaded mode for the ATM level. 0 No Multi-threading mode 1 Multi-thread operation is enabled. All the parameters required should be initialized and a special host command should be issued. **Important**: when IMA mode is enabled this bit should be cleared.
1	IDLE_ModEn	0 No Idle cells are transmitted. This is for normal operation of the ATM where the ATM traffic is on a Utopia bus 1 Enable transmission of idle cells. This is when Serial ATM code is performing the TC layer and Idle cells are required.
2	**TSR_Sel**	QUICC Engine timer prescale select for transmitter scheduling e.g. GCRA scheduler and APC flux mechanism. 0 CETSCR1 register is used to determine the time units using CETPS1. 1 CETSCR2 register is used to determine the time units using CETPS2. **Note:** For other timing involved parameters CETSCR1 is always used.
3	**Res**	Reserved. Should be cleared
4	—	Reserved, should be cleared.
5	**DYN_ACEn**	Dynamic address compression mode Enable. Set by the core when a dynamic change of address compression tables is needed. Reset by the QUICC Engine block upon completion. If set by the host it indicates the QUICC Engine block to swap sub-Page0 Configuration table ADD_COMP_LOOKUP_BASE parameter with DYN_ADD_COMP_BASE parameter and the new table is being used for the address compression.
6–7	UID	UTOPIA Bus ID. These two bits are assigned at Init by the risc and are used for address compression and for the APC table's location. The assignment is the following: UCC1, UCC3, UCC5, UCC7 have the UID=0b00, and UCC2, UCC4, UCC6, UCC8 have the UID=0b01. The user should not change this value after issuing Init host command.

Table 32-25. UCC_Modes Field Descriptions (continued)

Bits	Name	Description
8	**VPSW_En**	VP Switch mode enable. 0 PQII like operation. When GMODE[CUAB] is set, Upon detecting unallocated bits in the VC level the QUICC Engine block will discard the cell. 1 The QUICC Engine block will access offset 0 in the selected VCLT and look for a valid channel to be used as the destination channel for this VP cell. In case the MS bit in this entry is set the cell is dropped.
9	**NPL**	Non Pipe-lined. 0 The QUICC Engine block utilizes a pipe-line in the address look-up process. This bit is cleared when the UCC is connected to the UTOPIA interface and no IMA or serial ATM is enabled or when mini-CAM address look-up is disabled on this UCC. 1 The QUICC Engine block does not utilize a pipe-line in the address look-up process. This bit is set if this UCC is working with IMA enabled or when working under Serial ATM or when working in mini-CAM look-up
10	**MCAL**	Mini-Cam Address Look-up Mode. 0 The address look-up is based on GMODE[ALM] 1 The channel code is determined by an internal mini CAM table on a per PHY as described in 32.2.14.2, “Mini-CAM Address Look-Up
11		
12		
12–15	—	Reserved, should be cleared.

NOTE

The structure of the VP level is designed for future expansion. The PHY ID field contains 8 bits, supporting up to 256 PHYs per UTOPIA interface. The UID field contains two bits supporting up to four UTOPIA interfaces. PHY ID should be treated as the following: 5 LSBs represent the 5 address lines of the UTOPIA interface. Three MSBs represent the device ID. For this reason, the application should clear the bits which are not applicable for the device. Table 32-26 shows the setting for the VP level mask field in the Address Look-up table. This table contains the 4 bytes from offset 0x8 in the address look-up table.

32.3.2.7 Address Look-Up Table

The UCC is able to support up to 127 PHYs addresses. Eight address bits are available for usage as baseline for the address compression look-up. In cases the address compression tables are used globally for the QUICC Engine block, meaning all UCCs use the same address compression tables it is needed to differentiate identical PHY,VPI,VCI received on different utopia buses by their utopia bus ID. The ID of each utopia bus is assigned automatically by the QUICC Engine block at initialization. It has 2 bits assigned for this. The total number of bits entering the VP level address compression is up to 22 bits where 12 bits are for the VPI of the cell, 8 bits are for up to 256 PHYs ID’s and 2 more bits indicating the utopia bus ID. Table 32-26 contains the Address Look-Up parameters, It consists of three parameters as described in the table. It is pointed by Table 32-18 sub-page0 configuration table [ADD_COMP_LOOKUP_BASE].

Table 32-26. Address Look-Up Table

Offset	Name	Width	Description
0x00	VPT_BASE	Word	Base address of the address compression VP table. User-defined. If GMODE[EVPT]= 0 only 2 bytes offset from MURAM should be initialized.
0x04	VCT_BASE	Word	Base address of the address compression VC table. User-defined.
0x08	VCLT_SF	1 Byte	VC level table Scale factor 0x00- default. The address to the VC level table is calculated by VCT_BASE + VCOFFSET *4 0x01- a scale of 2 is added. Address is VCT_BASE + VCOFFSET *8 0x02- a scale of 4 is added. Address is VCT_BASE + VCOFFSET *16 0x03- a scale of 8 is added. Address is VCT_BASE + VCOFFSET *32 0x04- a scale of 16 is added. Address is VCT_BASE + VCOFFSET *64 If a larger scale factor is needed, this field could be programmed accordingly, e.g. 0x05 for a scale factor of 32, etc.
0x09	VP_LVL_MASK	3 bytes	A mask set by the s/w which determines which of the 22 available address information bits are used in the address compression operation as described in Section 32.2.14.1, “Address Compression.” See Figure 32-31 description of how to program the mask bits.

Note: The structure of the VP level is designed for future expansion. The PHY ID field contains 8 bits supporting up to 256 PHYs per Utopia interface and the UID field contains 2 bit supporting up to four Utopia i/f. For this reason the application should clear the bits which are not applicable for the device. Table 32-31 shows the setting for the VP Level mask field in the Address Look-up table.This table contains the 4 bytes from offset 0x8 in the address look-up table.

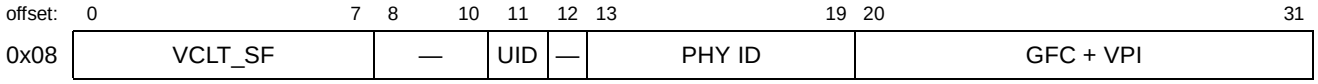

Figure 32-31. VP_LVL_MASK

32.3.2.8 Dynamic Address Compression Table change

The user may want to change dynamically the VPT_BASE and the VCT_BASE parameters, in order to support dynamic and more complex VP/VC ranges for the Address Compression mode.

This change is done automatically in synchronization with the ATM receiver flow. The Host should set the UCC_Modes[DYN_En] bit located in sub-page0 configuration table. As a reaction the QUICC Engine block will swap the ADD_COMP_LOOKUP_BASE with the DYN_ADD_COMP_BASE and from that point will use the alternative table as a base for the address compression calculations.

Upon completion of the dynamic change process the QUICC Engine block clears the DYN_AC_En entry. Until then the CPU shouldn’t toggle the DYN_AC_En entry.

32.3.2.9 Dynamic Address Look-Up Table

This is an identical table to the one described in Table 32-26. This is an alternative table which the user can initialize and use in case of a dynamic address compression change.

32.3.2.10 Mini-CAM Address Look-up Table

This data structure replaces the Dynamic Address compression Table and contains the UCC parameters required for the Mini-CAM look-up operation described in Section 32.2.14.2, "Mini-CAM Address Look-Up.' For each incoming ATM cell the header is searched in the Mini-CAM tables for a match. Upon a match a channel code is calculated for this VPI/VCI.

Table 32-27. Mini-CAM Look-Up Table

Offset	Name	Width	Description
0x00	Base_Channel#	HW	This is the base channel number for calculations of the ATM channel code. The final channel number assigned to an incoming cell on a match is determined using: Channel# = Base_Channel# + PHY_ID * Max_MC_size + Mini-CAM entry index
0x02	Mini-CAM_base	HW	Base offset in the MURAM to the mini CAM tables. Each entry is a four bytes entry described in Figure 32-33.
0x04	PHY_Table_base	HW	Base offset in the MURAM offset, to the PHY table. Each entry is a two bytes entry described in Figure 32-32.
0x06	Max_MC_size	byte	Number of entries in the largest mini CAM table in the system. Size of this table could be one of the following: 8,16,32,64. The value programmed in Max_MC_size is the power of 2 of the size so values are 3,4,5,6 respectively.
0x07	Max_UPC_Entries	byte	If Policing is enabled in this PHY up to 15 PID (Policer ID) are available for each PHY. This value is maximum value of UPCs used for any of the PHYs. This value should be rounded to the next power of 2. The value programmed in Max_UPC_Entries is the power of 2 of the size (for example if the maximum number of UPCs used per PHY is 5 set this value to 3)
0x08	First_PID	HW	The first Policer ID used in the system. Any of the UPCs used is calculated based on this number. The final PID number assigned to an incoming cell is determined using: PID# = First_PID + PHY_ID * Max_UPC_Entries + mini-CAM entry[PID]

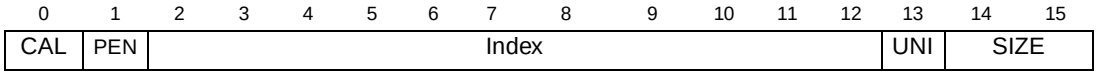

Figure 32-32. PHY Table Entry

Table 32-28. PHY Table Entry Description

Bit	Name	Description
0	CAL	Classical address compression look-up for this PHY. No mini-CAM operation
1	PEN	Policer Enable for this PHY
2–12	Index	Index to the mini-CAM table for this CAM. Address of the table is: Mini-CAM_base + Index*2^5
13	UNI	UNI mode. 0 Take the GFC value into the CAM search. 1 Mask the GFC field in the CAM search

Table 32-28. PHY Table Entry Description (continued)

Bit	Name	Description
14–15	Size	Size of mini-CAM table 00 size is 8 entries 01 size is 16 entries 10 size is 32 entries 11 size is 64 entries

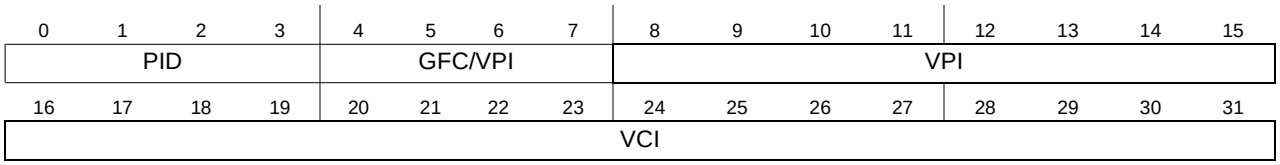

Figure 32-33. Mini-CAM Entry

Table 32-29. Mini-CAM Entry Description

Bit	Name	Description
0–3	PID	If PID=0x0 policer is disabled for this VPI/VCI If PID>0 Policing is enabled for this channel and the Policer ID is calculated by: PID# = First_PID + PHY_ID * Max_UPC_Entries + mini-CAM entry[PID]
4–7	GFC/VPI	The GFC/VPI value of the cell. If UNI bit is set in the PHY table entry this bits are ignored on the incoming cell.
8–15	VPI	VPI of the ATM cell
16–31	VCI	VCI of the ATM cell

32.3.3 Multi-Threading Structures

When working in Multi-Threading mode, see Section 32.2.3, “ATM Multi-Threading,” the user defines a pool of the available threads for processing the ATM traffic. The threads are available SNUM of the QUICC Engine block RISC and the user should initialize a table which contains a list of all the designated SNUMs. ThreadID number is according to it’s location in the table. First entry is thread 0, second entry is thread 1 etc. Figure 32-34 depicts an entry of the ATM Threads Table, which resides in the RAM and consists of as many entries as allocated by the user (up to 28 entries). The table is pointed from the Common MTH parameters Table[ATM_Threads_Table_Base].

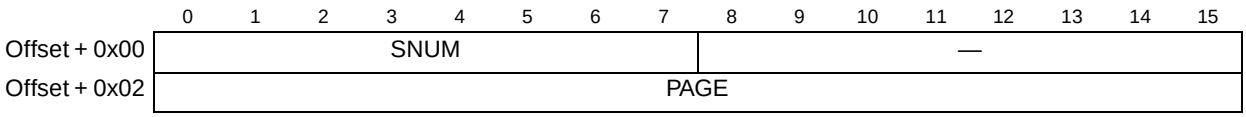

Figure 32-34. ATM Threads Table Entry

Table 32-30. ATM Threads Table Entry Description

Offset	Bits	Name	Description
0x00	0–7	SNUM	Back End SNUM. For available thread numbers see Table 20-15.
	8–15	—	Reserved. Should be cleared.
0x02	—	PAGE	Page pointer.

32.3.4 ATM Channel Code

Each ATM channel has a channel code used as an index to the channel's connection table entry. The first channel in the table has channel code one, the second has channel code two, and so on. Codes of 255 or less indicate internal channels; codes greater than 255 indicate external channels. Channel code one is reserved as the raw cell queue and cannot be used for another purpose. The channel code is used to specify a VC when sending a ATM TRANSMIT command, initiating the address compression tables or the mini-CAM tables and when the QUICC Engine block sends an interrupt to an interrupt queue.

Example:

Suppose a configuration supports 1,024 regular ATM channels. To allocate 4 Kbytes of multi-user RAM space to the internal connection table, determine that channel codes 0–63 are internal (64 VCs × 64 bytes (RCT and TCT) = 4 K). Channels 0–1 are reserved. The remaining 962 (1024 - 62) external channels are assigned channel codes 256–1217. See Figure 32-35.

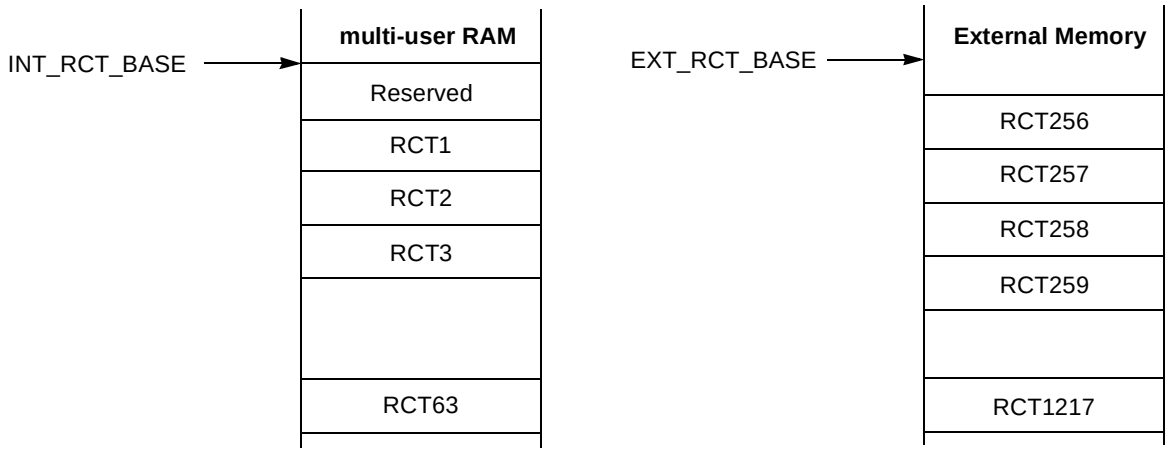

Figure 32-35. Example of a 1024-Entry Receive Connection Table

The general formula for determining the real starting address for all internal and external connection table entries is as follows:

Connection table base address + (channel code × 32)

Thus, the real starting address of the RCT entry associated with channel code 3 is as follows:

INT_RCT_BASE+ (3 × 32) = INT_RCT_BASE + 96

Even though it produces a gap in the connection table, the first external channel's real starting address of the RCT entry (channel code 256) is as follows:

$$EXT\_RCT\_BASE + (256 \times 32) = EXT\_RCT\_BASE + 8192$$

ATM channels from service type VBR, UBR+, GBR, or when Scalable mode is enabled, have an extension to their TCT table entry which is the channel's connection table extension (TCTE) entry. See Section 32.3.2, "Parameter RAM," to find all the connection table base address parameters. (The transmit connection table base address parameters are INT_TCT_BASE, EXT_TCT_BASE, INT_TCTE_BASE, and EXT_TCTE_BASE.)

32.3.4.1 Receive Connection Table (RCT)

Figure 32-36 shows the format of an RCT entry.

Figure 32-36. Receive Connection Table (RCT) Entry

Table 32-31 describes RCT fields.

Table 32-31. RCT Field Descriptions

Offset	Bits	Name	Description
0x00	0	—	Reserved, should be cleared.
	1	—	Reserved, should be cleared.
	2	GBL	Global. Asserting GBL enables snooping of data buffers, BD, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	BO	Byte ordering—used for data buffers. 00, 01, 11 Reserved 10 Big endian
	5	CETM	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1 and Section 5.4.3.7, "Debug Configuration."
	6	DTB	Data buffers bus 0 Data buffers reside on the coherent system bus. 1 Data buffers reside on the CE secondary bus.
	7	BDB	BD, interrupt queues, free buffer pool and external SRTS logic bus 0 Reside on the coherent system bus. 1 Reside on the CE secondary bus. Note that when using AAL5 or AAL1 CES in UDC mode, BDs must be placed on the same bus (RCT[DTB] = RCT[BDB]). This is necessary because in UDC mode the user-defined header, which is part of the cell data, is read using the same bus configuration (byte ordering and bus type) as the payload. Therefore, if data is placed on the CSB bus and the BD on the CE secondary bus, the SDMA accesses the UDC header on the CSB bus with the address of the CE secondary bus.
	8	—	Reserved, should be cleared.
	9	BUFM	Buffer mode. (AAL5 only) See 32.3.9.3/32-122. 0 Static buffer allocation mode. Each BD is associated with a dedicated buffer. 1 Global buffer allocation mode. Free buffers are fetched from global free buffer pools.
	10	SEGF	OAM F5 segment filtering 0 Do not send cells with PTI = 100 to the raw cell queue. 1 Send cells with PTI = 100 to the raw cell queue.
	11	ENDF	OAM F5 end-to-end filtering 0 Do not send cells with PTI=101 to the raw cell queue. 1 Send cells with PTI=101 to the raw cell queue.
	12–13	—	Reserved, should be cleared.
	14–15	INTQ	Points to one of four interrupt queues available.

Table 32-31. RCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0	—	Internal use only. Should be cleared.
	1	INF	(AAL5 only) Indicates the receiver state. Initialize to 0 0 In idle state. 1 In AAL5 frame reception state.
	2–12	—	Internal use only. Should be cleared.
	13–15	AAL	AAL type 000 AAL0—Reassembly with no adaptation layer 001 AAL1—ATM adaptation layer 1 protocol 010 AAL5—ATM adaptation layer 5 protocol 100 AAL2—ATM adaptation layer 2 protocol, see Chapter 41, “E2AAL2 Microcode” 101 AAL1_CES—Refer to AAL1, see Chapter 35, “ATM AAL1 Circuit Emulation Service” 110 MSP - Multi ServIce Protocol - switched ATM cells, see Chapter 39, “Enhanced MSP Microcode.” All others reserved.
0x04	—	RxDBPTR	Receive data buffer pointer. Holds real address of current position in the Rx buffer.
0x08	0–23	Cell Time Stamp	Used for reassembly time-out. Whenever a cell is received, the QUICC Engine time stamp timer is sampled and written to this field. See Section 20.3.9, “QUICC Engine Time-Stamp Control Register (CETSCR).” **Note**: In AAL5 8 LSb bits are always zero meaning the granularity of measurement is every 256 timer ticks.
0x0B		Res	Reserved, This byte is zero.
0x0C	—	RBD_Offset	RxBD offset from RBD_BASE. Points to the channel’s current BD. User-initialized to 0; updated by the QUICC Engine block.
0x0E–0x18		—	Protocol-specific area.
0x1A	—	MRBLR	Maximum receive buffer length. Used in both static and dynamic buffer allocation.
0x1C	0–1	—	Reserved, should be cleared.
	2–7	PMT	Performance monitoring table. Points to one of the available 64 performance monitoring tables. The starting address of the table is PMT_BASE+PMT $\times$ 32. Can be changed on-the-fly.
	8–15	RBD_BASE	RxBD base. Points to the first BD in the channel’s RxBD table. The 8 most-significant bits of the address are taken from BD_BASE_EXT in the parameter RAM. The four least-significant bits of the address are taken as zeros.
0x1E	0–11		
	12–14	—	Reserved, should be cleared.
	15	PM	Performance monitoring. Can be changed on-the-fly. 0 No performance monitoring for this VC. 1 Perform performance monitoring for this VC. Whenever a cell is received for this VC the performance monitoring table that its code is written in the PMT field is updated.

32.3.4.1.1 AAL5 Protocol-Specific RCT

Figure 32-37 shows the AAL5 protocol-specific area of an RCT entry.

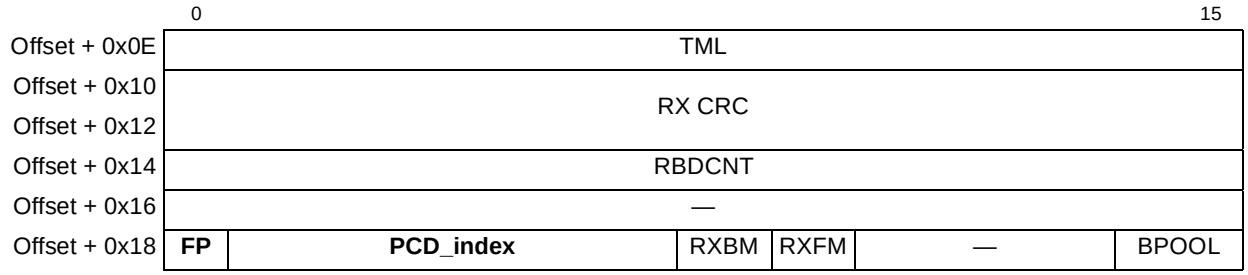

Figure 32-37. AAL5 Protocol-Specific RCT

Table 32-32 describes AAL5 protocol specific RCT fields.

Table 32-32. RCT Settings (AAL5 Protocol-Specific)

Offset	Bits	Name	Description
0x0E	—	TML	Total message length. This field is used by the QUICC Engine block.
0x10	—	RxCRC	CRC32 temporary result.
0x14	—	RBDCNT	RxBD count. Indicates how may bytes remain in the current Rx buffer. RBDCNT is initialized with MRBLR whenever the QUICC Engine block opens a new buffer.
0x16	—	—	QUICC Engine block internal use. Reserved, should be cleared.
0x18	0–8		Reserved, should be cleared.
	1–7		
	8	RXBM	Receive buffer interrupt mask. Determines whether the receive buffer event is disabled. Can be changed on-the-fly. 0 The event is disabled for this channel. (The RXB event is not sent to the interrupt queue when receive buffers are closed.) 1 The event is enabled for this channel.
	9	RXFM	Receive frame interrupt mask. Determines whether the receive frame event is disabled. Can be changed on-the-fly. 0 The event is disabled for this channel. (RXF event is not sent to the interrupt queue.) 1 The event is enabled for this channel.
	10–13	—	Reserved, should be cleared.
	14–15	BPOOL	Buffer pool. Global buffer allocation mode only. Points to one of four free buffer pools. See 32.3.9.2.4/32-120.

32.3.4.1.2 AAL1 Protocol-Specific RCT

Figure 32-38 shows the AAL1 protocol-specific area of an RCT entry.

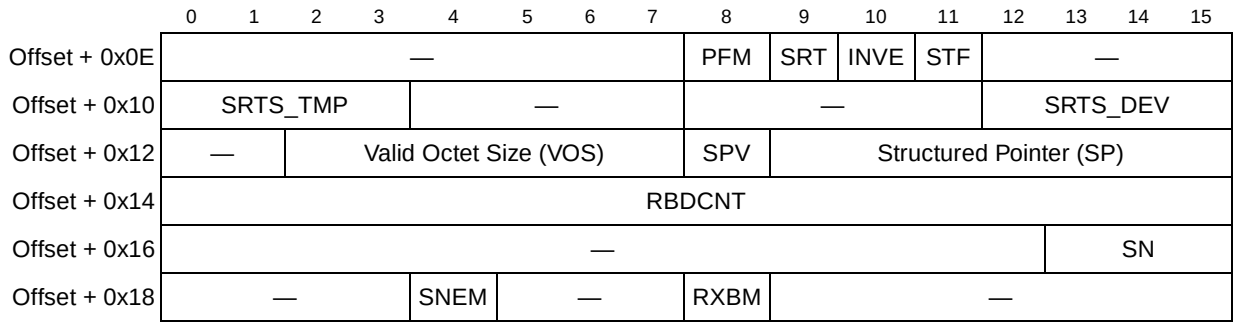

Figure 32-38. AAL1 Protocol-Specific RCT

Table 32-33 describes AAL1 protocol-specific RCT fields.

Table 32-33. AAL1 Protocol-Specific RCT Field Descriptions

Offset	Bits	Name	Description
0x0E	0–7	—	Reserved, should be cleared.
	8	PFM	Partially filled mode. 0 Partially filled cells mode is not used. 1 Partially filled cells mode is used. The receiver copies only valid octets from the AAL1 cell to the Rx buffer. The number of the valid octets from the beginning of the AAL1 user data field is specified in the VOS (valid octet size) field.
	9	SRT	Synchronous residual time stamp. Unstructured format only. The QUICC Engine block supports clock recovery using an external SRTS PLL. The QUICC Engine block tracks the SRTS from the incoming four cells with SN = 1, 3, 5, and 7 and writes it to the external SRTS device. Every eight cells the QUICC Engine block writes a valid SRTS to external logic. (See 32.2.22.4.1/32-48). 0 SRTS mode is not used. 1 SRTS mode is used.
	10	INVE	Inverted empty. 0 RxBD[E] is interpreted normally (1 = empty, 0 = not empty). 1 RxBD[E] is handled in negative logic (0 = empty, 1 = not empty).
	11	STF	Structured format 0 Unstructured format is used. 1 Structured format is used.
	12–15	—	Reserved, should be cleared.
0x10	0–3	SRTS_TMP	Used by the QUICC Engine block to store the received SRTS code. After a cell with SN = 7 is received, the QUICC Engine block writes the SRTS code to the external SRTS device.
	4–11	—	Reserved, should be cleared.
	12–15	SRTS_DEV	Selects an SRTS device, whose address is SRTS_BASE[0–27] + SRTS_DEV[28–31]. The 16 byte-aligned SRTS_BASE is taken from the parameter RAM.

Table 32-33. AAL1 Protocol-Specific RCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x12	0–1	—	Reserved, should be cleared.
	2–7	VOS	Valid octet size. Specifies the number of valid octets from the beginning of the AAL1 user data field. For unstructured, service values 1–47 are valid; for structured service, values 1-46 are valid. Partially filled cell mode only.
	8	SPV	Structured pointer valid. Should be user-initialized user to zero. Structured format only.
	9–15	SP	Structured pointer. Used by the QUICC Engine block to calculate the structured pointer. This field should be initialized by the user to zero. Used in structured format only.
0x14	—	RBDCNT	RxBD count. Indicates how may bytes remain in the current Rx buffer. Initialized with MRBLR whenever the QUICC Engine block opens a new buffer.
0x16	0–12	—	Reserved, should be cleared.
	13–15	SN	Sequence number. Used by the QUICC Engine block to check incoming cell's sequence number.
0x18	0–3	—	Reserved, should be cleared.
	4	SNEM	Sequence number error flag interrupt mask 0 This mode is disabled. 1 When an out-of-sequence error occurs, an RXB interrupt is sent to the interrupt queue even if RCT[RXBM] is cleared. Note that this mode is the buffer error reporting mechanism during automatic data forwarding (ATM-to-TDM bridging) when no buffer processing is required (RCT[RXBM]=0).
	5–7	—	Reserved, should be cleared.
	8	RXBM	Receive buffer interrupt mask 0 The receive buffer event of this channel is disabled. (The event is not sent to the interrupt queue.) 1 The receive buffer event of this channel is enabled.
	9–15	—	Reserved, should be cleared.

32.3.4.1.3 AAL0 Protocol-Specific RCT

Figure 32-39 shows the layout for the AAL0 protocol-specific RCT.

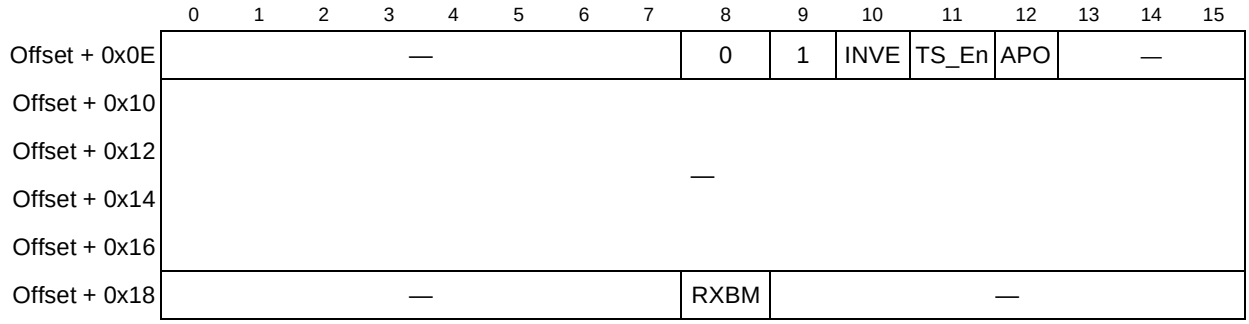

Figure 32-39. AAL0 Protocol-Specific RCT

Table 32-34 describes AAL0 protocol specific RCT fields.

Table 32-34. AAL0-Specific RCT Field Descriptions

Offset	Bits	Name	Description
0x0E	0–7	—	Reserved, should be cleared.
	8–9	0b01	Must be programmed to 0b01 for AAL0.
	10	INVE	Inverted empty. 0 RxBD[E] is interpreted normally (1 = empty, 0 = not empty). 1 RxBD[E] is handled in negative logic (0 = empty, 1 = not empty).
	11	TS_En	Time stamp Enable. 0 Time stamp is disabled. 1 The QUICC Engine block adds time stamp information to the end of the buffer (just after the end of the cell payload) which is related to this RCT. Useful for OAM support, when it is needed to sample the time of the received OAM cell. It is important that the user will allocate 4 extra bytes to the buffer, in order to use this feature properly.
	12	APO	ATM Payload Only. 0 All the cell including its header and UDC, if applicable, is written to the buffer. 1 Only the cell payload is written to the buffer.
	13–15	—	Reserved, should be cleared.
0x10	—	—	Reserved, should be cleared.
0x18	0–7	—	Reserved, should be cleared.
	8	RXBM	Receive buffer interrupt mask 0 The receive buffer event of this channel is masked. (The RXB event is not sent to the interrupt queue when receive buffers are closed.) 1 The receive buffer event of this channel is enabled.
	9–15	—	Reserved, should be cleared.

32.3.4.1.4 AAL1 CES Protocol-Specific RCT

Refer to Section 35.9.1, “Receive Connection Table (RCT).”

32.3.4.1.5 AAL2 Protocol-Specific RCT

Refer to Section 41.4.4.1, “AAL2 Receive Connection Tables.”

32.3.4.2 Transmit Connection Table (TCT)

Figure 32-40 shows the format of an TCT entry.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0x00	—		GBL	BO		CETM	DTB	BDB	AVCF		ATT		CPUU	VCON	INTQ	
Offset + 0x02	—	INF	—	—	—	—	—	—	—	—	—	—	—	AAL		
Offset + 0x04 Offset + 0x06	Tx Data Buffer Pointer (TXDBPTR)															
Offset + 0x08	TBDCNT															
Offset + 0x0A	TBD_OFFSET															
Offset + 0x0C	Rate Remainder								PCR Fraction							
Offset + 0x0E	PCR															
Offset + 0x10 Offset + 0x12 Offset + 0x14	Protocol Specific • For AAL5,Section 32.3.4.2.1, “AAL5 Protocol-Specific TCT.” • For AAL2, Section 41.3.5.1, “AAL2 Transmit Connection Tables” • For AAL1, Section 32.3.4.2.2, “AAL1 Protocol-Specific TCT.” • For AAL1 CES, Section 35.9.2.1, “AAL1 CES Protocol-Specific TCT” • For AAL0, Section 32.3.4.2.3, “AAL0 Protocol-Specific TCT.”															
Offset + 0x16	APC Linked Channel (APCLC)/GCRA Burst Tolerance (GCRA_BT)															
Offset + 0x18 Offset + 0x1A	ATM Cell Header (VPI,VCI,PTI,CLP)

Offset + 0x1E	TBD_BASE[16–27]												BNM	STPT	IMK	PM

Figure 32-40. Transmit Connection Table (TCT) Entry

Table 32-35 describes general TCT fields.

Table 32-35. TCT Field Descriptions

Offset	Bits	Name	Description
0x00	0	—	Reserved, should be cleared.
	1	—	Reserved, should be cleared.
	2	GBL	Global. Asserting GBL enables snooping of data buffers, BDs, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”
	3–4	BO	Byte ordering. This field is used for data buffers. 00, 01, 11 Reserved 10 Big endian
	5	CETM	QUICC Engine block transaction mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1and Section 5.4.3.7, “Debug Configuration.”

Table 32-35. TCT Field Descriptions (continued)

Offset	Bits	Name	Description
	6	DTB	Data buffer bus 0 Resides on the coherent system bus. 1 Resides on the CE secondary bus.
	7	BDB	BD, interrupt queue and external SRTS logic bus 0 Resides on the coherent system bus. 1 Resides on the CE secondary bus. **Note:** When using AAL5, AAL1 CES in UDC mode, BDs and data should be placed on the same bus (TCT[DTB]=TCT[BDB]).
	8	AVCF	Auto VC off. Determines the behavior of the APC when the last buffer associated with this VC has been sent and no more ready buffers are in the VC's TxBD table. 0 The APC does not remove this VC from the schedule table and continues to schedule it to transmit. 1 The APC removes this VC from the schedule table. To continue transmission after the host adds buffers for transmission, a new ATM TRANSMIT command is needed, which can be issued only after the QUICC Engine block clears TCT[VCON]. **Note:** When over-subscribing UBR or UBR+ channels, set AVCF so that the QUICC Engine block does not become overloaded polling non-active VCs.
	9	—	Reserved, should be cleared.
	10–11	ATT	ATM traffic type 00 Peak cell-rate pacing. The host must initialize PCR and the PCR fraction. Other traffic parameters are not used. 01 Peak and sustain cell rate pacing (VBR traffic). The APC performs a continuous-state leaky bucket algorithm (GCRA) to pace the channel-sustain cell rate. The host must initialize PCR, PCR fraction, SCR, SCR fraction, and BT (burst tolerance). 10 Peak and minimum cell rate pacing (UBR+ traffic). The host must initialize PCR, PCR fraction, MCR, MCR fraction, and MDA. If Scalable APC is enabled, then the user should allocate an additional 4–6 bytes (depend on the alignment) for the APC scheduling table. See Section 32.3.6.3/32-101, for more information. 11 Guaranteed Bit rate mode (GBR traffic). The host must initialize PCR & PCR fraction fields in this TCT and in the corresponding TCTE. For detailed description see 32.3.4.3/32-94.
	12	CPUU	CPCS-UU+CPI insertion (used for AAL5 only). 0 CPCS-UU+CPI insertion disabled. The transmitter clears the CPCS-UU+CPI fields. 1 CPCS-UU+CPI insertion enabled. The transmitter reads the CPCS-UU+CPI (16-bit entry) from external memory. It should be placed after the end of the last buffer (it should not be included in the buffer length).
	13	VCON (status)	Virtual channel is on. Should be set by the host before it issues an ATM TRANSMIT command. When the host sets TCT[STPT] (stop transmit), the QUICC Engine block deactivates this channel and clears VCON when the channel is next encountered in the APC scheduling table. The host can issue another ATM TRANSMIT command only after the QUICC Engine block clears VCON.
		VCON (mode)	Cleared by the host to enable the automatic activation in switch mode - AVCON/AVCF mechanism. When this mode is enabled, the TCT[AVCF] bit should be set. See ATM_AVCON_BASE parameter in Table 32-19 for more description.
	14–15	INTQ	Points to one of four interrupt queues available.

Table 32-35. TCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0	—	Internal use only. Should be cleared.
	1	INF	Used for AAL5 Only. Indicates the transmitter state. Initialize to 0 0 In idle state. 1 In AAL5 frame transmission state.
	2–12	—	Internal use only. Should be cleared.
	13–15	AAL	AAL type 000 AAL0—Reassembly with no adaptation layer 001 AAL1—ATM adaptation layer 1 protocol 010 AAL5—ATM adaptation layer 5 protocol 100 AAL2—ATM adaptation layer 2 protocol, see Chapter 41, “E2AAL2 Microcode”. 101 AAL1_CES—Refer to AAL1, see Chapter 35, “ATM AAL1 Circuit Emulation Service” 110 MSP - Multi ServIce Protocol - switched ATM cells, see Chapter 39, “Enhanced MSP Microcode” All others reserved.
0x04	—	TxDBPTR	Tx data buffer pointer. Holds the real address of the current position in the Tx buffer.
0x08	—	TBDCNT	Transmit BD count. Counts the remaining data to transmit in the current transmit buffer. Its initial value is loaded from the data length field of the TxBD when a new buffer is open; its value is subtracted for any transmitted cell associated with this channel.
0x0A	—	TBD_OffSet	Transmit BD offset. Holds offset from TBD_BASE of the current BD. Should be cleared initially.
0x0C	0–7	Rate Reminder	Rate remainder. Used by the APC to hold the rate remainder after adding the pace fraction to the additive channel rate. Should be cleared initially.
	8–15	PCR Fraction	Peak cell rate fraction. Holds the peak cell rate fraction of this channel in units of 1/256 slot for GCRA scheduler see 32.2.12.1/32-24 for details.
0x0E	—	PCR	Peak cell rate. Holds the peak cell rate (in units of APC slots) permitted for this channel according to the traffic contract. For GCRA scheduler this field is programmed in time units determined by the Time Stamp register. see 32.2.12.1/32-24 for details.
0x10	—	—	Protocol-specific
0x16	—	APCLC/ **GCRA_BT**	APC linked channel. Used by the QUICC Engine block. Initialize to 0 (null pointer). When working in GCRA scheduler this field is used to determine the Burst Tolerance allowed for this channel. The user should program the maximum delay allowed between the system time and the last time this channel was active. In case the delay exceeds this value the GCRA scheduler will adjust the channel credit to this value. It determines the maximum burst size for the channel.It is given in TSR Time units. NOTE: For VBR traffic this value should be initialized to 0xFFFF.
0x18	—	ATMCH	ATM cell header. Holds the full (4-byte) ATM cell header of the current channel. The transmitter appends ATMCH to the cell payload during transmission.

Table 32-35. TCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x1C	0–1	Res	Reserved. Should be cleared.
	2–7	PMT	Performance monitoring table. Points to one of the available 64 performance monitoring tables. The starting address of the table is PMT_BASE+PMT × 32. Can be changed on-the-fly.
	8–15	TBD_BASE [8–27]	TxBD base. Points to the first BD in the channel's TxBD table. The 8 most-significant bits of the address are taken from BD_BASE_EXT in the parameter RAM. The four least-significant bits of the address are taken as zero.
0x1E	0–11		
	12	BNM	Buffer-not-ready interrupt mask. Can be changed on-the-fly. 0 The transmit buffer-not-ready event of this channel is masked. (TBNR event is not sent to the interrupt queue.) 1 The buffer-not-ready event of this channel is enabled.
	13	STPT	Stop transmit. Should be cleared initially. When the host sets this bit, the QUICC Engine block deactivates this channel and clears TCT[VCON] when the channel is next encountered in the APC scheduling table. **Note1** For AAL5 if STPT is set and frame transmission is already started (TCT[INF]=1), an abort indication will be sent (last cell with zero length field). **Note2** When working in GBR mode, The sequence of stopping a channel is as follows: First the CBR priority takes the channel from the scheduling table and indicates to the UBR priority level to stop rescheduling the channel on the next appearance of it in the APC. At this point the TCT[VCON] bit is cleared. **Note3** When the channel is a multi-cast channel e.g. TCT[MC]=1 there is a special host command for removing a channel from the multicast group. The s/w should not set this bit for stopping such a channel.
0x1E	14	IMK	Interrupt mask. Can be changed on-the-fly. 0 The transmit buffer event of this channel is masked. (TXB event is not sent to the interrupt queue.) 1 The transmit buffer event of this channel is enabled.
	15	PM	Performance monitoring. Can be changed on-the-fly. 0 No performance monitoring for this VC. 1 Performance is monitored for this VC. When a cell is sent for this VC, the performance monitoring table indicated in PMT field is updated.

32.3.4.2.1 AAL5 Protocol-Specific TCT

Figure 32-41 shows the AAL5 protocol-specific TCT.

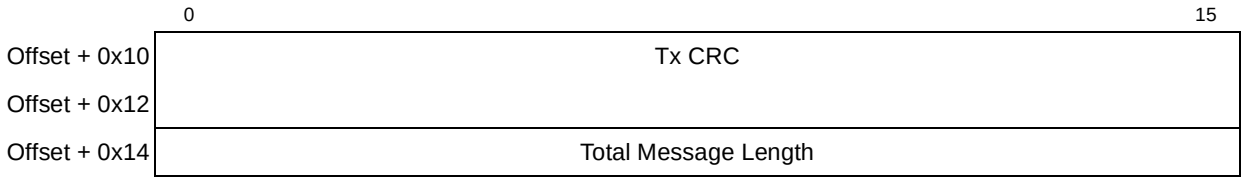

Figure 32-41. AAL5 Protocol-Specific TCT

Table 32-36 describes AAL5 protocol-specific TCT fields.

Table 32-36. AAL5-Specific TCT Field Descriptions

Offset	Name	Description
0x10	Tx CRC	CRC32 temporary result.
0x14	Total Message Length	This field is used by the QUICC Engine block.

32.3.4.2.2 AAL1 Protocol-Specific TCT

Figure 32-42 shows the AAL1 protocol-specific TCT.

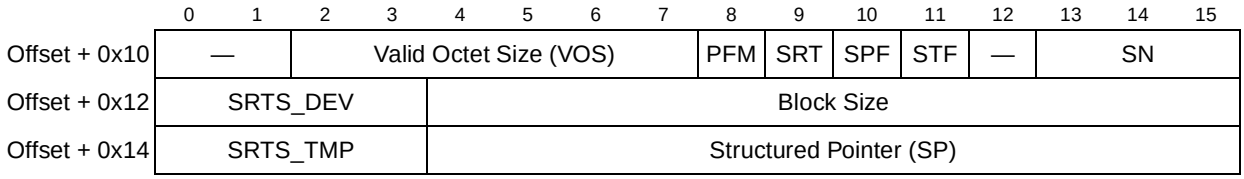

Figure 32-42. AAL1 Protocol-Specific TCT

Table 32-37 describes AAL1 protocol-specific TCT fields.

Table 32-37. AAL1 Protocol-Specific TCT Field Descriptions

Offset	Bits	Name	Description
0x10	0–1	—	Reserved, should be cleared.
	2–7	VOS	Valid octet size. Partially filled cell mode only. Specifies the number of valid octets from the beginning of the AAL1 user data field. For unstructured service, values 1-47 are valid; for structured service, values 1-46 are valid.
	8	PFM	Partially filled mode. 0 Partially filled cells mode is not used. 1 Partially filled cells mode is used. The transmitter copies only valid octets from the buffer to the AAL1 cell. The size of the valid octets from the beginning of the AAL1 user data field is specified in the VOS (valid octet size) field.
	9	SRT	Synchronous residual time stamp. Unstructured format only. The QUICC Engine block supports SRTS generation using external logic. If this mode is enabled, the QUICC Engine block reads the SRTS from external logic and inserts it into four cells for which SN = 1, 3, 5, or 7. The QUICC Engine block reads the new SRTS from external logic every eight cells. (See 32.2.22.4.1/32-48) 0 SRTS mode is not used. 1 SRTS mode is used.
	10	SPF	Structured pointer flag. Indicates that a structured pointer has been inserted in the current block. The user should initialize this field to zero. Used by the QUICC Engine block only.
	11	STF	Structured format 0 Unstructured format is used. 1 Structured format is used.
	12	—	Reserved, should be cleared.
	13–15	SN	Sequence number field. Used by the QUICC Engine block to generate and maintain the SN of the cell. Should be cleared initially.

Table 32-37. AAL1 Protocol-Specific TCT Field Descriptions

Offset	Bits	Name	Description
0x12	0–3	SRTS_DEV	Used to select a SRTS device. The SRTS device address is SRTS_BASE[0–27]+SRTS_DEV[28:31]. SRTS_BASE is taken from the parameter RAM and is 16-byte aligned.
	4–15	Block Size	Used only in structured format. Specifies the structured block size (Block Size = 0xFFF = 4 Kbytes maximum).
0x14	0–3	SRTS_TMP	Before a cell with SN = 1 is sent, the QUICC Engine block reads the SRTS code from external SRTS logic, writes it to SRTS_TMP, and then inserts SRTS_TMP into the next four cells with an odd SN.
	4–15	SP	Structured pointer. Used by the QUICC Engine block to calculate the structured pointer. Should be cleared initially. Structured format only.

32.3.4.2.3 AAL0 Protocol-Specific TCT

Figure 32-43 shows the AAL0 protocol-specific TCT.

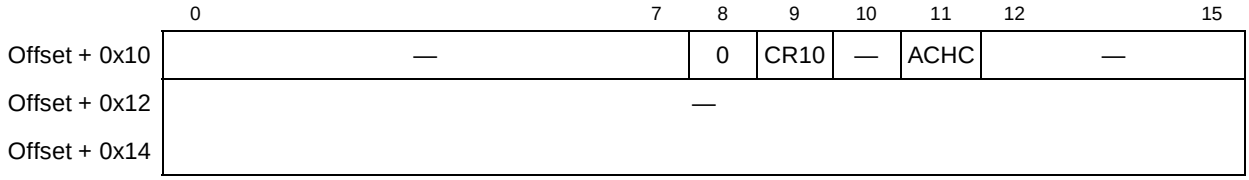

Figure 32-43. AAL0 Protocol-Specific TCT

Table 32-38 describes AAL0 protocol-specific TCT fields.

Table 32-38. AAL0-Specific TCT Field Descriptions

Offset	Bits	Name	Description
0x10	0–7	—	Reserved, should be cleared.
	8	0	Must be 0.
	9	CR10	CRC-10 0 CRC10 insertion is disabled. 1 CRC10 insertion is enabled.
	10	—	Reserved, should be cleared.
	11	ACHC	ATM cell header change 0 Normal operation ATM cell header is taken from AAL0 buffer. 1 VPI/VCI (28 bits) are taken from TCT.
	12–15	—	Reserved, should be cleared.
0x12–0x14	—	—	Reserved, should be cleared.

32.3.4.2.4 AAL1 CES Protocol-Specific TCT

Refer to Section 35.9.2, “Transmit Connection Table (TCT).”

32.3.4.2.5 AAL2 Protocol-Specific TCT

Refer to Section 41.3.5.1, “AAL2 Transmit Connection Tables.”

32.3.4.2.6 VBR Protocol-Specific TCTE

Figure 32-44 shows the VBR protocol-specific TCTE.

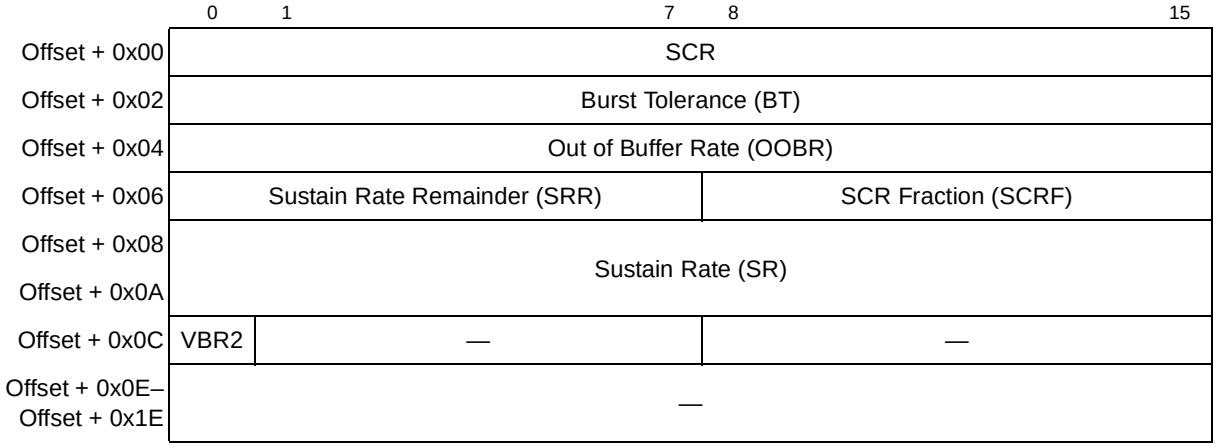

Figure 32-44. Transmit Connection Table Extension (TCTE)—VBR Protocol-Specific

Table 32-39 describes VBR protocol-specific TCTE fields.

Table 32-39. VBR-Specific TCTE Field Descriptions

Offset	Bits	Name	Description
0x00	—	SCR	Sustain cell rate. Holds the sustain cell rate (in slots) permitted for this channel according to the traffic contract. To pace the channel’s sustain cell rate, the APC performs a continuous-state leaky bucket algorithm (GCRA). For GCRA scheduler this field is programmed in time units determined by the Time Stamp register. see Section 32.2.12.1, “GCRA Scheduler Rate Programming for details.
0x02	—	BT	Burst tolerance. Holds the burst tolerance permitted for this channel according to the traffic contract. The relationship between the BT and the maximum burst size (MBS) is BT=(MBS-2) × (SCR-PCR) + SCR.
0x04	—	OOBR	Out-of-buffer rate. In out of buffer state (when the transmitter tries to open TxBD whose R bit is not set) the APC reschedules the current channel according to OOBR rate. For GCRA scheduler this field is programmed in time units determined by the Time Stamp register. see Section 32.2.12.1, “GCRA Scheduler Rate Programming for details.
0x06	0–7	SRR	Sustain rate remainder. Holds the sustain rate remainder after adding the pace fraction field to the additive channel sustain rate. Used by the APC to calculate the channel GCRA (leaky bucket) state. Initialized to 0.
	8–15	SCRF	Holds the sustain cell rate fraction of this channel in units of 1/256 slot.
0x08	—	SR	Sustain rate. Used by the APC to hold the sustain rate after adding the pace field to the additive channel sustain rate. Used by the APC to calculate the channel GCRA (leaky bucket) state.

Table 32-39. VBR-Specific TCTE Field Descriptions (continued)

Offset	Bits	Name	Description
0x0C	0	VBR2	VBR type 0 Regular VBR. CLP=0+1 cells are rescheduled by PCR or SCR according to the GCRA state. 1 VBR Type 2. CLP=0 cells are rescheduled by PCR or SCR according to the GCRA state. CLP=1 cells are rescheduled by PCR.
	1–7	—	Reserved, should be cleared.
	8–15	—	Reserved, should be cleared.
0x0E–0x1E	—	res	Reserved, should be cleared.

32.3.4.2.7 UBR+ Protocol-Specific TCTE***

Figure 32-45 shows the UBR+ protocol-specific TCTE.

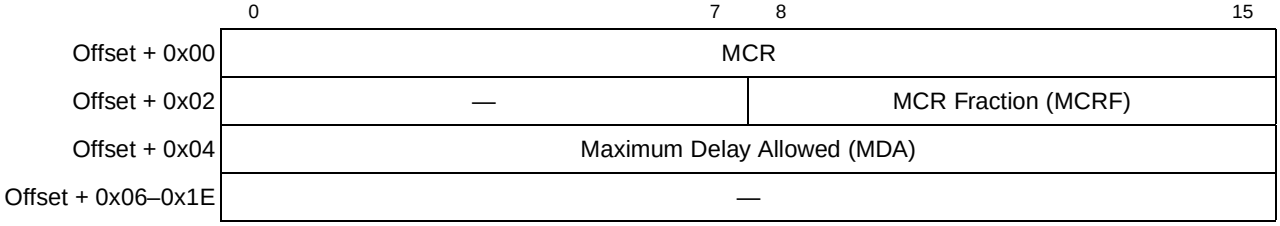

Figure 32-45. UBR+ Protocol-Specific TCTE

Table 32-40 describes UBR+ protocol-specific TCTE fields.

Table 32-40. UBR+ Protocol-Specific TCTE Field Descriptions

Offset	Bits	Name	Description
0x00	—	MCR	Minimum cell rate for this channel. MCR is in units of APC time slots. For GCRA scheduler this field is programmed in time units determined by the Time Stamp register. see Section 32.2.12.1, “GCRA Scheduler Rate Programming” for details.
0x02	0–7	—	Reserved, should be cleared.
	8–15	MCRF	Minimum cell rate fraction. Holds the minimum cell rate fraction of this channel in units of 1/256 slot.
0x04	—	MDA	Maximum delay allowed. The maximum time-slot service delay allowed for this priority level before the APC reduces the scheduling rate from PCR to MCR.
0x06–0x1E	—	—	Reserved, should be cleared.

32.3.4.2.8 Scalable-APC TCTE

Figure 32-46 shows the Scalable-APC TCTE.

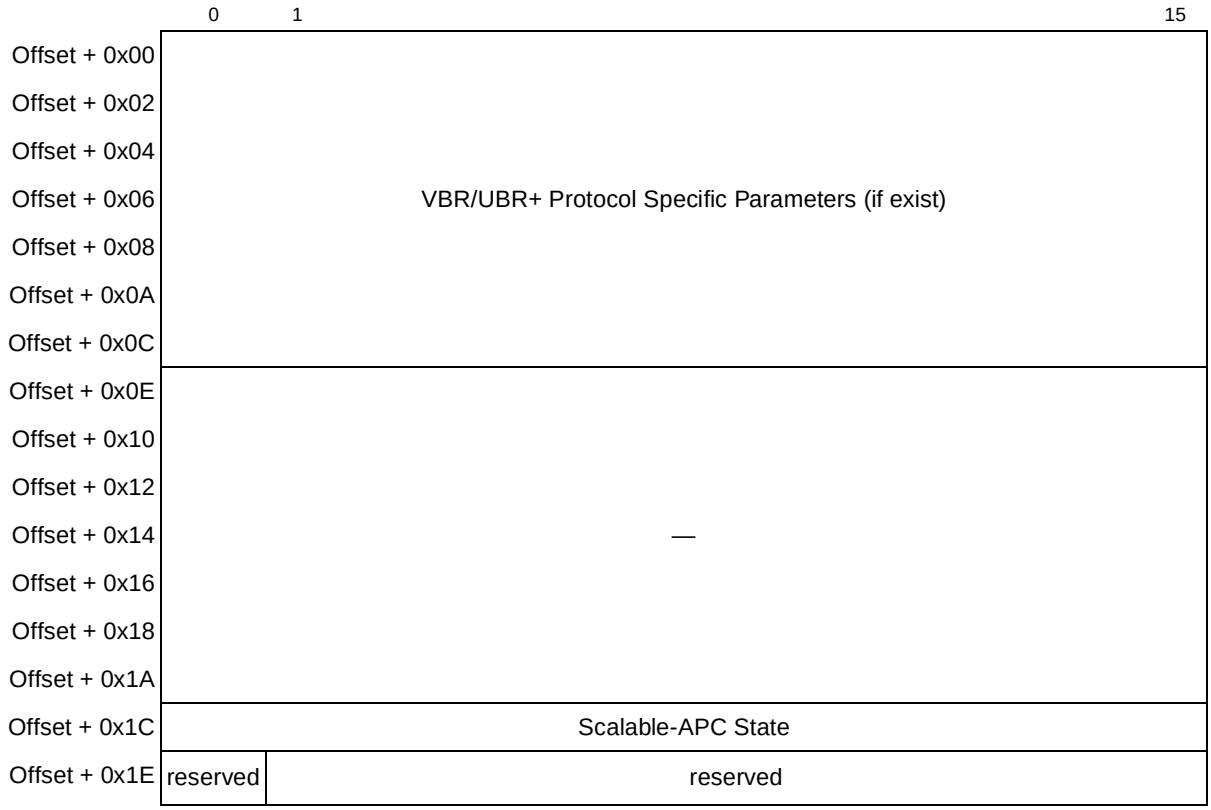

Figure 32-46. Scalable-APC TCTE

Table 32-41 describes Scalable-APC TCTE fields.

Note: This mode doesn't allow working in GBR- Guaranteed Bit Rate mode described in the Section 32.3.4.3, "GBR Programming Model."

Table 32-41. Scalable-APC TCTE Field Descriptions

Offset	Bits	Name	Description
0x00–0x0c	—	VBR/UBR+ Protocol Specific Parameters	VBR/UBR+ Protocol Specific Parameters (if exist).
0x0E–0x1A	—	—	Reserved, should be cleared.
0x1C–0x1D	—	Scalable-APC State	Reserved, should be cleared. When initiating an STPT command, if the channel is restarted again then these bits should be cleared.
0x1E–0x1F	0	—	reserved.
	1–15		reserved.

32.3.4.3 GBR Programming Model

Figure 32-47 depicts the GBR implementation.

An ATM channel is scheduled for transmission on two priority levels. One has a CBR contract residing on the highest priority level and the other has a UBR contract residing on any other lower priority scheduling table. The host should initialize both TCT & TCTE. The TCT contains the parameters which are common to both, the higher priority-CBR and lower priority-UBR. These parameters include the ATM cell header, BD ring information and internal statuses for the channel- (TBD_BASE, ATM Cell Header....) It also contains the CBR traffic parameters: PCR, Rate remainder, PCR fraction and APC Linked Channel. Its TCT[ATT]=0b11 indicating it's a GBR type. On the highest priority there is no need to set the control slot described in Section 32.3.6.3, "APC Scheduling Tables" for fetching the TCTE data structure.

On the UBR priority level the control slot should indicate the need for the TCTE data structure as this priority level is configured based on the parameters residing in this data structure. The TCTE contains the traffic parameters: PCR, PCR fraction and the APC Linked Channel on this priority level. It is described in Figure 32-48.

Working in GCRA scheduler requires programming the PHY parameters table and some predefined rules of how to set the channels in this mode. The TCT and TCTE are programmed according to the GCRA scheduler programming model.

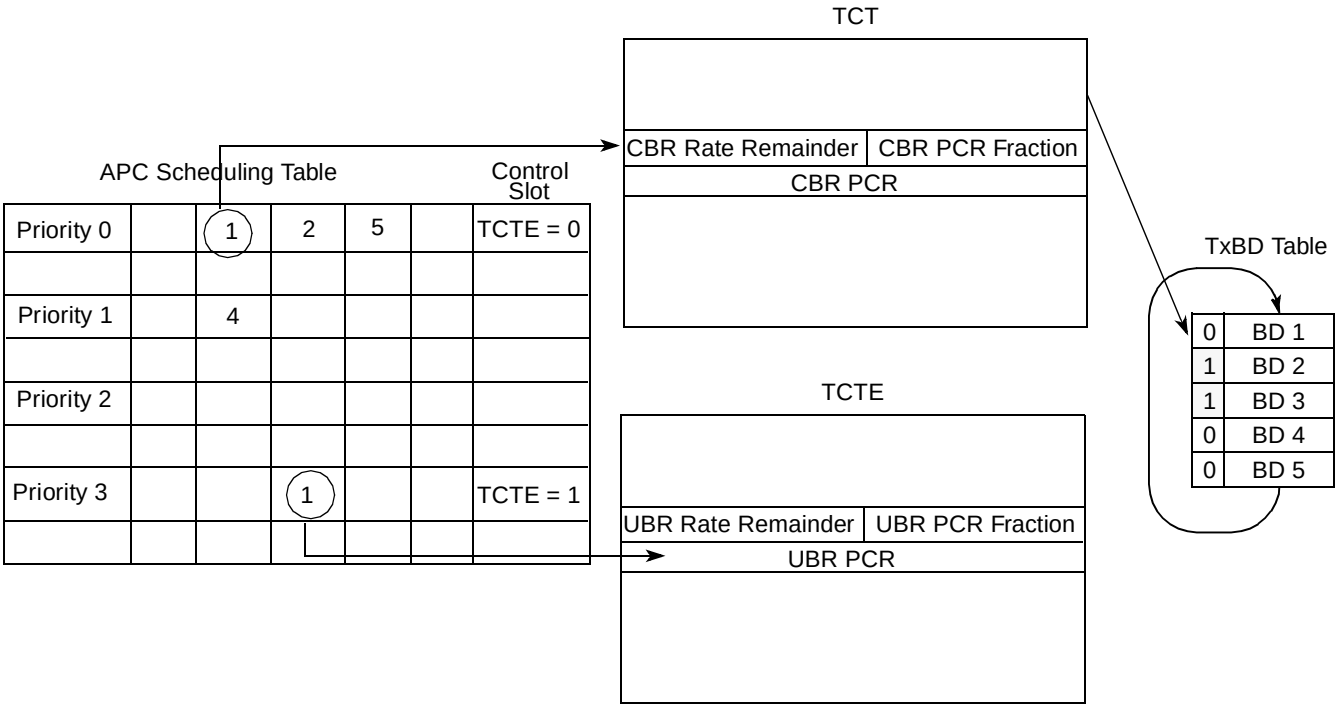

Figure 32-47. GBR Illustration

In termination mode activation of the GBR scheduling is done by two host commands. One for inserting a channel into the higher priority scheduling table and additional command for inserting the same channel into the UBR priority level. See Table 32-70.

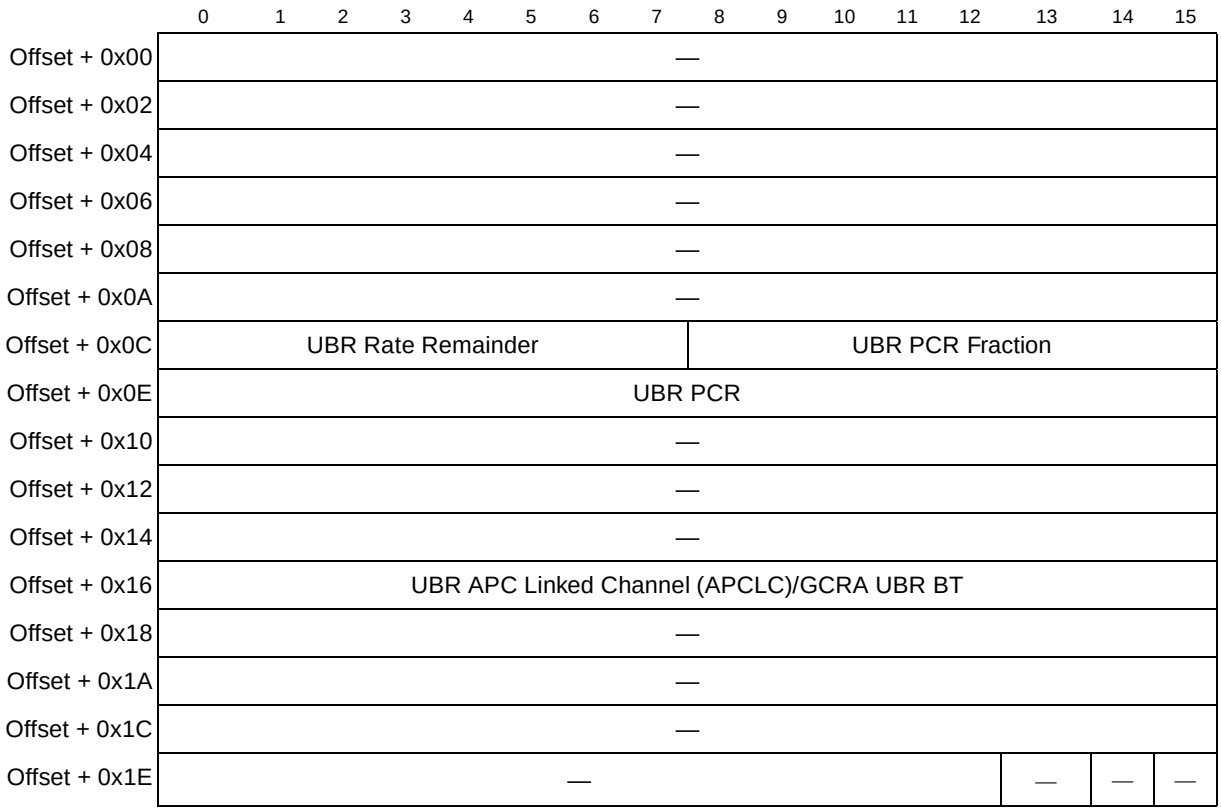

Figure 32-48. GBR Protocol-Specific TCTE

Table 32-42 describes the fields of the GBR protocol-specific TCTE.

Table 32-42. GBR Protocol-Specific TCTE Field Descriptions

Offset	Bits	Name	Description
0x00–0x0A	—	—	Reserved, should be cleared.
0x0C	0–7	**UBR Rate Reminder**	Rate remainder. Used by the APC to hold the rate remainder after adding the pace fraction to the additive channel rate. Should be cleared initially.
	8–15	**UBR PCR Fraction**	Peak cell rate fraction. Holds the peak cell rate fraction of this channel in units of 1/256 slot For GCRA scheduler see Section 32.2.12.1, “GCRA Scheduler Rate Programming” for details.
0x0E	—	**UBR PCR**	Peak cell rate. Holds the peak cell rate (in units of APC slots) permitted for this channel according to the traffic contract. For GCRA scheduler this field is programmed in time units determined by the Time Stamp register. see Section 32.2.12.1, “GCRA Scheduler Rate Programming” for details.
0x10–0x14	—	—	Reserved, should be cleared.
0x16	—	UBR APCLC/ GCRA UBR BT	APC linked channel. Used by the QUICC Engine block. Initialize to 0 (null pointer). For GCRA scheduling this is the BT value for the UBR priority.
0x18	—	—	Reserved, should be cleared.

Table 32-42. GBR Protocol-Specific TCTE Field Descriptions (continued)

Offset	Bits	Name	Description
0x1A	—	—	Reserved, should be cleared.
0x1C	—	—	Reserved, should be cleared.
0x1E	0–13	—	Reserved, should be cleared.
	14–15	—	Reserved, should be cleared.

The operation of GBR scheduling is as follow:

- Initialize an APC priority table for the highest priority (CBR).
- Initialize an APC priority table for the lower priority (UBR) with bit TCTE in the control slot set.
- Set the TCT[ATT] bits to 0b11.
- Initialize TCT[PCR], TCT[PCR fraction] and TCT[Rate remainder] with CBR related parameters.
- Initialize TCTE[PCR], TCTE[PCR fraction], TCTE[Rate remainder] with UBR related parameters.
- Issue an ATM transmit command related to CBR priority traffic:

  The PRI field in the COMM_INFO should be reset (highest priority) and ACT field should be reset too. This puts the channel into the highest priority on the APC.
- Issue an ATM transmit command for GBR-UBR related to UBR priority traffic. In this command, the channel code is the same as the previous ATM transmit command.

  The PRI field should be different from zero (not highest priority) and ACT field should be 0b10. For GCRA scheduler this should always be the lowest priority level. (For details on GCRA scheduler and GFR mode see Section 32.3.7.1.1, “GBR Operation in GCRA Scheduler Mode.”

32.3.5 OAM Performance Monitoring Tables

The OAM performance monitoring tables include performance monitoring block test parameters, as shown in Figure 32-49. Each block test needs a 32-byte performance monitoring table in the multi-user RAM. In the connection’s RCT and TCT, the user allocates an OAM performance table to a VCC or VPC. See Section 32.2.19, “Performance Monitoring.” PMT_BASE in the parameter RAM points to the base address of the tables. The starting address of each PM table is given by PMT_BASE + RCT/TCT[PMT] × 32.

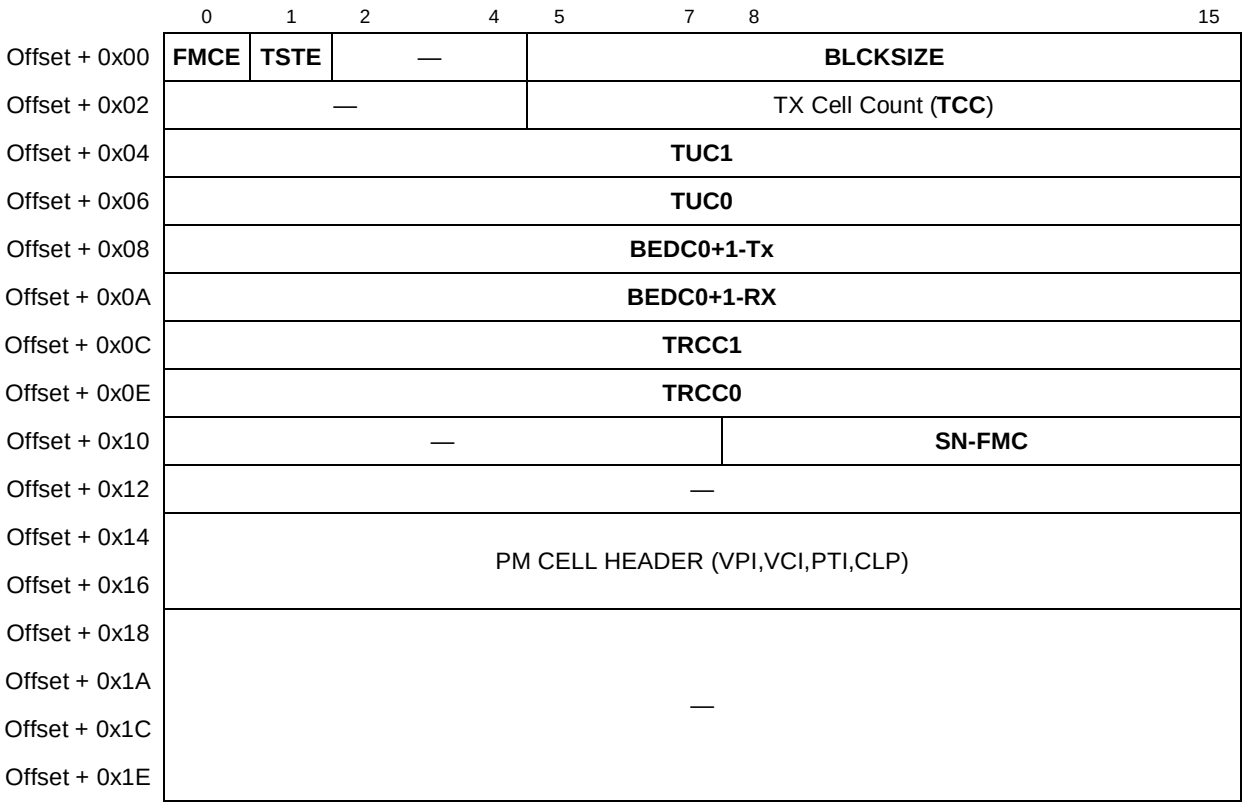

Figure 32-49. OAM Performance Monitoring Table

Table 32-43 describes the fields of the performance monitoring table.

Table 32-43. OAM—Performance Monitoring Table Field Descriptions

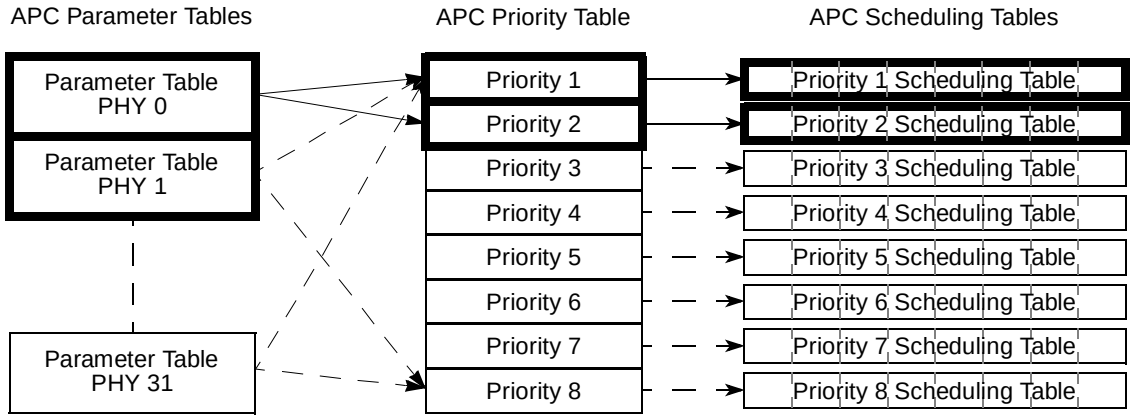
Offset	Bits	Name	Description
0x00	0	**FMCE**	Enables FMC transmission. Initialize to 1.
	1	**TSTE**	FMC time stamp enable 0 The time stamp field of the FMC is coded with all 1's. 1 The value of the time stamp timer is inserted into the time stamp field of the FMC.
	2–4	—	Reserved, should be cleared.
	5–15	**BLCKSIZE**	Performance monitoring block size ranging from 1 to 2,047 cells.
0x02	0–4	—	Reserved, should be cleared.
	5–15	**TCC**	TX cell count. Used by the QUICC Engine block to count data cells sent. Initialize to zero.
0x04	—	**TUC1**	Total user cell 1. Count of CLP = 1 user cells (modulo 65,536) sent. Should be cleared initially.
0x06	—	**TUC0**	Total user cell 0. Count of CLP = 0 user cells (modulo 65,536) sent. Should be cleared initially.
0x08	—	**BEDC0+1-Tx**	Block error detection code 0+1–transmitted cells. Even parity over the payload of the block of user cells sent since the last FMC. Should be cleared initially.

Table 32-43. OAM—Performance Monitoring Table Field Descriptions (continued)

Offset	Bits	Name	Description
0x0A	—	**BEDC0+1-RX**	Block error detection code 0+1–received cells. Even parity over the payload of the block of user cells received since the last FMC. Should be cleared initially.
0x0C	—	**TRCC1**	Total received cell 1. Count of CLP = 1 user cells (modulo 65,536) received. Should be cleared initially.
0x0E	—	**TRCC0**	Total received cell 0. Count of CLP = 0 user cells (modulo 65,536) received. Should be cleared initially.
0x10	0–7	—	Reserved, should be cleared.
	8–15	**SN-FMC**	Sequence number of the last FMC sent. Should be cleared initially.
0x12	—	—	Reserved, should be cleared.
0x14	—	**PMCH**	PM cell header. Holds the ATM cell header of the FMC, BRC to be inserted by the QUICC Engine block into the Tx cell flow.
0x18–0x1E	—	—	Reserved, should be cleared.

32.3.6 APC Data Structure

The APC data structure consists of three elements: the APC parameter tables for the PHY devices, the APC priority table, and the APC scheduling tables. See Figure 32-50.



Note: The highlighted areas represent the active structures for an example implementation of PHY 0 with two priorities. (The unhighlighted areas and dashed arrows represent unused structures.)

Figure 32-50. ATM Pace Control Data Structure

32.3.6.1 APC Parameter Tables

Each PHY's APC parameter table, shown in Table 32-44, holds parameters that define the priority table location, the number of priority levels, and other APC parameters. The table resides in the multi-user RAM. The parameter APCP_BASE, described in Section 32.3.2, "Parameter RAM," points to the base address of PHY#0's parameter table.

For multiple PHYs, the table structure is duplicated. Each table resides in 32 bytes of memory. The starting address of each APC parameter table is given by APCP_BASE + PHY# × 32. For multi device situation the device holds the MSB part of the PHY ID such that device 0 occupies PHY's 0–31, device 1 occupies PHY's 32–63 etc. Note however that in slave mode with multiple PHYs, the parameter table always resides at APCP_BASE regardless of the PHY address.

Table 32-44. APC Parameter Table

Offset[1]	Name	Width	Description
0x00	APCL_FIRST	Hword	Address of first entry in the priority table. Must be 8-byte aligned. User-initialized.
0x02	APCL_LAST	Hword	Address of last entry in the priority table. Must be 8-byte aligned. User-initialized as APCL_FIRST + 8 x (number_of_priorities - 1).
0x04	APCL_PTR	Hword	Address of current priority entry used by the QUICC Engine block. User-initialized with APCL_FIRST.
0x06	CPS	Byte	**Note:** Cells per slot. Determines the number of cells sent per APC slot. See 32.2.5.2/32-13. User-defined. (0x01 = 1 cell; 0xFF = 255 cells.)
0x07	CPS_CNT	Byte	Cells sent per APC slot counter. User-initialized to CPS; used by the QUICC Engine block.
0x08	MAX_ITERATION	Byte	Max iteration allowed. Number of scan iterations allowed in the APC. User-defined. This parameter limits the time spent in a single APC routine, thereby avoiding excessive APC latency.
0x09	—	Byte	Reserved. Should be cleared.
0x0A	FIRST_UBR+ _LEVEL	Hword	This field contains the address of the first UBR+ Priority level. For example, if the first UBR+ priority level is 4 then the address should be calculated as AFP_FIRST + 8 x (UBR+ priority level number- 1). See 32.2.10/32-21, for more information.
0xC	REAL_TSTP	Word	Real-time stamp pointer used internally by the APC. Should be cleared initially.
0x10	APC_STATE	Word	Used internally by the APC. Should be cleared initially.
0x14	—	Word	Reserved for QUICC Engine block use. Should be cleared.
0x18	APC_SLOT_DUR _VAL_INT	Word (31 bits)	APC Slot Duration Value Integer. Valid only when Scheduler_MODE[AFC] is set, See Table 32-45. Initialized by the user and it represent the expected time duration of each APC slot. The value programmed here should reflect the maximum rate of the selected PHY. i.e the minimum time required to the APC to send CPS cells. See description in Section 32.2.8, "APC Flux Compensation."
0x1C	APC_SLOT_DUR _VAL_Frac	HWord (16 bits)	APC Slot Duration Value Fraction. Valid only when Scheduler_MODE[AFC] is set, See Table 32-45 Initialized by the user and it represent the fraction of the expected time duration of each APC slot, See description in Section 32.2.8, "APC Flux Compensation."
0x1E	Scheduler_MODE	Hword	Defined in Table 32-45.

[1] Offset values are to APCP_BASE+PHY# × 32. However, in slave mode, the offset is from APCP_BASE regardless of the PHY address.

32.3.6.1.1 Scheduler_MODE

Figure 32-51 shows the layout of the Scheduler_MODE.

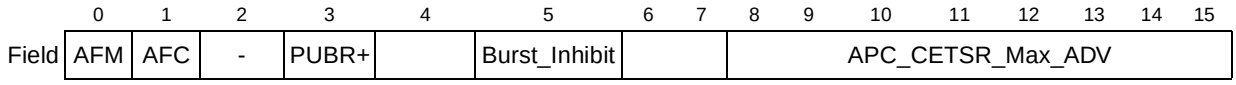


Figure 32-51. Scheduler_MODE

Table 32-45 describes Scheduler_MODE fields.

Table 32-45. Scheduler_MODE Field Descriptions

Bits	Name	Description
0	AFM	Scheduler Mode. if GMODE[MSP]=0) this bit is ignored if GMODE[MSP]=1) Meaning MSP operation is enabled in the system 0- This PHY's scheduling is eight FIFO queues. See "Section 39.10.3.2, Scheduler Parameter Table in WFQ Mode (AFM=0)" on page 53 1- This PHY's scheduling is APC based.
1	AFC	APC Flux Compensation mode. 0 - No time compensation mode. 1 -APC Time Compensation mode is enabled. See 32.2.8/32-19.
2	—	Reserved. Should be cleared.
3	PUBR+	Prioritized UBR+ mode. 0 - Prioritized UBR+ mode is disabled. 1 - Prioritized UBR+ mode is enabled. See 32.2.10/32-21, for more information.
4	—	Reserved. Should be cleared.
5	Burst_Inhibit	APC Burst Inhibit. Valid for Flux or traditional APC modes. 0 - APC Burst Inhibit is disabled. This means that theoretically there could be a situation in which the gap between the rptr and the sptr is too big, that even after rescheduling the channel will be allocated still before the rptr. This could lead to the case of burst traffic in line rate for this channel, assuming for example that it is the only channel in the APC scheduling table. 1 - APC Burst Inhibit is enabled. This means that burst traffic is eliminated, by avoiding reschedule of a channel before the RPTR. In this case, the channel will be reschedule to the RPTR itself.
6–7	—	Reserved. Should be cleared.
8–15	APC_CETSR_Max_ADV	APC Maximum CETSR Advanced value. Valid Only if AFC=1. User initialized to the maximum value the RPTRs in the APC table could be advanced. In cases where there is a big delay in the PHY this value sets the limitation of how many APC slots the CETSR should be advanced. It prevents the QUICC Engine block from doing extra calculation and assures proper operation of the APC. In any case this number should not exceed the (number of slots in the APC table-1)

32.3.6.2 APC Priority Table

Each PHY's APC priority table holds pointers to the APC scheduling table of each priority level. It resides in the multi-user RAM. The priority table can hold up to eight priority levels. Table 32-46 shows the structure of a priority table entry.

Table 32-46. APC Priority Table Entry

Offset	Name	Width	Description
0x00	APC_LEVi_BASE	Hword	APC level i base address. Pointer to the first slot in the APC scheduling table for level i. Should be half-word aligned. User-defined.
0x02	APC_LEVi_END	Hword	APC level i end address. Pointer to the last slot in the APC scheduling table for level i. Should be half-word aligned. User-defined.
0x04	APC_LEVi_RPTR	Hword	APC level i real-time/service pointers. APC table pointers used internally by the APC. Initialize both pointers to APC_LEVi_BASE.
0x06	APC_LEVi_SPTR	Hword	

32.3.6.3 APC Scheduling Tables

The APC uses APC scheduling tables (one table for each priority level) to schedule channel transmission. A scheduling table is divided into time slots, as shown in Figure 32-52. Each slot is a half-word entry. Note that the APC scheduling tables should be cleared before the APC unit is enabled.

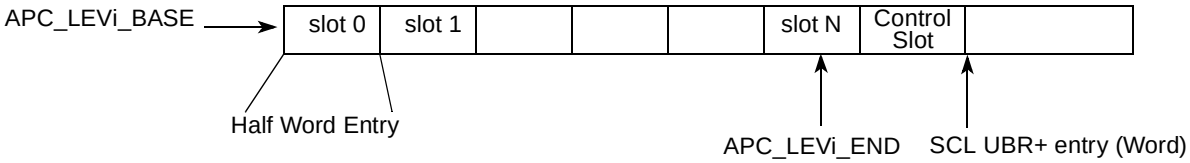

Figure 32-52. The APC Scheduling Table Structure

If working in APC Scalable mode and there are UBR+ channels in the APC table (SCL_UBR bit is set in the control slot see Figure 32-53), or the APC overload mechanism for AAL2 described in Section 41.4.3.1.2, “Automatic Bandwidth Allocation” is enabled, the user should allocate an extended control slot which consists of additional 4 or 6 bytes (besides the Control slot) to the APC scheduling table, This is for QUICC Engine block internal use only (should be initialized to 0). The requirement for the last 4 bytes to be word aligned so that the user should allocate additional 4 bytes for this entry if the control slot is at a Non-Word (Word is 4 bytes) aligned address, or allocate an addition of 6 bytes for this entry if the control slot is at a Word aligned address. In these cases the Ext_CS bit should be set see Figure 32-53

Slot N+1 is used as a control slot, as shown in Figure 32-53.

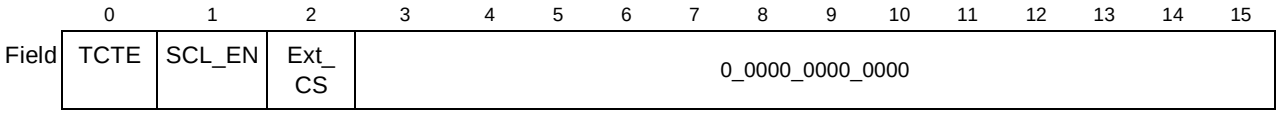

Figure 32-53. Control Slot

Table 32-47 describes control slot fields.

Table 32-47. Control Slot Field Description

Bits	Name	Description
0	TCTE	Used for external channels only. 0 Channels in this scheduling table do not use external TCTE. (None of: external VBR, UBR+, GBRor Scalable-APC channels) 1 Channels in this scheduling table use external TCTE. (External VBR, UBR+, GBRor Scalable-APC channels)
1	SCL_EN	Scalable APC mode. 0 Scalable APC mode is disabled. 1 Scalable APC mode is enabled. This requires clearing offsets 0x1C–0x1F in the TCTE tables of all the channels which resides in this scheduling table. See 32.2.7/32-18.
2	Ext_CS	Extended Control Slot. 0 No need for the extended size control slot. 1 SCL_EN mode is enabled and UBR+ channels for this APC priority table or the APC overload mechanism for AAL2 is enabled.
3–15	—	Reserved, should be cleared.

32.3.6.4 UBR+ Priority Decision Table Entry

When the UBR+ priority mode is enabled, the UBR+ priority decision table must be initialized, see Section 32.2.10, “Prioritized UBR+ Mode”. The UBR+ priority decision table is located at address Scheduler_Parameter_Table [AFP_LAST]+8, and each entry contains 4 bytes. Figure 32-54, describes the UBR+ priority decision table entry.

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Offset	Bit	Name	Description
0x00	0	—	Reserved. Should be initialized to 0.
	1–15	Reserved	Reserved. Initialize to zero.
0x02	0–15	THRESHOLD	This field contain the UBR+ MDA value for this priority level (In APC slot units).

32.3.7 GCRA Scheduler Structures

32.3.7.1 GCRA Scheduler PHY Parameter Table

The GCRA scheduler PHY Parameter RAM table occupies 32 bytes, see Figure 32-55. The user can configure each PHY to work in traditional APC or GCRA scheduler mode, by setting GCRA_SCHED bit. For more explanation about the GCRA scheduler mode see Section 32.2.12, “GCRA Scheduler”.

0x0c	—	Time Stamp Shadow Register3	Word	Reserved.Should be cleared.

Table 32-49. GCRA Scheduler PHY Parameter Table Description (continued)

Offset [1]	Bits	Name	Width	Description
0x10	0	**GCRASCHED**	—	GCRASCHED- Should be set. 0 - This PHY work using traditional APC. 1 - This PHY work using GCRA scheduler mode.
	1	**TCTE**	—	Used for external channels only. 0 Channels in this scheduling table do not use external TCTE. (No external VBR, UBR+, GBR) 1 Channels in this scheduling table use external TCTE. (External VBR, UBR+, GBR)
	2	**Expand**		Expand Mode- For better memory utilization and smaller memory footprint of the APC scheduling table the default maximum number of ATM channels supported for this APC is 32. In cases where the maximum number of channels in the APC is >= 32 the size of this table is increased by 0x10 bytes. see Table and Table 32-51 for details 0- Normal mode support for 32 channels. 1- Expanded size model enabled. Supports max of 64 channels per PHY.
	3	**GBR_En**	—	GBR mode is enabled on this GCRA scheduler. See details in Section 32.3.7.1.1, “GBR Operation in GCRA Scheduler Mode”
	4	**—**	—	Reserved. Should be set to 0.
	5		—	Reserved. Should be set to 0.
	6–7	**Last_Priority**	—	The highest Priority Number available for this PHY 00 - Priority 0 - the highest priority. 01 - Priority 1. 10 - Priority 2. 11 - Priority 3.
	8–15	**Size**	—	Size of the comparison table in bytes-1. User initialized to the number of ATM channels which are active in the GCRA scheduling table *2 -1. Each GBR channel is considered as two channels for this count
0x12	—	**FIRST_CC**	Hword	First CC value. User initialized to the first CC that fit to index 0 in the priority x MASK.
0x14	—	**GCRA_SCHEDTable_ptr_**	Word	GCRA Scheduler Table pointer. Initialized to the base address of the GCRA scheduler table. Should be aligned to 32 bytes. The maximum memory allocation for 64 ATM channels in expanded mode is: 32+64*2 = 160 bytes. For a table which has less then 32 channels the size is 16+ Num of channels*2.
0x18	—	—	4*Hword	Reserved. Should be cleared.

[1] Offset from PHY# * 0x20.

Table shows the GCRA scheduling table structure. The user can initialize maximum of 64 channels per PHY, plus extra 32 header bytes for the Pri_MASK entries. Therefore the maximum size of this structure is (32+64*2=) 160 bytes.

This table consists of the theoretical Finish Time (FT) of each of the potential 64 ATM channels codes residing under this PHY. The selection algorithm within this scheduling table is finding the entry which has the minimum Finish time in each priority, starting from the highest priority, and checking if this

minimum FT is smaller than the current system time (CETSR). If this is the case then the Channel Code is selected for transmission, and in the rescheduling process the FT will be updated according to the TCT[PCR] value (e.g. for CBR channel). On the other hand, if there is no channel for transmission from the highest priority, the QUICC Engine block continues to search a channel from lower priorities, and so on.

32.3.7.1.1 GBR Operation in GCRA Scheduler Mode

If GBR bit is set enabling Guaranteed Bit Rate scheduling, the QUICC Engine block requires a predefined channel code assignment for those GBR channels. The CBR part of this traffic is located in priority 0-identical to the standard APC. The UBR part of this traffic resides in the lowest priority ONLY. In this case the lowest priority is designated for the UBR part of the GBR traffic and should not have any other types of connections assigned to it. The host has to issue two host commands for inserting the same channel into two priority levels. Even though it is a single channel it consumes the space of two channels since each of the traffic priorities requires a Finish Time of its own. Upon issuing the host command for the CBR traffic the channel is inserted and the priority mask is updated according to the channel number. For the UBR priority the QUICC Engine block will automatically assign the next channel number and will set the priority mask accordingly even though there is no TCT/TCTE initialized for this channel number. The UBR priority must reside on the lowest priority level. The channel numbers of the CBR traffic must have even numbers and the UBR channels will have the following number. Once a UBR channel is selected for transmission the QUICC Engine block will fetch the TCT and TCTE of the CBR priority level.

For example if channel #368 is assigned to the CBR traffic, channel #369 should not be used in any other priority levels and is designated for the UBR priority level. TCT and TCTE for channel #369 should not ne initialized.

Offset	Bits	Name	Width	Description
0x00	—	**Pri0_MASK**	DWord	Priority 0 MASK. The relevant bits that corresponds to the active channels in priority 0 (up to 64 channels in all the priorities), are set by the QUICC Engine block. This parameter can be dynamically changed, if the channel is removed or being add to the APC. This can be done only by issuing host command. See 32.2.12.2/32-24. If GBR scheduling mode is enabled it implies that two consecutive channels are running, one having an even number- N, on this priority level and the other on the lowest priority level having an odd number N+1.
0x08	—	**Pri1_MASK**	DWord	Priority 1 MASK. The relevant bits that corresponds to the active channels in priority 1 (up to 64 channels in all the priorities), are set by the QUICC Engine block. This parameter can be dynamically changed, if the channel is removed or being add to the APC. This can be done only by issuing host command. See 32.2.12.2/32-24.
0x10	—	**Pri2_MASK**	DWord	Priority 2 MASK. The relevant bits that corresponds to the active channels in priority 2 (up to 64 channels in all the priorities), are set by the QUICC Engine block. This parameter can be dynamically changed, if the channel is removed or being add to the APC. This can be done only by issuing host command. See32.2.12.2/32-24.

Offset	Bits	Name	Width	Description
0x00	—	**Pri0_MASK**	DWord	Priority 0 MASK. The relevant bits that corresponds to the active channels in priority 0 (up to 32 channels in all the priorities), are set by the QUICC Engine block. This parameter can be dynamically changed, if the channel is removed or being add to the APC. This can be done only by issuing host command. See 32.2.12.2/32-24. If GBR scheduling mode is enabled it implies that two consecutive channels are running, one having an even number- N, on this priority level and the other on the lowest priority level having an odd number N+1.
0x04	—	**Pri1_MASK**	DWord	Priority 1 MASK. The relevant bits that corresponds to the active channels in priority 1 (up to 32 channels in all the priorities), are set by the QUICC Engine block. This parameter can be dynamically changed, if the channel is removed or being add to the APC. This can be done only by issuing host command. See 32.2.12.2/32-24.
0x8	—	**Pri2_MASK**	DWord	Priority 2 MASK. The relevant bits that corresponds to the active channels in priority 2 (up to 32 channels in all the priorities), are set by the QUICC Engine block. This parameter can be dynamically changed, if the channel is removed or being add to the APC. This can be done only by issuing host command. See 32.2.12.2/32-24.
0x0C	—	**Pri3_MASK**	DWord	Priority 3 MASK. The relevant bits that corresponds to the active channels in priority 3 (up to 32 channels in all the priorities), are set by the QUICC Engine block. This parameter can be dynamically changed, if the channel is removed or being add to the APC. This can be done only by issuing host command. See 32.2.12.2/32-24.
0x20–0x4F	—	**Ch x FT (x=0..31)**	Hword	Channel Finish Time. Initialized with 0. The QUICC Engine block updates the channel theoretical time for the next transmission. Number of entries to be allocated in the table is determined by the number of active channels in the APC.

32.3.8 Hierarchical Scheduling

In application where a single ATM VC has to carry a few traffic services with different QOS hierarchical scheduling is available. Selection process is performed per Frame or per cell of up to eight queues per single ATM channel using WFQ algorithm for transmission of AAL5 frames. This mode is depicted in Figure 32-57 and it requires data structures as described in the following paragraphs.

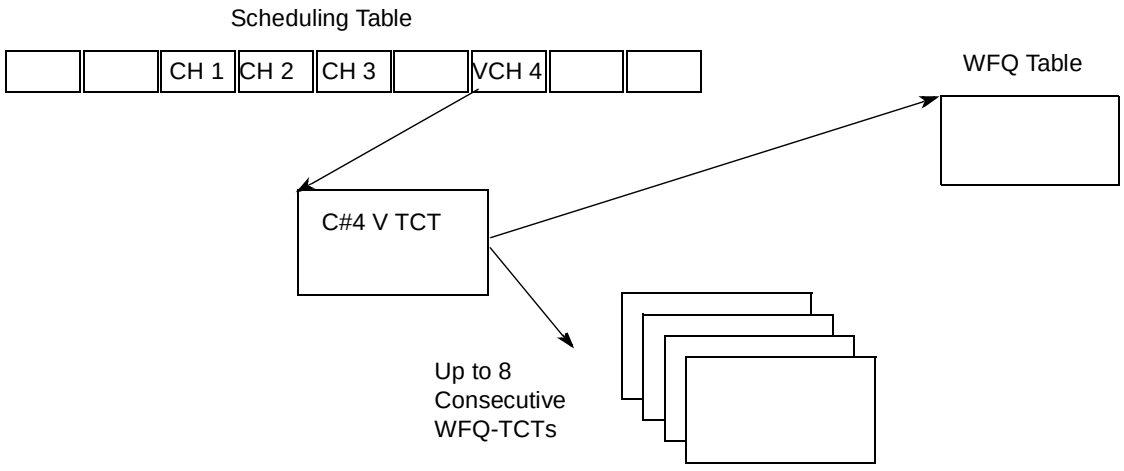

Figure 32-57. Hierarchical Scheduling

In hierarchical scheduling the scheduler schedules a virtual channel with a TCT (V-TCT) which is scheduled in the APC or the GCRA scheduler. This channel's TCT contains management parameters for a set of up to eight queues, each represented by a WFQ -TCT. These queues are represented as ATM channels and are not scheduled in the APC. Their channel numbers should be consecutive and always be assigned such that the first channel code of the eight is divisible by eight. Figure 32-58 describes programming model of the V-TCT Virtual channel TCT which is the root of the hierarchy. In case the channel has a VBR, GBR or UBR+ traffic contract a TCTE should be initialized as well.

The Hierarchical scheduling can operate in two modes of scheduling scheme: HFB- Hierarchical Frame Based and HCB- Hierarchical Cell based scheduling. The mode is determined by each of the WFQ-TCTs which are active under the root V-TCT. In the HFB mode the WFQ selection is performed once every AAL5 frame. Once a frame is transmitted the WFQ algorithm is triggered, the previously selected queue is penalized with the cost function specified in the WFQ data structure multiplied by the frame length and the next queue (WFQ-TCT) is selected for transmission of a complete frame. In HCB mode the WFQ selection is performed after completing transmission of a single ATM cell. In this case the penalty function takes the length value as 48 bytes which is the length of an ATM cell.

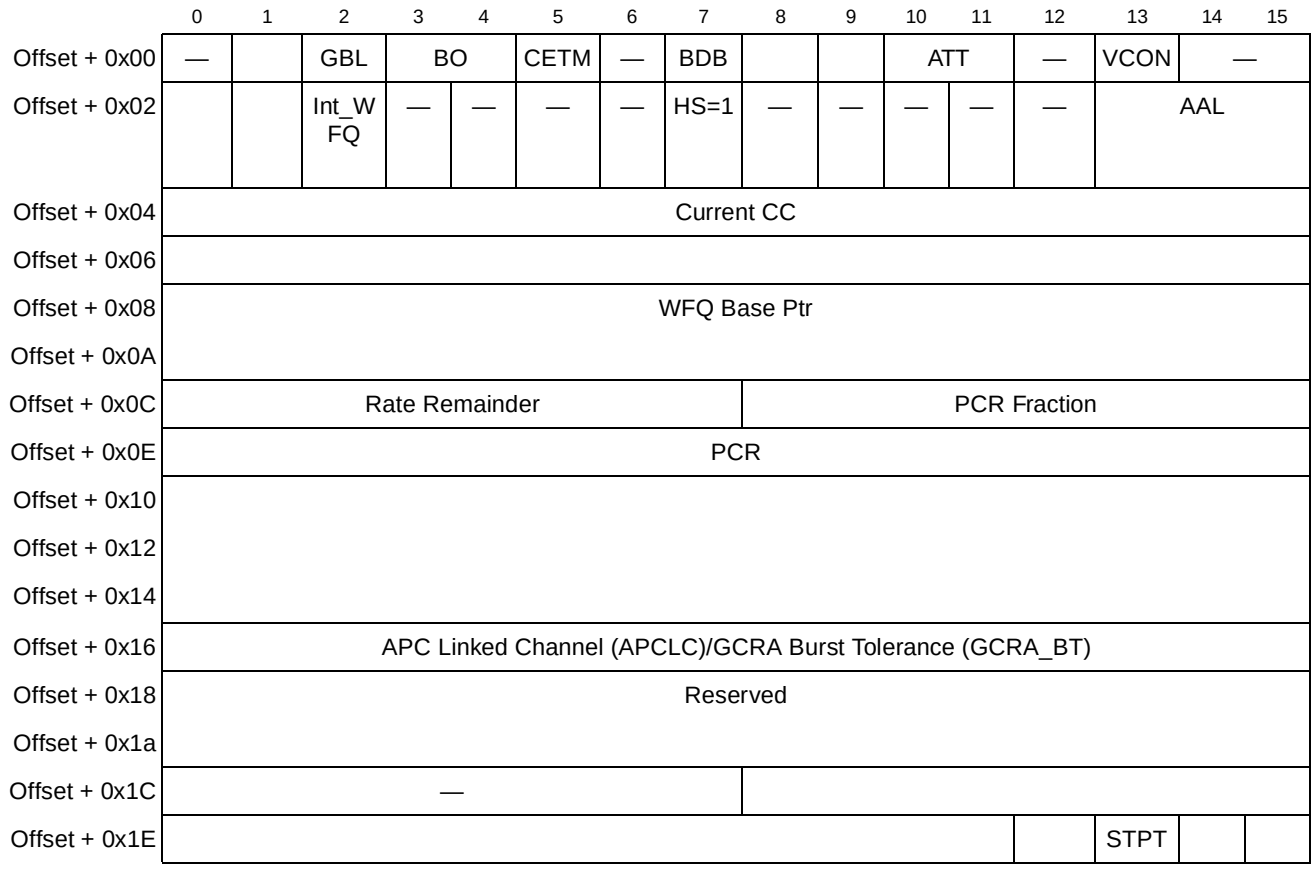

Figure 32-58. Virtual Transmit Connection Table (V-TCT) Entry

Table 32-53 describes the data structure fields.

Table 32-53. V-TCT Field Descriptions

Offset	Bits	Name	Description
0x00	0	—	Reserved, should be cleared.
	1	—	Reserved, should be cleared.
	2	GBL	Global. Asserting GBL enables snooping of data buffers, BDs, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”
	3–4	BO	Byte ordering. This field is used for data buffers. 00, 01, 11 Reserved 10 Big endian
	5	CETM	QUICC Engine block transaction mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1.and Section 5.4.3.7, “Debug Configuration.”
	6	—	Reserved. Should be cleared
	7	BDB	BDB Should have the identical value to ALL of the WFQ TCTs, as stated in the description of WFQ_Base_Ptr.
	8	—	Reserved. Should be cleared
	9	—	Reserved..
	10–11	ATT	ATM traffic type 00 Peak cell-rate pacing. The host must initialize PCR and the PCR fraction. Other traffic parameters are not used. 01 Peak and sustain cell rate pacing (VBR traffic). The APC performs a continuous-state leaky bucket algorithm (GCRA) to pace the channel-sustain cell rate. The host must initialize PCR, PCR fraction, SCR, SCR fraction, and BT (burst tolerance). 10 Peak and minimum cell rate pacing (UBR+ traffic). The host must initialize PCR, PCR fraction, MCR, MCR fraction, and MDA. If Scalable APC is enabled, then the user should allocate an additional 4–6 bytes (depend on the alignment) for the APC scheduling table. See Section 32.3.6.3, “APC Scheduling Tables,” for more information. 11 Guaranteed Bit rate mode (GBR traffic). The host must initialize PCR & PCR fraction fields in this TCT and in the corresponding TCTE. For detailed description see Section 32.3.4.3, “GBR Programming Model.”
	12	—	Reserved. Should be cleared
	13	VCON (status)	Virtual channel is on. Should be set by the host before it issues an ATM TRANSMIT command. When the host sets TCT[STPT] (stop transmit), the QUICC Engine block deactivates this channel and clears VCON when the channel is next encountered in the APC scheduling table. The host can issue another ATM TRANSMIT command only after the QUICC Engine block clears VCON.
		VCON (mode)	Cleared by the host to enable the automatic activation in switch mode - AVCON/AVCF mechanism. When this mode is enabled, the TCT[AVCF] bit should be set. See ATM_AVCON_BASE parameter in Table 32-19 for more description.
	14–15	—	Reserved. Should be cleared

Table 32-53. V-TCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0–1	—	Reserved. Should be cleared
	2	Int_WFQ	Internal WFQ table. When working in Hierarchical cell based mode it is recommended to locate the WFQ data structure in the MURAM. This will remove accessing external memory on a per cell basis. 0- External WFQ tables. In this case the size of the table is fixed to 32bytes (8 entries) 1- Internal WFQ tables. The WFQ tables reside in the MURAM and the size is determined in V-TCT[WFQ Size]
	3–6		Reserved. Should be cleared
	7	**HS**	Hierarchical scheduling enabled. 0- Not enabled 1- This channel is working in hierarchical frame based mode.
	8–12	—	Reserved. Should be cleared
	13–15	AAL	AAL type. For Frame based mode of operation only AAL5 is operational 010 AAL5—ATM adaptation layer 5 protocol
0x04	—	**Current CC**	This is the channel code that is currently selected by the WFQ algorithm for transmission. The user initialize this entry to **zero** when activating this channel into scheduling. Once any of the queues in the hierarchy is activated the QUICC Engine block will automatically update this field.
0x06			
0x08	—	**WFQ Base Ptr**	This is a pointer to 32 bytes table in external memory. The bus selection of this data structure is determined by the TCTs of the channels which are selected by this virtual channel. All these channels have their TCT[BDB] identical. Description of the WFQ table is in Figure 32-62.
0x0C	0–7	Rate Reminder	Rate remainder. Used by the APC to hold the rate remainder after adding the pace fraction to the additive channel rate. Should be cleared initially.
	8–15	PCR Fraction	Peak cell rate fraction. Holds the peak cell rate fraction of this channel in units of 1/256 slot for GCRA scheduler see Section 32.2.12.1, “GCRA Scheduler Rate Programming” for details.
0x0E	—	PCR	Peak cell rate. Holds the peak cell rate (in units of APC slots) permitted for this channel according to the traffic contract. For GCRA scheduler this field is programmed in time units determined by the Time Stamp register. see Section 32.2.12.1, “GCRA Scheduler Rate Programming” for details.
0x10	—	—	Reserved. Should be cleared.
0x16	—	APCLC/ **GCRA_BT**	APC linked channel. Used by the QUICC Engine block. Initialize to 0 (null pointer). When working in GCRA scheduler this field is used to determine the Burst Tolerance allowed for this channel. The user should program the maximum delay allowed between the system time and the last time this channel was active. In case the delay exceeds this value the GCRA scheduler will adjust the channel credit to this value. It determines the maximum burst size for the channel.It is given in TSR Time units. NOTE: For VBR traffic this value should be initialized to 0xFFFF.
0x18	—	Res	Reserved. Should be cleared

Table 32-53. V-TCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x1C	0–7	—	Reserved. Should be cleared
	8–15	WFQ Size	The size of the WFQ table in bytes minus 1. For example: for 5 WFQ TCTs the size of the WFQ table must be set to 5*4 - 1 = 19 If the table is located in external memory V-TCT[Int_WFQ]=0b0 the value of the WFQ Size should be programmed to 8*4 - 1 = 31
0x1E	0–12	—	Reserved. Should be cleared
	13	STPT	Stop transmit. Should be cleared initially. When the host sets this bit, the QUICC Engine block deactivates this channel and clears TCT[VCON] when the channel is next encountered in the APC scheduling table. **Note** The user should set this bit after all the WFQ channels have stopped transmission.
	14–15	—	Reserved. Should be cleared

Up to eight AAL5 TCTs are selected by the V-TCT. These TCT are called WFQ-TCTs and they contain all the channel parameters. The CC numbers of the channels participating in the WFQ selection should be assigned in a such a way that the first is divisible by eight. The data structure is described in Figure 32-59.

As stated, the selection process of the transmit queue could be performed per frame or per cell and it depends on the configuration of each of the WFQ-TCTs. The WFQ TCTs contain the ATM cell header information and so if Cell based scheduling is enabled the WFQ TCTs should have different values in the ATMCH field in order to prevent frame interleaving. If the scheduling is frame based the WFQ TCT could share a common VPI VCI and interleaving is prevented by the scheduler.

Figure 32-59. WFQ Transmit Connection Table (TCT) Entry

This WFQ- TCT is very similar to a standard AAL5 TCT. It is marked as HS- Hierarchical scheduling and differ from the standard TCT in the following entries:

Offset 0x02: Bit **HCB**: Hierarchical **Cell** Based schedule enabled.

When cleared, this WFQ TCT will be operating in Hierarchical Fame Based scheduling- HFB. The queue selection using the WFQ algorithm is triggered after **each frame** transmission.

When set, this WFQ TCT will be operating in Hierarchical Cell Based scheduling. The queue selection using the WFQ algorithm is triggered after **each cell** transmission. (The HS bit should be set as well for this mode). The assumption in this mode is that each of the WFQ TCT has a different VPI VCI associated with it and therefore there is no problem with interleaving of AAL5 frames when channels are transmitted in a mixed manner

Offset 0x0C: **WFQ INC**- This entry is the weight of this queue in the weighted Fair queue algorithm. The bandwidth allocated to the channel is inverse proportional to this number and the frame length transmitted from this queue. For every frame which is transmitted for a selected WFQ TCT the length of the frame is multiplied by this value and the result is accumulated in the WFQ Table described in Figure 32-62 in the entry which associated with the queue. Upon completion of transmitting a frame, the WFQ process selects the next queue for transmission. Selection is based on the queue which has the minimum value stored at the table and which is not empty at the time of the selection.

offset 0x0E:**Virtual CC**- This entry contains the channel number of the V-TCT which is the root of the hierarchy.

offset 0x16: **WFQ Default Length**- Default frame length size, which is used by the QUICC Engine block for the WFQ algorithm. This value is used in case when a BD is not ready for transmission in a middle of a frame and an Abort sequence is triggered. It is multiplied by the **WFQ INC** value which is programmed on each WFQ TCT and it acts as a penalty function. The value is used as a method for defining poling time on which this queue will be revisited on the next time. It is useful for systems without the AVCF (Automatic VC Off) mechanism enabled, since this requires reactivation of the channel by the host.

By setting different values in the WFQ INC field of each of the WFQ TCTs assigned under a V-TCT the application can achieve different scheduling schemes between the eight queues which are assigned to the V-TCT.

For example:

Simple Weighted Fair Queue Scheduling

	WFQ TCT1	WFQ TCT1	WFQ TCT2	WFQ TCT3	WFQ TCT4	WFQ TCT5	WFQ TCT6	WFQ TCT7
WFQ INC	3	5	2	30	2	5	30	3

Figure 32-60. Example of Simple WFQ Among all FIFOs

For simplification of the calculation we assume frame size on each of the queues is identical and therefore has no affect on the result. The formula for getting the bandwidth for each FIFO, assuming FIFO #i has WFQ INC Ki (i=0-7)

FIFO #i BW = line_rate × (1/Ki)/[1/K1+1/K2+..+1/Kn]

For the above example FIFO0 receives 0.16 of the line rate, FIFO1 receives 0.09 and etc. The algorithm implement true WFQ, in the sense that at any given time all FIFOs are examined, and the one with the smallest finish time is chosen.

Strict Priority

Strict priority is a mode in which as long a high priority FIFO has data available for transmission this queue is chosen. Implementation of strict priority among all FIFOs (queue0 is highest, and queue7 is lowest priority) depends on the mode of operation. For systems with no Auto VC Off/ON enabled the application should program all WFQ INC values to a small value, for example 0x01. The value of the **WFQ Default Length** should be set in a way that will not prevent other queues from transmission when there is no data available for higher priority queues. (The value will be big enough to enable other queues to be polled)

Mixed Mode

To implement a mixed mode where one queue has high priority and others are scheduled with WFQs, the strict priority queues should be assigned with the lowest WFQ INC and the other queues are assigned with the relative WFQ INC according to their relative weight. The cost function should be such that the high priority queue will not block the rest of the queues.

	WFQ TCT1	WFQ TCT1	WFQ TCT2	WFQ TCT3	WFQ TCT4	WFQ TCT5	WFQ TCT6	WFQ TCT7
WFQ INC	1	2	3	30	2	5	30	3

Figure 32-61. Example of Mixed Mode WFQ

In this example queue0 will get most of the bandwidth as long as there is data available. Once data is not available the cost function will open a window for other queues for transmission but still pole the highest priority queue. Of the remaining bandwidth the remaining queues are allocated the bandwidth according to their relative weight.

Figure 32-59 depicts the WFQ table associated with each V-TCT. It is pointed from the V-TCT[WFQ Base Ptr]. Each table consists of up to eight entries, each is four bytes. Each entry should be initialized by the host with the value of 0x8000_0000. The MSB of each entry indicates that the queue is Empty. When issuing a host command for a specific queue, the QUICC Engine block will clear the relevant bit for the specific queue and it will take part in the WFQ selection.

Memory allocation for the table varies if it resides in external memory or internal MURAM. See description in V-TCT[WFQ Size]. If external memory is used the data structure is always 32 bytes and should be aligned for this size. In MURAM it should be 4 bytes aligned.

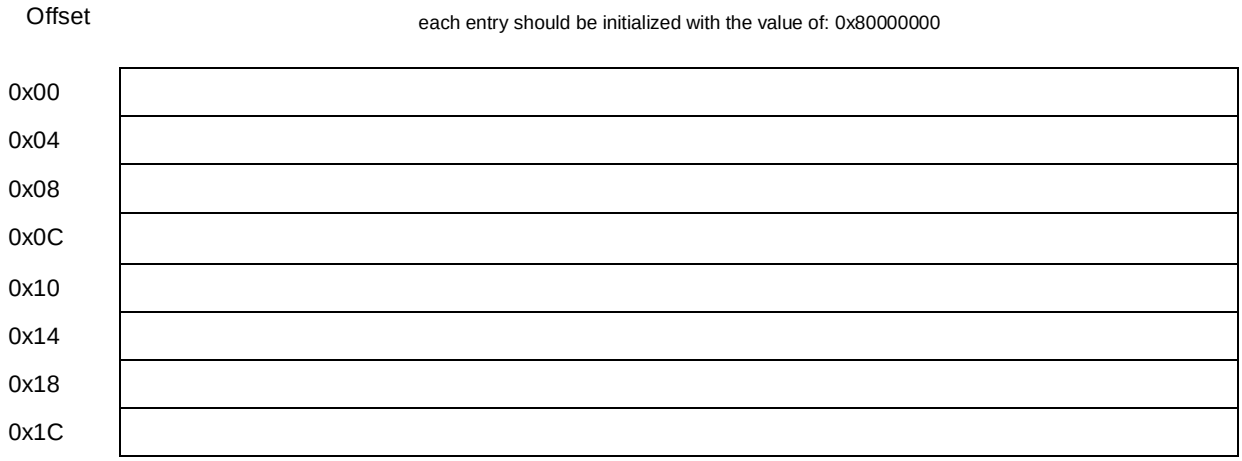

Figure 32-62. WFQ Structure

32.3.8.1 Initialization of Hierarchical Channels

The host should follow this sequence in order to activate hierarchical scheduling.

- Initialize a V-TCT with the desired traffic parameters.
- Initialize the WFQ structure as described in Figure 32-62
- Initialize the WFQ-TCTs taking part in the WFQ selection. according to the numbers of channels
- For WFQ channels which **are not** members in a multicast group perform the following steps:
  - Issue a host command for inserting the WFQ channel into the WFQ structure. Repeat this command for each channel participating in the WFQ selection. This is an ATM transmit

command with special parameters described in Section 32.4.1, "ATM Commands." The ACT field is set to 0b11 and the Virtual CC is given in the BT field in the command info area.

— Issue an host command for scheduling the V-TCT. This is an ATM transmit command with parameters for inserting the CC into the scheduling table (APC or GCRA scheduler). If the V-TCT is scheduled in GBR mode another host command should be issued for inserting the channel to the UBR level and the Command info[ACT]=0b10.

32.3.9 ATM Controller Buffer Descriptors (BDs)

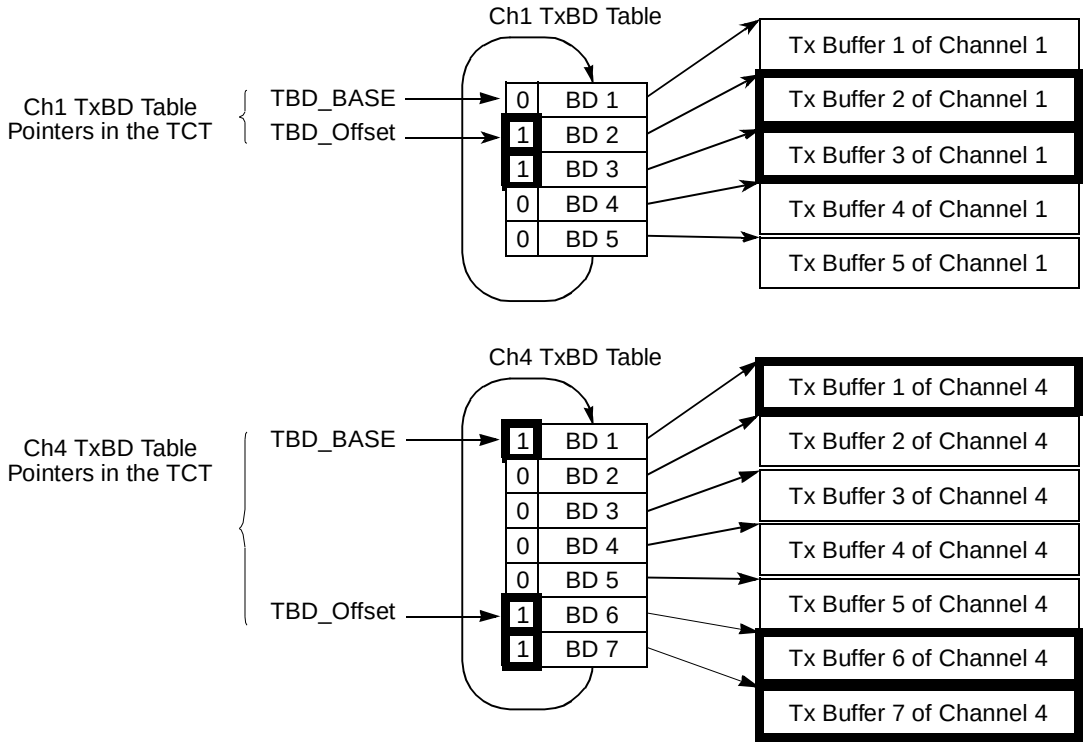
Each ATM channel has separate receive and transmit BD tables. The number of BDs per channel and the size of the buffers is user-defined. The last BD in each table holds a wrap indication. Each BD in the TxBD table points to a buffer to send. At the receive side, the user can choose one of two modes:

- Static buffer allocation. In this mode, the user allocates dedicated buffers to each ATM channel (that is, the user associates each BD with one buffer). Static buffer allocation is useful when the connection rate is known and constant and when data must be reassembled in a particular memory space.
- Global buffer allocation. Available for AAL5 only. In this mode, buffer allocation is dynamic. The user allocates receive buffers and places them in global buffer pools. When the QUICC Engine block needs a receive buffer, it first fetches a buffer pointer from one of the global buffer pools and writes the pointer to the current RxBD. Global buffer allocation is optimized for allocating memory among many ATM channels with variable data rates.

32.3.9.1 Transmit Buffer Operation

The user prepares a table of BDs pointing to the buffers to be sent. The address of the first BD is put in the channel's TCT[TBD_BASE]. The transmit process starts when the core issues an ATM TRANSMIT command. The QUICC Engine block reads the first TxBD in the table and sends its associated buffer. When the current buffer is finished, the QUICC Engine block increments TBD_Offset, which holds the offset from TBD_BASE to the current BD. It then reads the next BD in the table. If the BD is ready (TxBD[R] = 1), the QUICC Engine block continues sending. If the current BD is not ready, the QUICC Engine block polls the ready bit at the channel rate unless TCT[AVCF] = 1, in which case the QUICC Engine block removes the channel from the APC and clears TCT[VCON]. The core must issue a new ATM TRANSMIT command to restart transmission.

Figure 32-63 shows the ready bit in the TxBD tables and their associated buffers for two example ATM channels.



Note: The highlighted buffers are ready to be sent; unhighlighted buffers are waiting to be prepared.

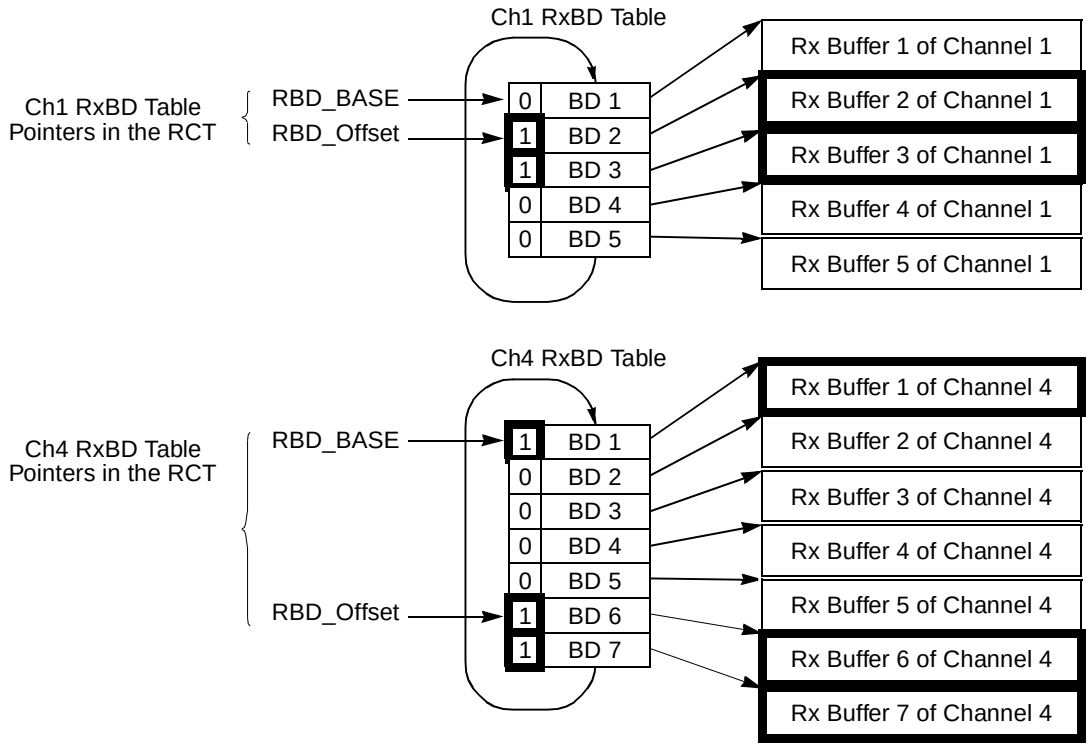
Figure 32-63. Transmit Buffers and BD Table Example

32.3.9.2 Receive Buffer Operation

For AAL5 channels, the user should choose to operate in static buffer allocation or in global buffer allocation by writing to RCT[BUFM]. AAL1 CES and AAL0 channels must use static buffer allocation.

32.3.9.2.1 Static Buffer Allocation

The user prepares a table of BDs pointing to the receive buffers. The address of the first BD is put in the channel's RCT[RBD_BASE]. When an ATM cell arrives, the QUICC Engine block opens the first BD in the table and starts filling its associated buffer with received data. When the current buffer is full, the QUICC Engine block increments RBD_Offset, which is the offset to the current BD from RBD_BASE, and reads the next BD in the table. If the BD is empty (RxBD[E] = 1), the QUICC Engine block continues receiving. If the BD is not empty, a busy condition has occurred and a busy interrupt is sent to the event queue. Figure 32-64 shows the empty bit in the RxBD tables and their associated buffers for two example ATM channels.



Note: The highlighted buffers are empty; unhighlighted buffers are waiting to be processed.

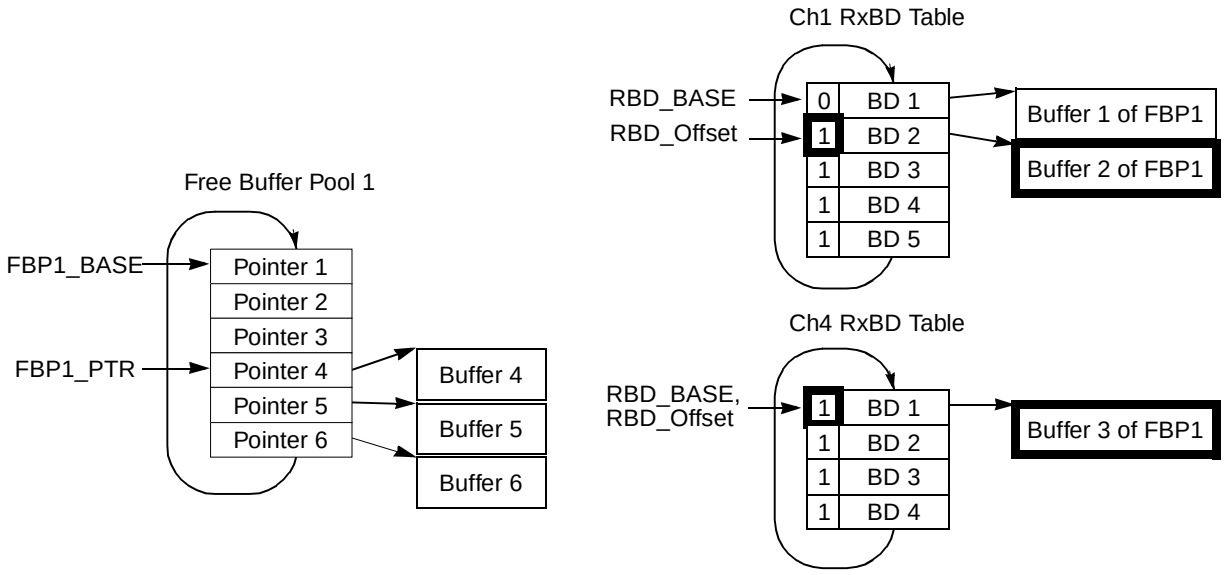
Figure 32-64. Receive Static Buffer Allocation Example

32.3.9.2.2 Global Buffer Allocation

The user prepares a table of BDs without assigning buffers to them (no buffer pointers). The address of the first BD is put into the channel's RCT[RBD_BASE]. The user also prepares sets of free buffers (of size RCT[MRBLR]) in up to four free buffer pools (chosen in RCT[BPOOL]); see Section 32.3.9.2.3, "Free Buffer Pools."

When an ATM cell arrives, the QUICC Engine block opens the first BD in the table, fetches a buffer pointer from the free buffer pool associated with this channel, and writes the pointer to RxBD[RXDBPTR], the receive data buffer pointer field in the BD. When the current buffer is full, the QUICC Engine block increments RBD_Offset, which is the offset from the RBD_BASE to the current BD, and reads the next BD in the table. If the BD is empty (RxBD[E] = 1), the QUICC Engine block fetches another buffer pointer from the free buffer pool and reception continues. If the BD is not empty, a busy condition occurs and a busy interrupt is sent to the event queue specifying the ATM channel code. As software then processes each full buffer (RxBD[E] = 0), it sets RxBD[E] and copies the buffer pointer back to the free buffer pool.

Figure 32-65 shows two ATM channels' BD tables and one free buffer pool. Both channels are associated with free buffer pool 1. The QUICC Engine block allocates the first two buffers of buffer pool 1 to channel 1 and the third to channel 4.



Notes: Buffers 2 and 3 are receiving data. After buffer 1 is processed, it can be returned to the pool.

Figure 32-65. Receive Global Buffer Allocation Example

32.3.9.2.3 Free Buffer Pools

As Figure 32-66 shows, when a buffer pointer is fetched from a pool, the QUICC Engine block clears the entry's valid bit and increments FBP#_PTR. After the QUICC Engine block uses an entry with the wrap bit set (W = 1), it returns to the first entry in the pool. After a buffer pointer is returned to the pool, the user should set V to indicate that the entry is valid. If the QUICC Engine block tries to read an invalid entry (V = 0), the buffer pool is out of free buffers; the global-buffer-pool-busy event is then set in UCCE[GBPB] and a busy interrupt is sent to the interrupt queue specifying the ATM channel code associated with the pool.

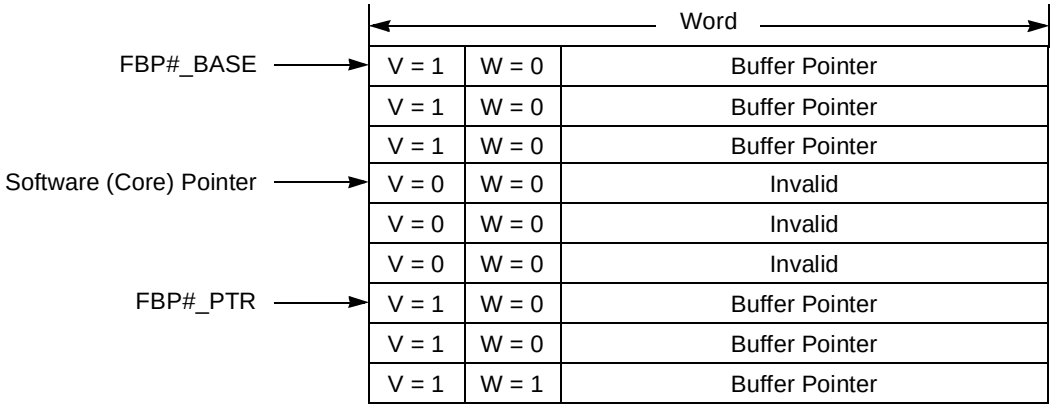


Figure 32-66. Free Buffer Pool Structure

Figure 32-67 describes the structure of a free buffer pool entry.

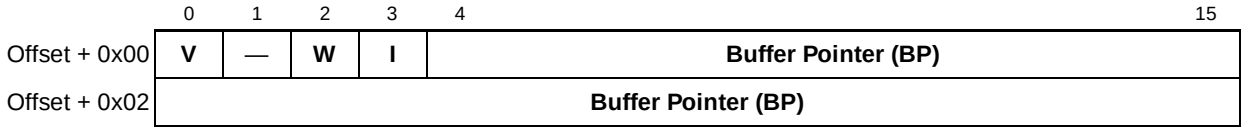

Figure 32-67. Free Buffer Pool Entry

Table 32-54 describes free buffer pool entry fields.

Table 32-54. Free Buffer Pool Entry Field Descriptions

Offset	Bits	Name	Description
0x00	0	**V**	Valid buffer entry. 0 This free buffer pool entry contains an invalid buffer pointer. 1 This free buffer pool entry contains a valid buffer pointer.
	1	—	Reserved, should be cleared.
	2	**W**	Wrap bit. When set, this bit indicates the last entry in the circular table. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	3	**I**	Red-line interrupt. Can be used to indicate that the free buffer pool has reached a red line and additional buffers should be added to this pool to avoid a busy condition. 0 No interrupt is generated. 1 A red-line interrupt is generated when this buffer is fetched from the free buffer pool.
	4–15	**BP**	Buffer pointer. Points to the start address of the receive buffer. The four msbs are control bits, and the four msbs of the real buffer pointer are taken from the four msbs of the parameter FBP_ENTRY_EXT in the free buffer pool parameter table.
0x02	0–15		

32.3.9.2.4 Free Buffer Pool Parameter Tables

The free buffer pool parameters are held in parameter tables in the MURAM. FBT_BASE in the parameter RAM points to the base address of these tables. Each of the four free buffer pools has its own parameter table with a starting address given by FBT_BASE+ RCT[BPOOL] × 16.

Management of the FBP is different under different mode of operation and requires different s/w behavior. In Non Multi-threading mode the operation and programming model is identical to this of the PQII family and is depicted in Table 32-55.

Table 32-55. Free Buffer Pool Parameter Table-Non Multi-Threading Mode

Offset [1]	Bits	Name	Width	Description
0x00	—	**FBP_BASE**	**W**	Free buffer pool base. Holds the pointer to the first entry in the free buffer pool. FBP_BASE should be word aligned. User-defined.
0x04		**FBP_PTR**	**W**	Free buffer pool pointer. Pointer to the current entry in the free buffer pool. Initialized to FBP_BASE.
0x08	—	**FBP_ENTRY_EXT**	**HW**	Free buffer pool entry extension. FBP_ENTRY_EXT[0–3] holds the four left bits of FBP_ENTRY. FBP_ENTRY_EXT[4–15] should be cleared. User-defined.

Table 32-55. Free Buffer Pool Parameter Table-Non Multi-Threading Mode (continued)

Offset [1]	Bits	Name	Width	Description
0x0A	0	**BUSY**	**HW**	The QUICC Engine block sets this bit when it tries to fetch buffer pointer with V bit clear. UCCE[GBPB] is also set. Initialize to zero.
	1	**RLI**		Red-line interrupt. Set by the QUICC Engine block when it fetches a buffer pointer with I = 1. UCCE[GRLI] is also set. Initialize to zero.
	2–7	—		Reserved, should be cleared.
	8	**EPD**		Early packet discard. 0 Normal operation. 1 AAL5 frames in progress are received, but new AAL5 frames associated with this pool are discarded. Can be used to implement EPD under core control.
	9–15	**—**		Reserved, should be cleared.
0x0C	—	**FBP_ENTRY**	**W**	Free buffer pool entry. Initialize with the first entry of the free buffer pool. Note that FBP_ENTRY must be re initialized with the entry pointed to by FBP_PTR when a busy state occurs to reenable free buffer pool processing.

1 Offset from FBT_BASE+RCT[BPOOL] × 16

The maximum size of the FBP is 16K entries for Multi-thread mode.

Table 32-56. Free Buffer Pool Parameter Table- Multi-Threading Mode

Offset [1]	Bits	Name	Width	Description
0x00	—	**FBP_BASE**	**W**	Free buffer pool base. Holds the pointer to the first entry in the free buffer pool. FBP_BASE should be word aligned. User-defined.
0x04		**FBP_OFFSET_OUT**	**HW**	Free buffer pool QUICC Engine block offset. Offset to the current QUICC Engine block entry in the free buffer pool. **Initialize to 0x04**. The actual address of the FBP entry is FBP_BASE+FBP_OFFSET_OUT. The QUICC Engine block will advance this entry each time a new buffer is taken from the buffer pool. Once reaching the FBP_OFFSET_IN value the QUICC Engine block assumes the pool is empty and no buffer is available
0x06		**FBP_OFFSET_IN**	**HW**	Free buffer pool host offset. Offset to the current entry in the free buffer pool to where the host returns buffer to the pool. Initialize to 0. The actual address of the FBP entry is FBP_BASE+FBP_OFFSET_IN. **Initialize to 0x0.** The Host must maintain this offset in the data structure so that synchronization is kept with the QUICC Engine block. IMPORTANT: The host should never advance this value so it matches the FBP_OFFSET_OUT value. WHen the value of FBP_OFFSET_OUT is equal to the value of FBP_OFFSET_IN it indicates that the pool is empty with no buffers available. In this way the pool size is effectively smaller by one entry.
0x08	—	**FBP_ENTRY_EXT**	**HW**	Free buffer pool entry extension. FBP_ENTRY_EXT[0–3] holds the four left bits of FBP_ENTRY. FBP_ENTRY_EXT[4–15] should be cleared. User-defined.

Table 32-56. Free Buffer Pool Parameter Table- Multi-Threading Mode (continued)

Offset [1]	Bits	Name	Width	Description
0x0A	0	**BUSY**	**HW**	The QUICC Engine block sets this bit when it tries to fetch buffer pointer with V bit clear. UCCE[GBPB] is also set. Initialize to zero.
	1	**RLI**		Red-line interrupt. Set by the QUICC Engine block when it fetches a buffer pointer with I = 1. UCCE[GRLI] is also set. Initialize to zero.
	2–7	—		Reserved, should be cleared.
	8	**EPD**		Early packet discard. 0 Normal operation. 1 AAL5 frames in progress are received, but new AAL5 frames associated with this pool are discarded. Can be used to implement EPD under core control.
	9–15	**—**		Reserved, should be cleared.
0x0C	—	**FBP_Size**	**HW**	User initialized to the Size in **bytes** of the FBP entries. (Each entry is 4 bytes.)
0x0E		**Res**	**HW**	Reserved- should be cleared

1 Offset from FBT_BASE+RCT[BPOOL] × 16

The maximum size of the FBP is 16K entries for Multi-thread mode.

32.3.9.3 ATM Controller Buffers

Table 32-57 describes properties of the ATM receive and transmit buffers for better bus utilization.

Table 32-57. Receive and Transmit Buffers

AAL	Receive		Transmit	
	Size	Alignment	Size	Alignment
AAL5	Multiple of 48 octets (except last buffer in frame)	Double word aligned	Any	No requirement
AAL1	At least 47 octets	No requirement	At least 47 octets	No requirement
AAL0	52-64 octets.	Burst-aligned	52–64 octets.	No requirement

32.3.9.4 AAL5 RxBD

Figure 32-68 shows the AAL5 RxBD fields.

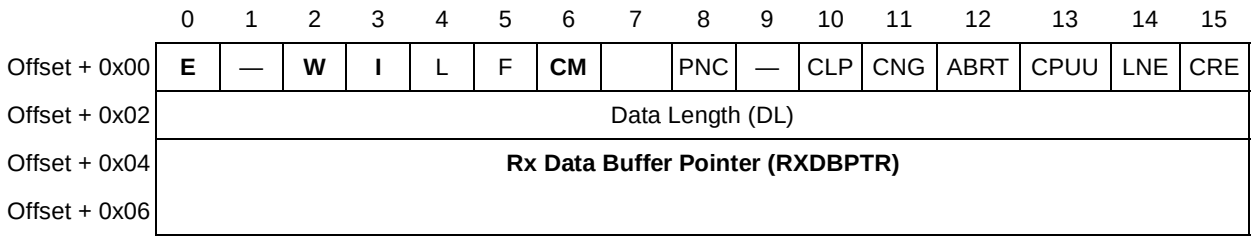

Figure 32-68. AAL5 RxBD

Table 32-58 describes AAL5 RxBD fields.

Table 32-58. AAL5 RxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**E**	Empty. 0 The buffer associated with this RxBD is full or data reception was aborted due to an error. The core can read or write any fields of this RxBD. The QUICC Engine block does not use this BD again while E remains zero. 1 The buffer associated with this RxBD is empty or reception is in progress. This RxBD and its receive buffer are controlled by the QUICC Engine block. Once E is set, the core should not write any fields of this RxBD.
	1	—	Reserved, should be cleared.
	2	**W**	Wrap (final BD in table) 0 This is not the last BD in the RxBD table of the current channel. 1 This is the last BD in the RxBD table of this current channel. After this buffer has been used, the QUICC Engine block receives incoming data into the first BD in the table. The number of RxBDs in this table is programmable and is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer has been used. 1 An Rx buffer event is sent to the interrupt queue after the ATM controller uses this buffer. UCCE[GINT*x*] is set in the event register when INT_CNT reaches the global interrupt threshold.
	4	L	Last in frame. Set by the ATM controller for the last buffer in a frame. 0 Buffer is not last in a frame. 1 Buffer is last in a frame. ATM controller writes frame length in DL and updates the error flags.
	5	F	First in frame. Set by the ATM controller for the first buffer in a frame. 0 The buffer is not the first in a frame. 1 The buffer is the first in a frame.
	6	**CM**	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear the empty bit after this BD is closed, allowing the associated buffer to be overwritten automatically when the QUICC Engine block next accesses this BD.
	7		
	8	PNC	UPC Non Conformance. PNC is set by the UPC if the buffer contains a cell, which was not conformed by one of the buckets, but was not dropped. In frame mode (UPCT[UPCM]=10/11), this bit will also be set in the last BD, if the frame has a cell which was not conformed by one (or both) of the buckets, whether it was dropped or not. In GFR mode (UPCT[UPCM]=11), if there is CLP change inside frame or the frame exceed MFS that will also cause setting this bit in the last BD of the frame.
	9	—	Reserved, should be cleared.
	10	CLP	Cell loss priority. At least one cell associated with the current message was received with CLP = 1. May be set at the last buffer of the message.
	11	CNG	Congestion indication. The last cell associated with the current message was received with PTI middle bit set. CNG may be set at the last buffer of the message.

Table 32-58. AAL5 RxBD Field Descriptions (continued)

Offset	Bits	Name	Description
	12	ABRT	Abort message indication. The current message was received with Length field zero. When set the LNE and CRE bits may be set as well and should not be regarded as a different event.
	13	CPUU	CPCS-UU+CPI indication. Set when the CPCS-UU+CPI field is non zero. CPUU may be set at the last buffer of the message.
	14	LNE	Rx length error. AAL5 CPCS-PDU length violation. May be set only for the last BD of the frame if the pad length is greater than 47 or less than zero octets. when set the CRE bit could also be set and should not be treated as a different event.
	15	CRE	Rx CRC error. Indicates CRC32 error in the current AAL5 PDU. Set only for the last BD of the frame.
0x02	—	DL	Data length. The number of octets written by the QUICC Engine block into this BD's buffer. It is written by the QUICC Engine block once the BD is closed. In the last BD of a frame, DL contains the total frame length.
0x04		**RXDBPTR**	Rx data buffer pointer. Points to the first location of the associated buffer; may reside in internal or external memory. For better bus performance this pointer should be burst-aligned.

Note: In cases where the AAL5 frame length is close to an integer multiple of the MRBLR value specified in the RCT of each ATM channel, it can happen that last BD in a frame which has its L bit set and the DL field value for the complete frame contains no payload data. It contains the AAL5 trailer only and the rest is the AAL5 padding. In this case the BDs which are prior to the last one will have a DL fields which sums up to a number which is equal or greater to the frame length. In this case the application should subtract the difference of frame length from the total sum of the length and ignore this data in the buffer which is prior to the last buffer.

32.3.9.5 AAL1 RxBD

Figure 32-69 shows the AAL1 RxBD.

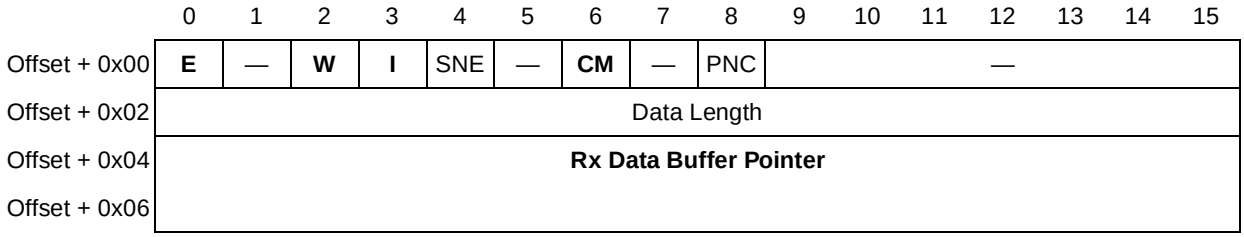

Figure 32-69. AAL1 RxBD

Table 32-59 describes AAL1 RxBD fields.

Table 32-59. AAL1 RxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**E**	Empty 0 The buffer associated with this RxBD is filled with received data or data reception was aborted due to an error. The core can read or write any fields of this RxBD. The QUICC Engine block cannot use this BD again while E = 0. 1 The buffer is not full. This RxBD and its associated receive buffer are owned by the QUICC Engine block. Once E is set, the core should not write any fields of this RxBD.
	1	—	Reserved, should be cleared.
	2	**W**	Wrap (final BD in table) 0 This is not the last BD in the RxBD table of the current channel. 1 This is the last BD in the RxBD table of this current channel. After this buffer is used, the QUICC Engine block receives incoming data into the first BD in the table. The number of RxBDs in this table is programmable and is determined only by the W bit. The current table overall space is constrained to 64 Kbytes.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer has been used. 1 An Rx buffer event is sent to the interrupt queue after the ATM controller uses this buffer. UCCE[GINT*x*] is set when the INT_CNT reaches the global interrupt threshold.
	4	SNE	Sequence number error. SNE is set when a sequence number error is detected in the current AAL1 CES buffer.
	5	—	Reserved, should be cleared.
	6	**CM**	Continuous mode 0 Normal operation. 1 The empty bit (RxBD[E]) is not cleared by the QUICC Engine block after this BD is closed, allowing the associated buffer to be overwritten automatically when the QUICC Engine block next accesses this BD.
	7	—	Reserved, should be cleared.
	8	PNC	UPC Non Conformance. PNC is set by the UPC if the buffer contains a cell, which was not conformed by one (or both) of the buckets, but was not dropped.
	9–15	—	Reserved, should be cleared.
0x02	—	DL	Data length. The number of octets the QUICC Engine block writes into the buffer once its BD is closed.
0x04	—	**RXDBPTR**	Rx data buffer pointer. Points to the first location of the associated buffer; may reside in either internal or external memory. For better bus performance this pointer should be burst-aligned.

32.3.9.6 AAL0 RxBD

Figure 32-70 shows the AAL0 RxBD.

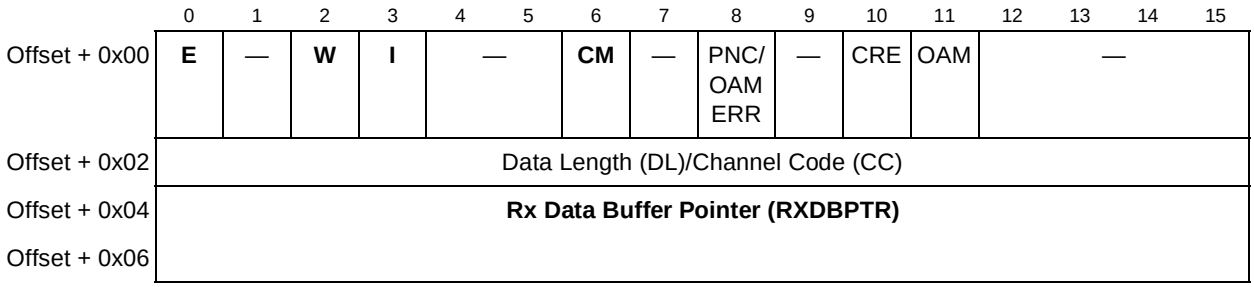

Figure 32-70. AAL0 RxBD

Table 32-60 describes AAL0 RxBD fields.

Table 32-60. AAL0 RxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**E**	Empty 0 The buffer associated with this RxBD is filled with received data, or data reception was aborted due to an error. The core can examine or write to any fields of this RxBD. The QUICC Engine block does not use this BD again while E remains zero. 1 The Rx buffer is empty or reception is in progress. This RxBD and its associated receive buffer are owned by the QUICC Engine block. Once E is set, the core should not write any fields of this RxBD.
	1	—	Reserved, should be cleared.
	2	**W**	Wrap (final BD in table) 0 This is not the last BD in the RxBD table of the current channel. 1 This is the last BD in the RxBD table of the current channel. After this buffer has been used, the QUICC Engine block will receive incoming data into the first BD in the table. The number of RxBDs in this table is programmable and is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer has been used. 1 An Rx buffer event is sent to the interrupt queue after the ATM controller uses this buffer. UCCE[GINT*x*] is set when the INT_CNT reaches the global interrupt threshold.
	4–5	—	Reserved, should be cleared.
	6	**CM**	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear the E bit after this BD is closed, allowing the associated buffer to be overwritten automatically when the QUICC Engine block next accesses this BD.
	7	—	Reserved, should be cleared.

Table 32-60. AAL0 RxBD Field Descriptions (continued)

Offset	Bits	Name	Description
	8	PNC/ OAMERR	UPC Non Conformance/OAMERR. If RxBD[OAM] is set (and MSP mode is enabled), this field functions as OAMERR; otherwise it is PNC. PNC - PNC is set by the UPC if the buffer contains a cell, which was not conformed by one (or both) of the buckets, but was not dropped. OAMERR - When MSP is enabled, and an erroneous OAM cell received by the switch, them this bit is set by the QUICC Engine block. See Chapter 39, "Enhanced MSP Microcode."
	9	—	Reserved, should be cleared.
	10	CRE	Rx CRC error. Indicates a CRC10 error in the current AAL0 buffer. The CRE bit is considered an error only if the received cell had a CRC10 field in the cell payload.
	11	OAM	Operation and maintenance cell. If OAM is set, the current AAL0 buffer contains an OAM cell. This cell is associated with the channel indicated by the channel code field (CC field).
	12–15	—	Reserved, should be cleared.
0x02	—	DL/CC	Data length/channel code. If RxBD[OAM] is set, this field functions as CC; otherwise, it is DL. Data length is the size in octets of this buffer (MRBLR value). Channel code specifies the channel code associated with this OAM cell. If the RCT[TS_EN] is set a four bytes time stamp value is appended to the cell content. In this case the application should allocate 4 more bytes for each buffer.
0x04	—	**RXDBPTR**	Rx data buffer pointer. Points to the first location of the associated buffer; may reside in either internal or external memory. For better bus performance this pointer should be burst-aligned.

32.3.9.7 AAL1 CES RxBD

Refer to Section 35.12.1, "AAL1 CES RxBD."

32.3.9.8 AAL2 RxBD

Refer to Section 41.4.4.6, "CPS Receive Buffer Descriptor (RxBD)."

32.3.9.9 AAL5, AAL1 CES User-Defined Cell—RxBD Extension

In user-defined cell mode, the AAL5and AAL1 CES RxBDs are extended to 32 bytes; see Figure 32-71.

NOTE

For AAL0, a complete cell, including the UDC header, is stored in the buffer; the AAL0 BD size is always 8 bytes.

Offset + 0x08	Extra Cell Header. Used to store the user-defined cell's extra cell header. The extra cell header can be 1–12 bytes long.
Offset + 0x14	Reserved (12 bytes)

Figure 32-71. User-Defined Cell—RxBD Extension

32.3.9.10 AAL5 TxBDs

Figure 32-72 shows the AAL5 TxBD.

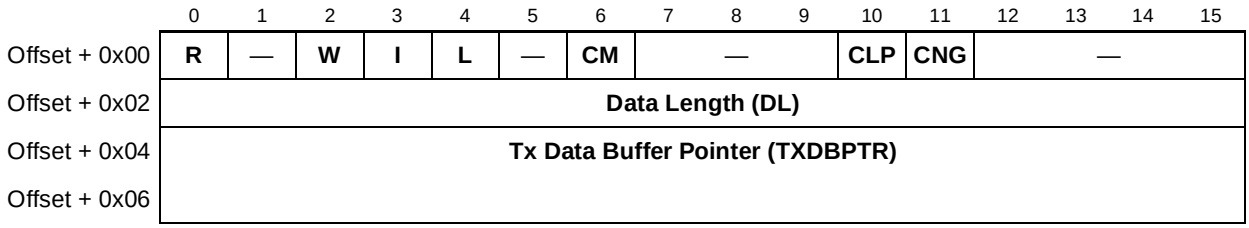

Figure 32-72. AAL5 TxBD

Table 32-61 describes AAL5 TxBD fields.

Table 32-61. AAL5 TxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**R**	Ready 0 The buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated buffer. The QUICC Engine block clears R after the buffer is sent or after an error condition is encountered. 1 The user-prepared buffer has not been sent or is currently being sent. No fields of this BD may be written by the user once R is set.
	1	—	Reserved, should be cleared.
	2	**W**	Wrap (final BD in table) 0 Not the last BD in the TxBD table. 1 Last BD in the TxBD table. After this buffer is used, the QUICC Engine block sends outgoing data from the first BD in the table (the BD pointed to by the channel's TCT[TBD_BASE]). The number of TxBDs in this table is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer has been serviced. 1 A Tx Buffer event is sent to the interrupt queue after this buffer is serviced. UCCE[GINT*x*] is set when the INT_CNT counter reaches the global interrupt threshold.
	4	**L**	Last in frame. Set by the user to indicate the last buffer in a frame. 0 Buffer is not last in a frame. 1 Buffer is last in a frame.
	5	—	Reserved, should be cleared.
	6	**CM**	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear R after this BD is closed, allowing the associated buffer to be retransmitted automatically when the QUICC Engine block next accesses this BD. However, the R bit is cleared if an error occurs during transmission, regardless of CM.
	7–9	—	Reserved, should be cleared.
	10	**CLP**	The ATM cell header CLP bit of the cells associated with the current frame are ORed with this field. This field is valid only in the first BD of the frame.
	11	**CNG**	The ATM cell header CNG bit of the cells associated with the current frame are ORed with this field. This field is valid only in the first BD of the frame.
	12–15	—	Reserved, should be cleared.
0x02	—	**DL**	The number of octets the ATM controller should transmit from this BD's buffer. It is not modified by the QUICC Engine block. The value of DL should be greater than zero.
0x04	—	**TXDBPTR**	Tx data buffer pointer. Points to the address of the associated buffer, which may or may not be 8-byte-aligned. The buffer may reside in either internal or external memory. This value is not modified by the QUICC Engine block.

32.3.9.11 AAL1 TxBDs

Figure 32-73 shows the AAL1 TxBD.

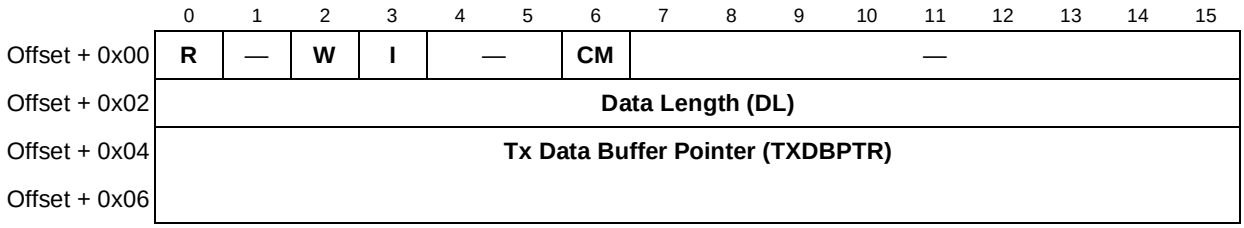

Figure 32-73. AAL1 TxBD

Table 32-62 describes AAL1 TxBD fields.

Table 32-62. AAL1 TxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**R**	Ready 0 The buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated buffer. The QUICC Engine block clears this bit after the buffer has been sent or after an error condition is encountered. 1 The buffer prepared for transmission by the user has not been sent or is being sent. No fields of this BD may be written by the user once R is set.
	1	—	Reserved, should be cleared.
	2	**W**	Wrap (final BD in table) 0 Not the last BD in the TxBD table. 1 Last BD in the TxBD table. After this buffer is used, the QUICC Engine block sends outgoing data from the first BD in the table (the BD pointed to by the channel's TCT[TBD_BASE]). The number of TxBDs in this table is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer has been serviced. 1 A Tx buffer event is sent to the interrupt queue after this buffer is serviced. UCCE[GINT*x*] is set when the INT_CNT counter reaches the global interrupt threshold.
	4–5	—	Reserved, should be cleared.
	6	**CM**	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear the ready bit after this BD is closed, allowing the associated buffer to be retransmitted automatically when the QUICC Engine block next accesses this BD.
	7–11	—	Reserved, should be cleared.
0x02	—	**DL**	The number of octets the ATM controller should transmit from this BD's buffer. It is not modified by the QUICC Engine block. The value of DL should be greater than zero.
0x04	—	**TXDBPTR**	Tx data buffer pointer. Points to the address of the associated buffer. The buffer may reside in either internal or external memory. This value is not modified by the QUICC Engine block.

32.3.9.12 AAL0 TxBDs

Figure 32-74 shows AAL0 TxBDs. Note that the data length field is calculated internally as 52 bytes, plus the extra header length (defined in UPSMR[TEHS]) when in UDC mode.

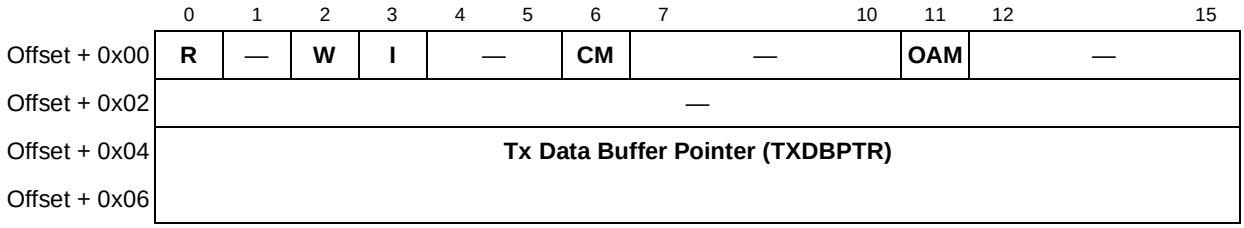

Figure 32-74. AAL0 TxBDs

Table 32-63 describes AAL0 TxBD fields.

Table 32-63. AAL0 TxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**R**	Ready 0 The buffer is not ready for transmission. The user can manipulate this BD or its buffer. The QUICC Engine block clears R after the buffer has been sent or after an error occurs. 1 The buffer that the user prepared for transmission has not been sent or is being sent. No fields of this BD may be written by the user once R is set.
	1	—	Reserved, should be cleared.
	2	**W**	Wrap (final BD in table) 0 Not the last BD in the TxBD table. 1 Last BD in the TxBD table. After this buffer is used, the QUICC Engine block sends outgoing data from the first BD in the table (the BD pointed to by the channel's TCT[TBD_BASE]). The number of TxBDs in this table is determined by the W bit. The current table is constrained to 64 Kbytes.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer has been serviced. 1 A Tx buffer event is sent to the interrupt queue after this buffer is serviced. UCCE[GINT*x*] is set when the INT_CNT counter reaches the global interrupt threshold.
	4–5	—	Reserved, should be cleared.
	6	**CM**	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear the ready bit after this BD is closed, allowing the associated buffer to be retransmitted automatically when the QUICC Engine block next accesses this BD.
	7–10	—	Reserved, should be cleared.
	11	**OAM**	Operation and maintenance cell. If OAM is set, the current AAL0 buffer contains an F5 or F4 OAM cell. Performance monitoring calculations are not done on OAM cells.
	11–15	—	Reserved, should be cleared.

Table 32-63. AAL0 TxBD Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	—	—	Reserved, should be cleared.
0x04	—	**TXDBPTR**	Tx data buffer pointer. Points to the address of the associated buffer, which may or may not be 8-byte-aligned. The buffer may reside in either internal or external memory. This value is not modified by the QUICC Engine block.

32.3.9.13 AAL1 CES TxBDs

Refer to Section 35.12.2, "AAL1 CES TxBDs."

32.3.9.14 AAL2 TxBDs

Refer to Section 41.3.5.6, "SSSAR Transmit Buffer Descriptor."

32.3.9.15 AAL5, AAL1 User-Defined Cell—TxBD Extension

In user-defined cell mode, the AAL5 and AAL1 TxBDs are extended to 32 bytes, see Figure 32-75. The extra cell header value should be identical for all the BD's in the ring.

NOTE

For AAL0 a complete cell, including the UDC header, is stored in the buffer; the AAL0 BD size is always 8 bytes.

Offset + 0x08	Extra Cell Header. Used to store the user-defined cell's extra cell header. The extra cell header can be 1–12 bytes long.
Offset + 0x14	Reserved (12 bytes)

Figure 32-75. User-Defined Cell—TxBD Extension

32.3.10 UPC Structures

32.3.10.1 UPC Table

The UPC Table structure is depicted in Figure 32-76. The field "offset" refers to the address generated in the following way (see PID description in Table 32-5 and Table 32-2):

For internal UPC Tables (PID value 1–31) -

Offset = UPC_PARAM_Table (INT_UPC_BASE) + PID × 48.

For external UPC Tables (PID value 32-1023) -

Offset = UPC_PARAM_Table (EXT_UPC_BASE) + PID × 64.

Note that the UPC table structure is only 48 bytes long. Therefore in external UPC tables, there is some wasted space between the structures. The UPC procedure reads the whole 48 bytes of the UPC table, but

writes back only the first 32 bytes, in this way enable software to dynamically change the UPC table parameters which are located in the last 16 bytes.

Figure 32-76. UPC Table

[1] Bolded parameters are user initialized.

Table 32-64 describes UPC table fields.

Table 32-64. UPC Table Field Descriptions

Offset	Bits	Name	Description
0x00	0–8	—	Reserved, should be cleared.
	9	NCCLPIE	NCCLP0 &NCCLP1 counters overflow interrupt Enable bit. 0 NCCLP0 &NCCLP1 overflow interrupt is disable. 1 NCCLP0 &NCCLP1 overflow interrupt is enable.
	10	CLPIE	CLP0 & CLP1 counters overflow interrupt Enable bit. 0 CLP0 & CLP1 overflow interrupt is disable. 1 CLP0 & CLP1 overflow interrupt is enable.
	11	CDCIE/ FCIE	If UPCM=01 then this bit is Cell Drop Counter overflow interrupt enable bit. if UPCM=10/11 then this bit is Frame Counters (FDC & FC) overflow interrupt enable bit. 0 FDC & FC/CDC overflow interrupt is disable. 1 FDC & FC/CDC overflow interrupt is enable.
	12	CLPDM	CLP Drop Mode. This bit is relevant only in GFR mode [UPCM=11]). Should be cleared otherwise. 0 Do not drop cells due to CLP value. 1 Drop remain cells of frame if there is CLP change within the frame.
	13	IND	Independent bit. 0 If a cell is dropped by the UPC, the theoretical arrival time, of both buckets will NOT be updated. **Important**: When working in this mode VP policing is not allowed 1 The bucket theoretical arrival time is updated only due to the bucket decision.
	14–15	UPCM	UPC operation Mode. 00 Not defined. Should not be used. 01 Cell base mode. See 32.2.20.2.1/32-43. 10 Frame awareness mode. See 32.2.20.2.2/32-43 (applied only for AAL5). 11 GFR mode. See 32.2.20.2.3/32-43. The UPC work as frame awareness mode, and also MFS and CLP changes are checked (applied only in AAL5).
0x02	—	—	Reserved, should be cleared.
0x04	—	CLP0	16 bit counter for all cells with CLP=0. Maskable interrupt is asserted upon wrap of counter. Initialize to zero.
0x06	—		Reserved, should be cleared.
0x08	—	CLP1	16 bit counter for all cells with CLP=1. Maskable interrupt is asserted upon wrap of counter. Initialize to zero.
0x0a	—	FC	Frame Counter. Count all the frame which go through the policer. Maskable interrupt is asserted upon wrap of counter. Initialize to zero.
0x0c	—	NCCLP0	16 bit counter for CLP0 cells which were not conformed by both buckets. Maskable interrupt is asserted upon wrap of counter. Initialize to zero.
0x0e	—	NCCLP1	16 bit counter for CLP1 cells which were not conformed by both buckets. Maskable interrupt is asserted upon wrap of counter. Initialize to zero.
0x10	—	FDC/CDC	Frames Drop Counter/Cell Drop Counter. 16 bit counter. If UPCM=10/11, When frame or part of it is dropped by the UPC, FDC is updated. If UPCM=01, When cell is dropped by the UPC, CDC is updated. Maskable interrupt is asserted upon wrap of counter. Initialize to zero.

Table 32-64. UPC Table Field Descriptions (continued)

Offset	Bits	Name	Description
0x12	0–11	B1TF[0–11]	Bucket1 Theoretical arrival time, Fraction part.
	12–15		Reserved, should be cleared
0x14	—	B1TI[0–31]	Bucket1 Theoretical arrival time, Integer part.
0x18	—	UPCMFS	UPC Maximum Frame Size. This field should be programed to (MFS-1)*48, where MFS is maximum frame size in cell unit. This field is relevant only in GFR mode [UPCMD=11]). Should be cleared otherwise.
0x1a	0–11	B2TF[0–11]	Bucket2 Theoretical arrival time, Fraction part.
	12–15		Reserved, should be cleared.
0x1c	—	B2TI[0–31]	Bucket2 Theoretical arrival time, Integer part.
0x20	—	B1II	Bucket1 Increment Integer part.
0x22	0–11	B1IF[0–11]	Bucket1 Increment Fraction part.
	12	DM1	Bucket1 nonconforming Discard Mode. 0 Cell which was not conformed by bucket1 will be tagged. 1 Cell which was not conformed by bucket1 will be dropped. Tagging is done by setting PNC bit in RXBD. In frame mode (UPCM=10/11), if a cell is dropped, all remaining cells of that frame are dropped, except the last cell (in this case the PNC bit in the last RXBD will be set). If the first cell of a frame is dropped, then the whole frame is dropped.
	13–15	LBF1	Leaky Bucket1 Filter, see 0xLBF - The Leaky Bucket Filter
0x24	—	B1Lim[0–31]	Bucket1 Limit. Most Significant bit must be cleared.
0x28	—	B2II	Bucket2 Increment Integer part.
0x2a	0–11	B2IF[0–11]	Bucket2 Increment Fraction part.
	12	DM2	Bucket2 nonconforming Discard Mode. 0 Cell which was not conformed by bucket2 will be tagged. 1 Cell which was not conformed by bucket2 will be dropped. Tagging is done by setting PNC bit in RXBD. In frame mode (UPCM=10/11), if a cell is dropped, all remaining cells of that frame are dropped, except the last cell (in this case the PNC bit in the last RXBD will be set). If the first cell of a frame is dropped, then the whole frame is dropped.
	13–15	LBF2	Leaky Bucket2 Filter, see 0xLBF - The Leaky Bucket Filter
0x2c	—	B2Lim[0–31]	Bucket2 Limit. Most Significant bit must be cleared.

Note: When working with AAL2 traffic DM1 and DM2 should always be set. Tagging mode is not available.

32.3.11 AAL1 Sequence Number (SN) Protection Table

The 32-byte sequence number protection table, pointed to by AAL1_SNPT_BASE in the ATM parameter RAM, resides in multi-user RAM and is used for AAL1 only. The table should be initialized according to Figure 32-77.

	0 – 15
Offset + 0x00	0x0000

Figure 32-77. AAL1 Sequence Number (SN) Protection Table

32.3.12 UNI Statistics Table

The UNI statistics table, shown in Table 32-65, resides in the multi-user RAM and holds UNI statistics parameters. UNI_STATT_BASE points to the base address of this table. Each PHY's own table has a starting address given by UNI_STATT_BASE+ PHY# × 4.

Table 32-65. UNI Statistics Table

Offset[1]	Name	Width	Description
0x00	UTOPIAE	Hword	Counts cells dropped as a result of UTOPIA/ATM protocol violations. Violations include the following: 1. Parity error 2. HEC error 3. Invalid timing of RxSOC. If RxClav is asserted for the selected PHY, RxSOC should be asserted the cycle immediately following the assertion of $\overline{\text{RXENB}}$. A violation occurs if RxSOC is not asserted at that time (i.e. is late or is missing).
0x02	MIC_COUNT	Hword	Counts miss-inserted cells dropped as a result of address look-up failure.

1 Offset from UNI_STATT_BASE+PHY# × 4

32.3.13 ATM Exceptions

The ATM controller interrupt handling involves two principal data structures: UCCEs (UCC event registers) and circular interrupt queues.

Five priority interrupt queues are available.

Four queues are available for termination mode By programming RCT[INTQ] and TCT[INTQ], the user determines which queue receives the interrupt. Channel Rx buffer, Rx frame, or Tx buffer events can be masked by clearing interrupt mask bits in RCT and TCT. These queues are numbered 0–3.

After an interrupt request, the host reads UCCE. If UCCE[GINT*x*] = 1, at least one entry was added to one of the interrupt queues. After clearing UCCE[GINT*x*], the host processes all the valid interrupt queue entries and clears each entry's valid bit. The host follows this procedure until it reaches an entry with V = 0. See Section 32.3.13.3, "ATM Termination Interrupt Queue Entry." This procedure implies that it is possible to get an interrupt and that the interrupt queue doesn't contain any valid entry as it was already processed in the previous interrupt handling.

The host controls the number of interrupts sent to the core using a down counter in the interrupt queue's parameter table; see Section , "". For each event sent to an interrupt queue, a counter (that has been initialized to a threshold number of interrupts) is decremented. When the counter reaches zero, the global interrupt, UCCE[GINT*x*], is set. In Multi Threading operation this counter is indicating a minimum value for generating an interrupt.

32.3.13.1 ATM Event Register (UCCE)/Mask Register (UCCM)

The UCCE register is the ATM controller event register when the UCC operates in ATM mode. When it recognizes an event, the ATM controller sets the corresponding UCCE bit. Interrupts generated by this register can be masked in UCCM. UCCE is memory-mapped and can be read at any time. Bits are cleared by writing ones to them; writing zeros has no effect. Unmasked bits must be cleared before the QUICC Engine block clears the internal interrupt request.

UCCM is the ATM controller mask register. The UCCM has the same bit format as UCCE. Setting an UCCM bit enables and clearing a bit masks the corresponding interrupt in the UCCE.

Figure 32-78 shows UCCE and UCCM bits.

Figure 32-78. UCC Event Register (UCCE)/Mask Register (UCCM)

Table 32-66 describes UCCE fields.

Table 32-66. UCCE/UCCM Register Field Descriptions

Bits	Name	Description
0–4	—	Reserved, should be cleared.
5	TIRU	Transmit internal rate underrun. A transmit internal rate counter expired and a cell was not sent because the transmit FIFO was empty. TIRU may be set only when using transmit internal rate mode.
6	GRLI	Global red-line interrupt. GRLI is set when a free buffer pool's RLI flag is set. The RLI flag is also set in the free buffer pool's parameter table.
7	GBPB	Global buffer pool busy interrupt. GBPB is set when a free buffer pool's BUSY flag is set. The BUSY flag is also set in the free buffer pool's parameter table.
8–11	GINT*x*	Global interrupt. Set when the number of events sent to the corresponding interrupt queue reaches the corresponding event threshold. See Section 32.3.13, "ATM Exceptions."
12–15	INTO*x*	Interrupt queue overflow. Set when an overflow condition occurs in the corresponding interrupt queue. This occurs when the QUICC Engine block attempts to overwrite a valid interrupt entry. See Section 32.3.13.2, "Interrupt Queues."
17–19	—	Reserved, should be cleared.
21–26	—	Reserved, should be cleared.
28–30	—	Reserved, should be cleared.

32.3.13.2 Interrupt Queues

Interrupt queues are located in external memory. The parameters of each queue are stored in a table. See Table 32-68 and Table 32-69

When an interrupt occurs, the QUICC Engine block writes a new entry to the interrupt queue, the V bit is set, and the queue pointer (INTQ_PTR) is incremented. Once the QUICC Engine block uses an entry with W = 1, it returns to the first entry in the queue. If the QUICC Engine block tries to overwrite a valid entry (V = 1), an overflow condition occurs and the queue's overflow flag, UCCE[INTO*x*], is set.

The interrupt queue structure is displayed in Figure 32-79.

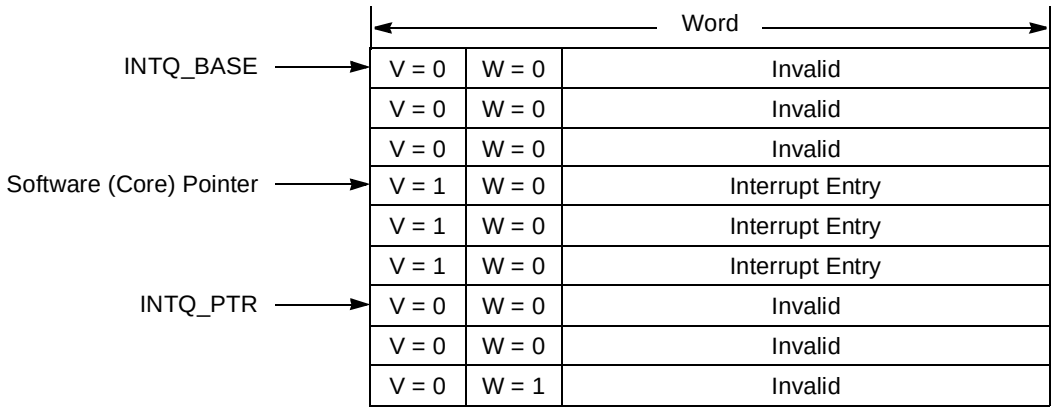

Figure 32-79. Interrupt Queue Structure

32.3.13.3 ATM Termination Interrupt Queue Entry

Each one-word interrupt queue entry provides detailed interrupt information to the host. Figure 32-80 shows an entry for Non UPC- Policer events

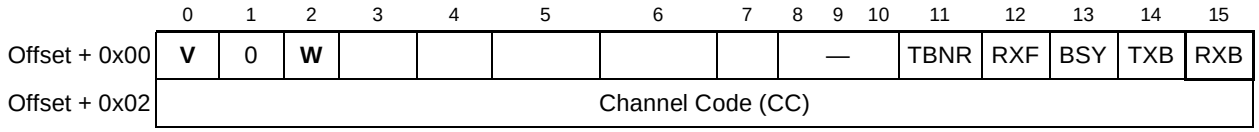

Figure 32-80. Interrupt Queue Entry—Non UPC

Figure 32-81 shows an entry which is a result of a UPC-ATM Policer event. Bits 1,10 and 12 are set in order to distinguish between a UPC event and all other events on the ATM.

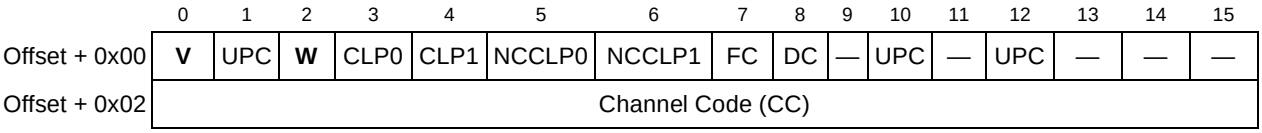

Figure 32-81. Interrupt Queue Entry—UPC Event

Important: For AAL2 there are different interrupt queue entries. See “Section 41.8, AAL2 Exceptions” on page 60 for details.

32.3.13.4 Interrupt Queue Parameter Table

Table 32-67 describes interrupt queue entry fields.

Table 32-67. Interrupt Queue Entry Field Description

Offset	Bits	Name	Description
0x00	0	**V**	Valid interrupt entry 0 This interrupt queue entry is free and can be use by the QUICC Engine block. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	UPC	UPC interrupt bit. 0 This interrupt was not generated by the UPC. 1 This interrupt was generated by the UPC.
	2	**W**	Wrap bit. When set, this is the last interrupt circular table entry. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	3	CLP0	CLP0 counter overflow. Valid only if UPC bit is set. 0 No CLP0 counter overflow. 1 CLP0 counter overflow.
	4	CLP1	CLP1 counter overflow.Valid only if UPC bit is set. 0 No CLP1 counter overflow. 1 CLP1 counter overflow.

Table 32-67. Interrupt Queue Entry Field Description (continued)

Offset	Bits	Name	Description
0x00	5	NCCLP 0	NCCLP0 counter overflow.Valid only if UPC bit is set. 0 No NCCLP0 counter overflow. 1 NCCLP0 counter overflow.
	6	NCCLP 1	NCCLP1 counter overflow.Valid only if UPC bit is set. 0 No NCCLP1 counter overflow. 1 NCCLP1 counter overflow.
	7	FC	Frame Counter overflow.Valid only if UPC bit is set. 0 No FC counter overflow. 1 FC overflow.
	8	DC	Cell/Frame Discard Counter.Valid only if UPC bit is set. 0 No FDC/CDC overflow. 1 FDC/CDC overflow.
	9–10	—	Reserved.
	11	TBNR	Tx buffer-not-ready. Set when a transmit buffer-not-ready interrupt is issued. This interrupt is issued when the QUICC Engine block tries to open a TxBD that is not ready (R = 0). This interrupt is sent only if TCT[BNM] = 1. This interrupt has an associated channel code. Note that for AAL5, this interrupt is sent only if frame transmission is started. In this case, an abort frame transmission is sent (last cell with length=0), the channel is taken out of the APC, and the TCT[VCON] flag is cleared.
	12	RXF	Rx frame. RXF is set when an Rx frame interrupt is issued. This interrupt is issued at the end of AAL5 PDU reception. This interrupt is issued only if RCT[RXFM] = 1. This interrupt has an associated channel code.
	13	BSY	Busy condition. The BD table or the free buffer pool associated with this channel is busy. Cells were discarded due to this condition. This interrupt has an associated channel code.
	14	TXB	Tx buffer. TXB is set when a transmit buffer interrupt is issued. This interrupt is enabled when both TxBD[I] and TCT[IMK] = 1. This interrupt has an associated channel code.
	15	RXB	Rx buffer. RXB is set when an Rx buffer interrupt is issued. This interrupt is enabled when both RxBD[I] and RCT[RXBM] = 1. This interrupt has an associated channel code.
0x02	—	CC	Channel code specifies the channel associated with this interrupt.

The interrupt queue parameters are held in parameter tables in the multi-user RAM; This table has a different programming model when the QUICC Engine block operates in a backwards compatible mode and when Multi-Threading mode is activated. Table 32-68 and Table 32-69 describes the parameter tables programming under each mode of operation. INTT_BASE in the parameter RAM points to the base address of these tables. Each of the four interrupt queues has its own parameter table with a starting address given by INTT_BASE+ RCT/TCT[INTQ] $\times$ 16.

Important:

- For proper operation Receiver and transmitter interrupts should reside on different interrupt queues
- Each UCC should assign it own interrupt queue management tables. They should not be shared by several UCCs.

Table 32-68. PQII-like Interrupt Queue Parameter Table-Non Multi-Threading

Offset [1]	Name	Width	Description
0x00	**INTQ_BASE**	Word	Base address of the interrupt queue. User-defined.
0x04	**INTQ_PTR**	Word	QUICC Engine block actual Pointer to interrupt queue entry. Initialize to INTQ_BASE. Managed by the QUICC Engine block.
0x08	**INT_CNT**	Half Word	Interrupt counter. Initialize with INT_ICNT. The QUICC Engine block decrements INT_CNT for each interrupt. When INT_CNT reaches zero, the queue's global interrupt flag UCCE[GINT*x*] is set.
0x0A	**INT_ICNT**	Half Word	Interrupt initial count. User-defined global interrupt threshold—the number of interrupts required before the QUICC Engine block issues a global interrupt (UCCE[GINT*x*]).
0x0C	**INTQ_ENTRY**	Word	Interrupt queue entry. Must be initialized to the entry pointed to by INTQ_PTR, which is initially the first empty entry of the queue. Note that after an overrun occurs, this entry must be reset to the entry pointed to by INTQ_PTR to reenable interrupt processing.

1 Offset from INTT_BASE+RCT/TCT[INTQ] × 16

NOTE

When working in Non Multi-Threading mode the events of the receiver and transmitter should reside on different interrupt queues.

Table 32-69. Multi-Threading Mode Interrupt Queue Parameter Table

Offset [1]	Name	Width	Description
0x00	**INTQ_BASE**	Word	Base address of the interrupt queue. User-defined.
0x04	**INTQ_OFFSET_OUT**	Half Word	The software offset to interrupt queue entry. Initialize to 0. Managed by the software (host). The actual host entry pointer is equal to INTQ_BASE+INTQ_OFFSET_OUT.
0x06	**INTQ_OFFSET IN**	Half Word	The QUICC Engine offset to the interrupt queue entry. Initialize to 0. Managed by the QUICC Engine block. The actual QUICC Engine entry pointer is equal to INTQ_BASE+INTQ_OFFSET_IN.
0x08	**INT_CNT**	Half Word	Interrupt counter. Initialize with INT_ICNT. The QUICC Engine block decrements INT_CNT for each interrupt. When INT_CNT reaches zero, the queue's global interrupt flag UCCE[GINT*x*] is set.
0x0A	**INT_ICNT**	Half Word	Interrupt initial count. User-defined global interrupt threshold—the number of interrupts required before the QUICC Engine block issues a global interrupt (UCCE[GINT*x*]).
0x0C	**Res**	Half Word	Reserved. Should be cleared
0x0E	**INTQ_Size**	Half Word	Size in bytes of the interrupt queue entries table.

1 Offset from INTT_BASE+RCT/TCT[INTQ] × 16

NOTE

For Multi-thread mode the maximum size of the interrupt queue is limited to 16 K entries.

32.4 ATM Controller—Application Information

32.4.1 ATM Commands

The host initializes and activates the ATM operation using the host commands.

This is done by two memory mapped registers depicted here: the CECE and the CECDR. Detailed description is located at RISC control chapter:

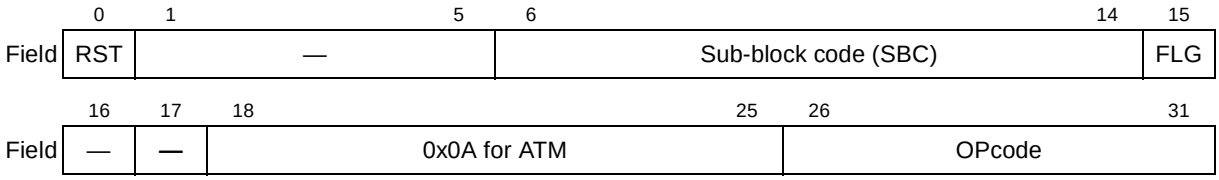

Figure 32-82. CE Command Register (CECR)

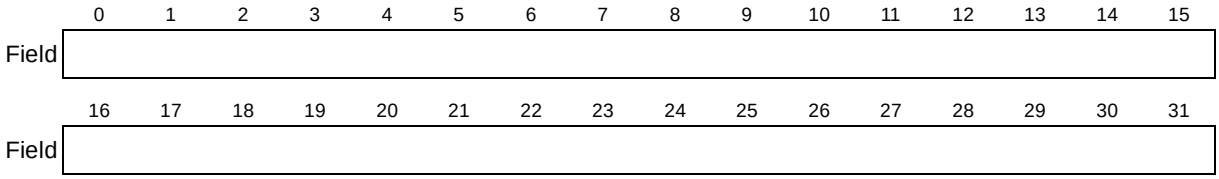

Figure 32-83. CE Command Data Register (CECDR)

The host commands for the ATM are the following

32.4.1.1 ATM Transmit Command

The ATM transmit command turns a passive channel into an active channel by inserting it into the APC scheduling table. Note that an ATM transmit command should be issued only after the channel's TCT is completely initialized and the channel has BDs ready to transmit. The CECR register has the following settings:

Opcode is:0x001010

SBC: determined by the UCC.

Before issuing the command, the user should initialize COMM_INFO fields in the Global ATM Parameters described in Table 32-19 The information is described in Figure 32-84.

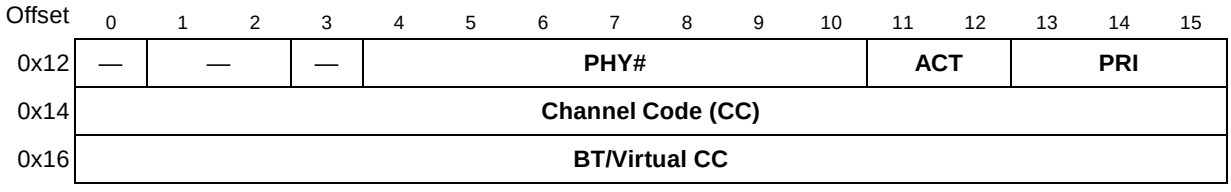

Figure 32-84. COMM_INFO Field

NOTE
Backward Compatibility

The PHY# and the CTB bits locations were changed.

Table 32-70 describes COMM_INFO fields.

Table 32-70. COMM_INFO Field Descriptions

Offset	Bits	Name	Description
0x12	0	—	Reserved, should be cleared.
	1–2	—	Reserved, should be cleared.
	3	—	Reserved, should be cleared.
	4–10	PHY#	PHY number. In single PHY mode this field should be cleared. In multiple PHY mode this field is an index to the APC parameter table associated with this channel.
	11–12	ACT	ATM channel type 00 Other channel 01 VBR channel 10 GBR-UBR channel. This is valid for inserting the lower priority UBR channel for transmission. 11 For Hierarchical frame based activation of a channel into the WFQ selection
	13–15	PRI	APC priority level. 000 Highest priority (APC_LEVEL1) 111 Lowest priority (APC_LEVEL8). For GCRA scheduler only 4 priority levels are available. 0x00–0x03
0x14	0–15	CC	Channel code. The channel code associated with the current channel.
0x16	0–15	BT/ Virtual CC	Burst tolerance. For use by VBR channels only (ACT field is 0b01). Specifies the initial burst tolerance (GCRA burst credit) of the current VC. When ACT=0b11, e.g. inserting a channel into the hierarchical frame based scheduling this entry is the CC of the Virtual channel acting as the root of the hierarchy.

32.4.1.2 Assign Page

The host can assign each UCC its page and override the default page assignment for the UCCs.

This is done by issuing the Assign Page command.

When using this command the host should first issue the command for the desired UCC. Then initialize all the parameters in the allocated page and only then continue with the Multi-threading and terminator initialization.

32.4.1.3 ATM Multi-Thread Init

This command will initialize the UCC for a multi-threading operation. It should be issued only once for all the UCCs which are sharing the same thread pool.

The command parameters are:

Opcode: 0x010000

SBC should match the snum of one of the UCCs who are utilizing the common multi-threading table. The information in Table 32-20 and Table 32-30 should be initialized by the host prior to issuing this command.

The QUICC Engine block will scan the Multi-threading table and assign each of the threads the MURAM allocated to it by the host.

32.4.2 Configuring the ATM Controller for Maximum QUICC Engine Performance

The following sections recommend ATM controller configurations to maximize QUICC Engine performance.

32.4.2.1 Configuration of Internal Rates timers

Use the transmit internal rate mode and configure the internal rate clock to the maximum bit rate required. The PHY then automatically fills the unused bandwidth with idle cells, not the ATM controller.

For example, suppose a system uses a 155.52-Mbps OC-3 device as PHY0, but the maximum required data rate is only 100 Mbps. In transmit internal rate mode, the user can configure the internal rate mechanism to clock the ATM transmitter at a cell rate of 100 Mbps. If the system clock is 133 MHz, program a BRG to divide the system clock by 563 to generate a transmit cell request every 563 QUICC Engine clocks:

$$\frac{(133\text{MHz} \times (53 \times 8))}{100\text{Mbps}} = 563$$

Set FTIRR*x*_PHY0[TRM] to enable the transmit internal rate mode and clear FTIRR*x*_PHY0[Initial Value] since there is no need to further divide the BRG.

32.4.2.2 APC Configuration

32.4.2.2.1 APC CPS

Maximizing the number of cells per slot (CPS) defined in the APC data structure improves QUICC Engine performance. CPS defines the maximum number of ATM cells allowed to be sent during a time slot. (See Section 32.2.5.3.1, “Determining the Cells Per Slot (CPS) in a Scheduling Table.”) The scheduling algorithm is more efficient sending multiple cells per time slot using the linked-channel field. Therefore, choose the maximum number of cells per slot allowed by the application.

32.4.2.2.2 APC Priority Levels

Minimizing the number of priority levels defined in the APC data structure improves QUICC Engine performance. The user can configure the APC data structure to have from one to eight priority levels. (See Section 32.2.11, “Determining the Priority of an ATM Channel.”) For each time slot, the scheduling algorithm scans all priority levels and maintains pointers for each level. Therefore, enable only the minimum number of priority levels required.

32.4.2.2.3 APC Flux Compensation

For variable bit rate PHY (e.g. radio link), which can fall below the transmission bandwidth defined by the APC internal rate timers, the ATM APC does not use the remaining bandwidth for higher priority traffic only. Using the APC Flux Compensation mechanism could improve the performance of this system. Also it could be useful for supporting system with many UBR connections, see Section 32.2.8, "APC Flux Compensation".

The penalty for using the APC Flux Compensation mechanism is in terms of QUICC Engine performance.

32.4.2.2.4 Scalable APC mode

If an ATM system requires connections with very high variance in bit rates that spans orders of magnitude, the code offers a way to reduce the space required by the APC scheduling table without impacting the scheduling itself. Also it is very useful if we have Multi-PHY application (up to 127 PHYs), and we would like to reduce the APC table sizes in the multi-user RAM as much as possible.

The penalty for using the Scalable APC mode is:

1. Reducing the QUICC Engine performance.
2. Increase the cell delay variation time.

32.4.2.2.5 UBR+ prioritized mode

Systems that requires several priority levels for UBR+ channels, the prioritized UBR+ mechanism should be enabled. The penalty for using this mode is in terms of QUICC Engine performance.

32.4.2.3 GCRA Scheduler mode

As described in Section 32.2.12, "GCRA Scheduler", the user should use the GCRA scheduler mode for systems where the number of PHYs per UCC is big and the number of channels per PHY is relative small (up to 64 channels), and the variance between the channels rate is big. This is normally the case in DSLAM. The big advantage of the GCRA scheduler method compared with the traditional APC algorithm, is the economical RAM usage, and the improvement of performance.

32.4.2.4 ATM Multi-thread Mode

As described in Section 32.2.3, "ATM Multi-Threading", in order to support higher ATM traffic rates, as overall bandwidth of OC-12, the user should use the Multi-Threading mode. This mode enables better bus/QUICC Engine block utilization, by using additional available request resources in the QUICC Engine block. This mode is enabled per UCC by configuring in the CECR[MCN], when issuing an UCC init Rx/Tx parameters command.

32.4.2.5 Buffer Configuration

Using statically allocated buffers of optimal sizes also improves QUICC Engine performance:

- Buffer size. Opening and closing buffer descriptors consumes QUICC Engine block processing time. Because smaller buffers require more opening and closing of BDs, the optimal buffer size for maximum QUICC Engine performance is equal to the packet size (an AAL5 frame, for example).

- Free buffer pool. When the free buffer pool is used, the QUICC Engine block dynamically allocates buffers and links them to a channel's BD. In static buffer allocation, the core assigns a fixed data buffer to each BD. (See Section 32.3.9.2, "Receive Buffer Operation.") When allowed by the application, use static buffer allocation to increase QUICC Engine performance.

Chapter 33
UTOPIA POS Bus Controller (UPC)

33.1 Overview

The UPC (UTOPIA/POS-PHY L2 bus Controller) is the UTOPIA/POS-PHY MAC peripheral of the QUICC Engine block. The QUICC Engine block supports UTOPIA/POS-PHY level 2 for both master and slave modes.

The QUICC Engine block has two UPCs, referred to as UPC1 and UPC2. In this document, the term "UPC" applies to both. In some diagrams, a reference for a specific UPC is made for clarity, but unless stated otherwise, the UPCs have the same functionality[1].

The UPC is a MAC, and therefore is not independent from the UCCs (which can be roughly described as the "FIFOs" or "queues"). Unlike the other MACs of the QUICC Engine block which are integrated within the UCC, the UPC can route the data path to 1-4 UCCs[2] (see Figure 33-1, routing example in Figure 33-3). This routing is required for certain bus configurations in order to achive the required bus performance.

As master, the UPC controls one UL2/PL2 bus with up to 124/128 PHYs. The UPC implements Appendix 1 to the UTOPIA L2 standard with 4 Clav/PxPA and Enb signal pairs. The group of PHYs controlled by a common Clav/Enb signals pair are called a device within this chapter. Each device could be either a multi PHY or a single PHY. Each device can be routed to any UCC in multi PHY (MPHY) configuration. Only a single device can be routed to any UCC in single PHY (SPHY) configuration.

As slave, the UPC can operate in SPHY or in MPHY mode. In slave mode configuration only a single UCC is routed to the UPC.

Transmit and receive functions on the UPC are independent, and can be set to either master or slave mode. The device routing is also configured independently for Rx and Tx. As transmitter, the UPC supports an Internal Rate mechanism. This mechanism enables the allocation of a precise bandwidth to each port in an MPHY or SPHY distribution. The transmission rate is determined by the UPC internal rate timers. The source clock of the internal rate timers can be the serial clock, or derived from a baud rate generator or from an external clock source. The Internal Rate works differently for SPHY and for MPHY devices. In SPHY mode the internal rate paces the line rate and the transmit FIFO becomes a leaky bucket. In MPHY mode the internal rate paces the FIFO fill rate (the polling status is qualified by the internal rate, and the FIFO only contains cells for PHYs which are actively requesting data). In the Receive direction, a selection based on programmable priority is used to prioritize cell transfers from the ports to the UCC. For POS, the Internal rate has another option, to control the packets per second rate.

1. Except that the two UPCs might have different I/O options, please check with the parallel I/O specification.
2. UPC1 can be routed only to UCC1, UCC3, UCC5, UCC7., UPC2 can be routed only to UCC2, UCC4, UCC6, UCC8.

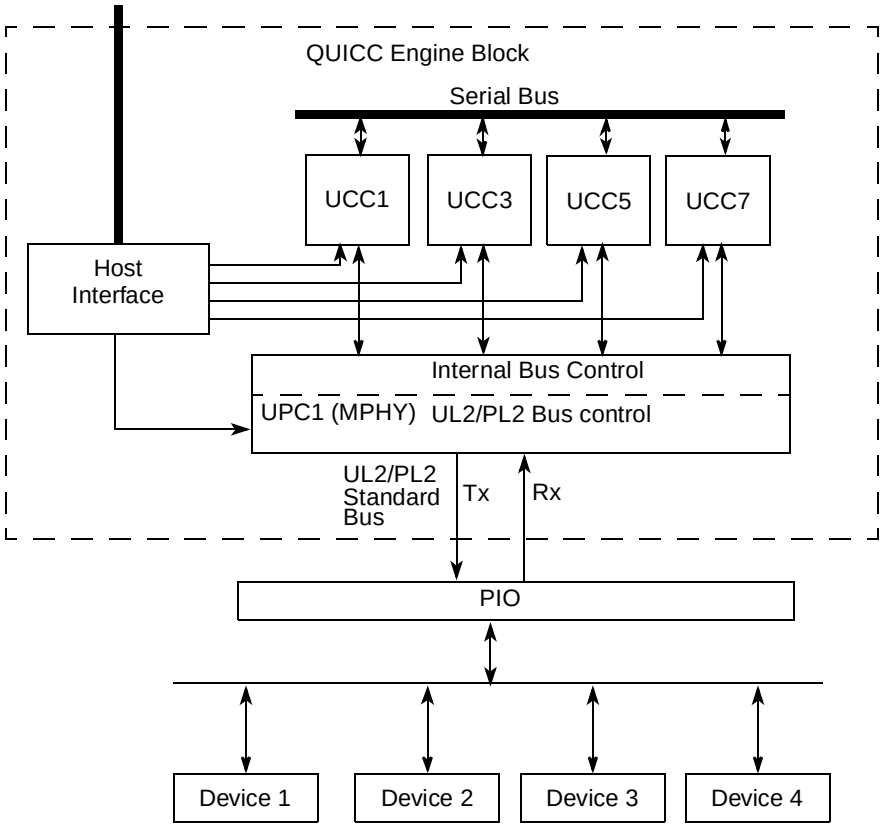

Figure 33-1. QUICC Engine Block with UPC1 (4 devices, up to 124 ports)

33.2 Features

33.2.1 UPC Features

- Connection to 4 devices through one UL2/PL2[1] Standard bus I/F (compliant with appendix 1 of UTOPIA L2 spec).
- UL2 protocol:
  - Up to 124 addresses for 4 physical devices in normal address mode (5-bit address).
  - Up to 128 addresses for 8 physical devices in 6-bit addressing MPHY mode.
  - Connection to 4 UCCs, each with deep, programmable size FIFOs.
  - Internal Loop-back mode
- PL2 protocol:
  - Up to 31 addresses for 1 physical devices in normal address mode (5-bit address).
  - Up to 32 addresses for 2 physical devices in 6-bit addressing MPHY mode.
  - No internal loop-back mode.
- Routing of each device to each UCC in MPHY

1. POS supports only a single device.

- Routing of a single device to a UCC as SPHY
- Slave can tri-state its outputs when not selected (Slave in MPHY system)

NOTE

To maximize performance, the UTOPIA/POS-PHY bus bandwidth should be at least 1.1 times the aggregated throughput on the bus.

33.2.2 UL2 Features

- Conforms to ATF UL2 standard version 1.0, June 1995
- 8/16 bit UL2 bus clocked at 50 MHz with 4 devices (50 pF)
- Cell level handshake support
- Up to 4 devices on the UL2 bus, each with separated Clav/Enb (Per Rx/Tx). Each could be set to either 8 or 16 bit data port width.
- SPHY: Up to 4 devices can be configured as SPHY. Clav is assumed as direct status or as always valid.
- MPHY: Each device can be configured as MPHY, with single Clav polling method per device (there is a separate Clav/Enb control pair for each device).
- Default address mode (5-bit address) for 124 PHYs (4 devices, each with up to 31 PHYs).
- Extended address mode (6-bit address) for 128 PHYs (8 Devices, each with up to 16 PHYs). The devices in extended mode are standard compliant (5-bit address).
- Internal Rate:
  - 4 internal rates for each device (16 total)
  - Programmable max credit value for each device (Useful for PON or xDSL applications).
- Tx internally discards idle cells.
- Rx discard idle cells option.
- Tx scheduling:
  - SPHY: Internal rate shapes the actual transmission rate on the UTOPIA bus. Cells are prefetched to the Virtual TxFIFO.
  - Request arbitration is handled in a fixed or round robin (for fairness) priority scheme among pending qualified PHYs within the same device. Arbitration is in round robin order among the devices routed to the same UCC.
  - Transmit arbitration is handled in round robin among different UCCs.
  - SPHY in multi-port mode: Up to 32 logical ports with internal rate and fixed or round priority among them are funneled to the same PHY.
  - Optional back to back transmission per UCC. This feature is useful for SPHY, for which back to back cell transmission is desired. It is recommend to use this option for PHYs that are allocated more then 50% of the bus BW.
- Tx cell transfer
  - Back to back cell transfer without dead cycle in SPHY.
  - Dead cycle on back to back transfer on MPHY or when changing device.

  - Programmable HEC field (common to all devices).
  - Automatic data parity generation.
- Rx selection (two priority levels decision):
  - Arbitration is in round robin priority among devices with optional back to back reception per UCC to prioritize a UCC (in SPHY mode this is a PHY level back to back).
  - 2 priority levels per PHY (reduce worst case round trip latency time for high priority PHY).
  - Arbitration is in round robin priority among all PHYs within a device of the same priority level.
- Rx cell transfer
  - Optional Idle Cell discard
  - Back to back cell transfer with single dead cycle.
  - Optional HEC check (COSET optional)
  - Optional data parity check (Odd parity)
  - Framing error detection (missing SOC error)
  - Error on RSOC violation
- Polling
  - Polling is periodic and fair.
  - Independently programmable last PHY address for Rx and for Tx.
  - Parallel polling over 4 devices in single-Clav method.
  - Maskable polling per port (Rx, Tx or both).
- Slave mode
  - Slave is a single device, using device 1 xClav/xEnb control pairs.
  - Direct status polling method in SPHY mode.
  - Configurable slave address in MPHY mode (independent Rx and Tx settings).
  - Support pause, halt (Master initiated TxEnb, RxEnb flow control).
  - Support back to back Tx cell transfer (without negation of TxEnb).

33.2.3 PL2 Features

33.2.4 PL2 Features

- Conformal to Saturn Group PL2 specification, November 1998.
- 16 bit PL2 bus clocked at 50 MHz with 1 device (50 pF).
- Packet level handshake support.
- SPHY: device can be configured as SPHY. PxPA is assumed as always valid or as a direct status polling indication (DxPA).
- Packet interleaving among multiple PHYs in transmit and receive (switching between ports during packets transfer).
- As master, user should configure the transmit segment size to be less or equal to the PHY's PTPA threshold.

- Internal rate mechanism to set the packets per second (PPS) rate.
- Generate TxErr in case of Tx underrun.
- Reports Overrun, RxErr, Parity error, Protocol errors.
- MPHY: Each device can be configured as MPHY, with single PxPA polling status indication per device.
- Default address mode (5-bit address) for 31 PHYs (1 device).
- Extended address mode (6-bit address) for 32 PHYs (2 Devices, each with up to 16 PHYs). The devices in extended mode are standard compliant (5-bit address).
- Internal Rate:
  - 4 internal rates groups.
  - The internal rate should be set either to PPS mode or to external rate mode.
- Tx scheduling:
  - SPHY: Internal rate shapes the actual transmission rate on the POS-PHY bus. Packets are prefetched to the Virtual TxFIFO.
  - Transmit ordering arbitration is handled in a fixed or round robin (for fairness) priority scheme among pending qualified PHYs within the same device.
  - SPHY in multi-port mode: Up to 32 logical ports with internal rate and fixed or round priority among them are funneled to the same PHY.
- Tx Packet Transfer
  - Interleave packet transfer to multiple ports.
  - Automatic Odd or Even data parity generation
- Rx selection (two priority levels decision):
  - Within a device, round robin selection among all PHYs of the same priority.
  - 2 priority levels per PHY (reduce worst case round trip latency time for high priority PHY).
- Rx Packet transfer
  - Performs segmentation of received packets from multiple ports.
  - Segment size programmable in UPHEC register.
  - Overrun detection if FIFO is full.
  - Detection of framing errors: Double or late SOP in segment, no RVAL.
  - Switching when RVAL negated.
  - Optional data parity check (Even or Odd parity are supported)
  - Back to back packet transfer with two dead cycles switch time.
- Polling
  - Polling is periodic and fair.
  - Independently programmable last PHY address for Rx and for Tx.
  - Direct status polling is assumed for SPHY device.
  - Internal Rate mechanism to pace polling on transmit MPHY or en-queuing in SPHY
  - Maskable polling per port (rx, tx or both)

33.2.5 Internal Rate Features

Internal rate paces the Transmit FIFO de-queuing rate for SPHY and the en-queuing rate for MPHY. In general, the internal rate is set in the initialization process, but it can be changed dynamically. Each Phy has an expiration counter that tracks transmit rate variation (jitter) in the transmit rate, which can be compensated by a burst of cells at a rate higher than the prescribed internal rate. If this variation exceeds a programmable watermark, a transmit time-out event is reported.

- Supprt external rate (internal rate timers disabled)
- Fastest PHY to Slowest PHY transmit rate ratio of 32768 (for example, the fastest PHY could be set to 622 Mbps and the slowest PHY to19 Kbps).
- Configurable expiration counter threshold (cell/packet burst size) per device (1 to 16). When setting to 1 (POS PPS mode), transmit internal rate underrun is not reported.
- Sub rate dividers:
  - Serial clock as the basic rate for internal sub-rates. (An internal BRG clock could also be used).
  - Pre-scalar divider for each device.
  - 4 sub rates for each device. Each PHY in a device can be assigned any of those rates.
  - Divide clock up to 32768 of the basic rate.
- Transmit internal rate underrun event per PHY, in the event of a mismatch of up to 16 cells/segments[1] over any interval of time between the number of PHY transmit requests (which are polled at the Internal Rate) and the actual number of transmitted cells/packets.

33.3 Modes of Operation

33.3.1 UTOPIA Mode

The QUICC Engine ATM controller interfaces with a PHY device through the UPC UTOPIA interface. The QUICC Engine block supports UTOPIA level 2 for both master and slave modes.

33.3.1.1 UTOPIA Master Mode

As master, the UPC controls one UL2 bus with up to 4 devices, and can route each to any one of 4 UCCs. Each device can operate as SPHY or MPHY.

1. 16 or less, configured in UPRP[TIREC].

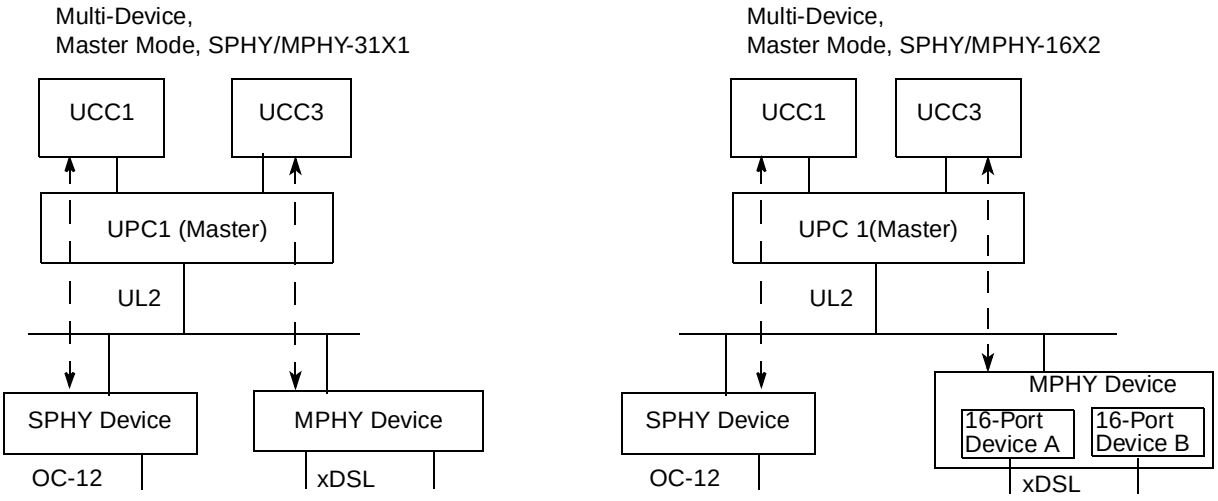

Figure 33-2. Example: Multi-Device Configurations in Master Mode

33.3.1.1.1 UTOPIA Master MPHY Operation

The cell transfer in a multiple-PHY ATM port uses cell-level handshaking as defined in the UTOPIA standards. When a device is configured to operate as a MPHY, the UPC as a transmitter fetches a cell for any port in the MPHY device if there is a pending, qualified Clav for that port.

In multi-device or single-device modes, single-Clav polling is applied. There is one Clav and one Enb signal per device for up to 4 devices in default MPHY mode or 4 device pairs in 6-bit addressing MPHY mode. During the polling phase, all devices sample the address bus and each device uses its Clav to indicate the status of the corresponding PHY. During the selection phase, the selected PHY address appears on the common address bus, but only the selected device's Enb signal is asserted.

33.3.1.1.2 Default Addressing MPHY Mode

Up to 31 PHYs can be supported on a device, for a total of 124 PHYs in default MPHY mode (total of 124 PHYs). The routing method for default MPHY mode devices is displayed in Figure 33-3.

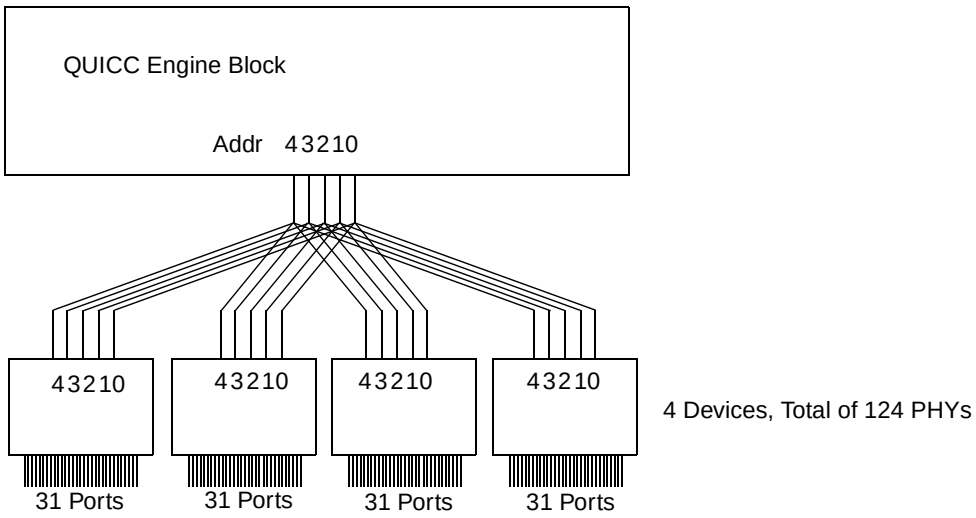

Figure 33-3. Default MPHY Devices address bus routing

33.3.1.1.3 6-bit Addressing MPHY Mode

Up to 32 PHYs can be supported on a device pair of 16-ports physical devices (termed 1A, 1B; 2A, 2B; 3A, 3B; 4A, 4B) in 6-bit addressing MPHY mode (total of 128 PHYs). An extra address bus msb is driven to support two devices on each enb/clav pairs, with address range 0-0xF per device. The routing method for 6-bit addressing MPHY mode devices is displayed in Figure 33-4.

33.3.1.2 UTOPIA Slave Mode

The UPC can function as a single UL2 slave, in SPHY or MPHY mode. The slave is always configured as device 1 (registers, I/O) and it can be routed to one of any of the 4 UCCs. The outputs/inputs of devices 2,3,4 (such as Enb[2:4]) are inactive. The UPC use direct status polling for SPHY, and 1-clav status polling for PHYs in the MPHY system. By default, the slave is represented internally as port 0. If UPDC[PE] = 0, the port enable register has no function in slave mode. If UPDC[PE] != 0, PPER[0] enables the slave regardless of the PHY address. For a slave in a multi-endpoint configuration, PPER[0:31] is used in the same way as for a master.

33.3.1.2.1 UTOPIA Slave MPHY Operation

The QUICC Engine block supports one slave in MPHY configuration. The slave address in MPHY mode is configurable (independent address for Tx slave and Rx slave).

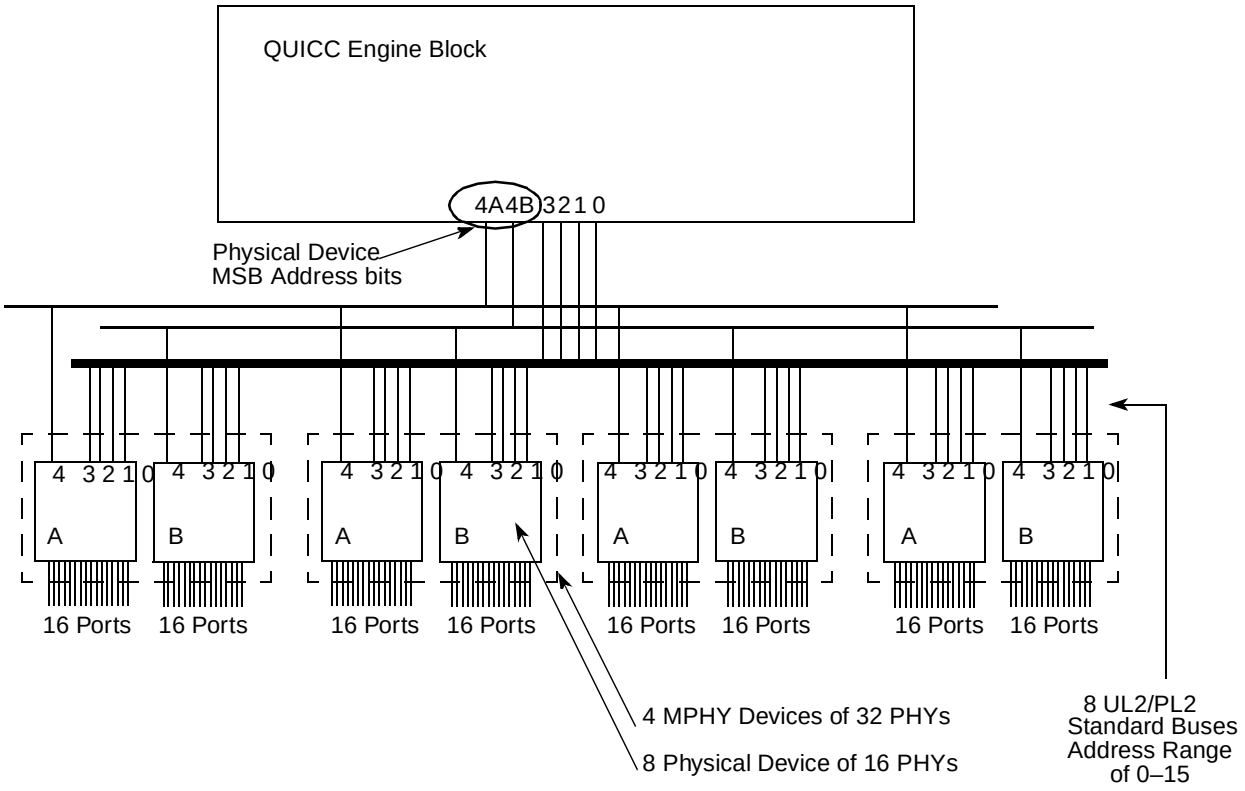

Figure 33-4. 6-bit Addressing MPHY Devices Address Bus Routing

In multiple PHY UTOPIA slave mode, cells are transferred using cell-level handshake as defined by the UTOPIA level-2 standard. The user should write the ATM controller PHY address in UPLPAy[PHY ID].

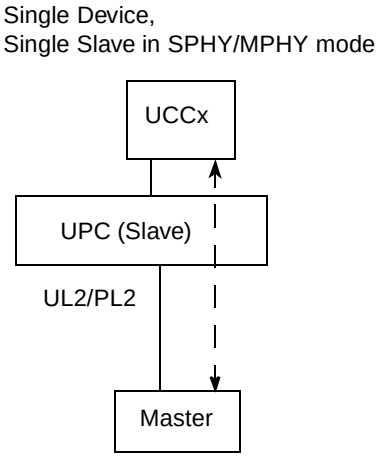

Figure 33-5. SPHY/MPHY Configuration in Slave mode

33.3.2 POS Mode

PL2 works according to POS packet-level handshake.

NOTE

POS supports one device, up to 32 ports in Master mode and does not support internal loopback.

33.3.2.1 POS Master Mode

The UPC as PL2 Master can interleave the transfer of several packets to/from differnt ports by switching. Switching is the use of flow control (pause) to de-select and re-select ports during packet transfer even before the end of the packet. The UPC as Rx Master perform segmentation of packets based on the segment size programmed in the UPHEC register (back to back transfer is optional for SPHY devices). The default and 6-bit addressing modes are displayed in Figure 33-3, and Figure 33-4.

33.3.2.1.1 Internal rate settings for POS Tx (PPS mode)

For POS, the UPC internal rate registers should be configured for the desired time interval between start of packet and the start of the next packet. See section Section 33.3.3, “Transmit Internal/External Rate Modes. For MPHY, the internal rate expiration counter has to be programmed to 1 (UPRPx[TIREC]=1). For single PHY, it is also possible to use external rate (UPRPx[TIREC]=0).

33.3.2.2 POS Slave Mode

The UPC can function as one PL2 slave, in SPHY or MPHY mode. The slave is using only device 1 and it can be routed to one of any of the 4 UCCs. The outputs/inputs of devices 2,3,4 (such as Enb[2:4]) are inactive. The slave address in MPHY mode is configurable in UPLPAy[PHY ID].

The UPC Packet availale indications are direct status packet avaibale (DRPA/DTPA) for SPHY, and polled status packet available (PTPA/PRPA) for PHYs in MPHY system.

In Rx Slave mode, PTPA and STPA signals logic is based on the DCS’s Rx FIFO threshold. The POS Rx FIFO threshold is 64 bytes. Once the FIFO has less than 64 bytes of empty space, the STPA signal is deasserted.

As Slave, the UPC force the Master to do segmentation of the packets. The UPC as Tx Slave (Rx Slave from perspective of POS Rx Master) negate PRPA after selection, so the Master is required to end the selection not beyond the programmed segment size. Likewise, the UPC as Rx Slave (Tx Slave from perspective of POS Tx Master) negate STPA and PTPA after selection so the Master is required to end the selection not beyond the programmed segment size.

33.3.3 Transmit Internal/External Rate Modes

The UPC controller supports the following two rate modes:

- **External Rate (ER) mode** (UPRPx[TIREC]=0) - The total transmission rate is determined by the PHY transmission rate. External rate mode is the default configuration, and it is useful for users who want to have 8260-like behavior of external rate ATM without idle cells, and for POS with variable length packets.
- **Internal rate mode** - The total transmission rate is determined by the UPC internal rate timers. The internal rate mechanism is supported for up to 32 PHYs on 4 devices. Each device has its own 4 internal rate values, defined in UPTIRRx. The UPTIRRx includes the initial value of the internal rate timer. A cell transmit request is sent when an internal rate timer expires.

33.3.3.1 Using Transmit Internal Rate Mode

Internal rate programming sequence:

1. Calculate the cell to cell time delay (Delay): Delay= (Number of bits in cell or packet) / (Required bit rate in Mbps).
2. Calculate the cell to cell bus cycles delay (Normalize Delay to the bus frequency): CYC = Delay / (Serial clock cycle in micro-sec)
3. Round down CYC for an upper bound for the internal rate.
4. Repeat for up to 4 different bit rates per device, up to 16 bit rates in total.
5. Find an applicable common denominator for all rates of a device. Program the prescalar to divide with this number.
6. Program the sub rate counters.

Example 1:

Configure a 155.52-Mbps OC-3 PHY to 100 Mbps, for 8 bit UTOPIA bus at 25 Mhz (200 Mbps bus). 100 Mbps is equivalent to a cell every 106 cycles. In transmit internal rate mode, configure the sub rate divider to 105. This would pace the ATM scheduler at the prescribed rate.

Example 2:

Configure a 622 Mbps PHY and 32 Kbps PHY, for 16 bit UTOPIA bus at 50 MHz (800 Mbps bus). 622 Mbps is equivalent to a cell every 34.1 cycles.
Applying the formulation above, the process is:

1. Delay = 424/ 32E-3 = 13250
2. CYC = Delay/ 20E-3 = 622500
3. The only applicable common denominator for 34 and 622500 is 34.
4. Program the prescalar to divide by 34
5. Program sub rate 1 to divide by 1
6. Program sub rate 2 to divide by 18308

33.3.3.2 External Rate-Like Mode in PL2

The equivalent of an idle cell is a null packet. A null packet decrements the expiration counter from 1 to 0 for this PHY, and will be masked for a time set by its rate settings.

33.3.4 SPHY System Design

This section applies to master mode only.

33.3.4.1 Single Device System

When the system includes only one SPHY device, clear the MultiPHY mode for the UCCs routed to the SPHY in UPUC register (UPUCx[TMP]=0). For receive, clear MultiPHY mode in UPDCy[RMP]. The Clav must be a direct status (always valid). If the address bus is used, refer to Section 33.3.4.2, “Multiple Devices System.”

33.3.4.2 Multiple Devices System

If multiple devices are connected to the UPC, each one that is a SPHY device should be routed to a dedicated UCC and configured as SPHY in the UPC (UPUCx[TMP] = 0). Because there are multiple devices on the UTOPIA/POS-PHY buses, the device must tri-state its outputs (except Clav/PxPA) when not selected. The Clav/PxPA outputs must not be tri-stated. Therefore, some some PHYs must be configured for a multi-PHY bus with direct status indication. The user should pull down the Rx and Tx address bus of the PHY, configure the device to tri-state its outputs when not selected, configure the PHY address to zero, and configure a direct-status Clav indication. The last step (direct-status) may or may not be required because the address lines are static. Consult the PHY data sheet. The Clav should be always active, and the PHY is selected for Rx or Tx cell transfer by assertion of the respective Enb signal.

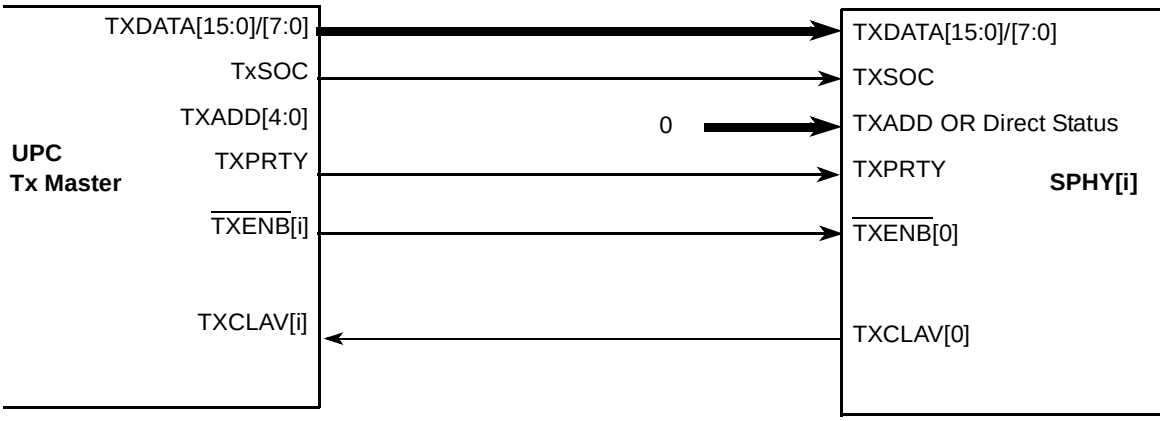

Figure 33-6. UPC with Tx UTOPIA SPHY System

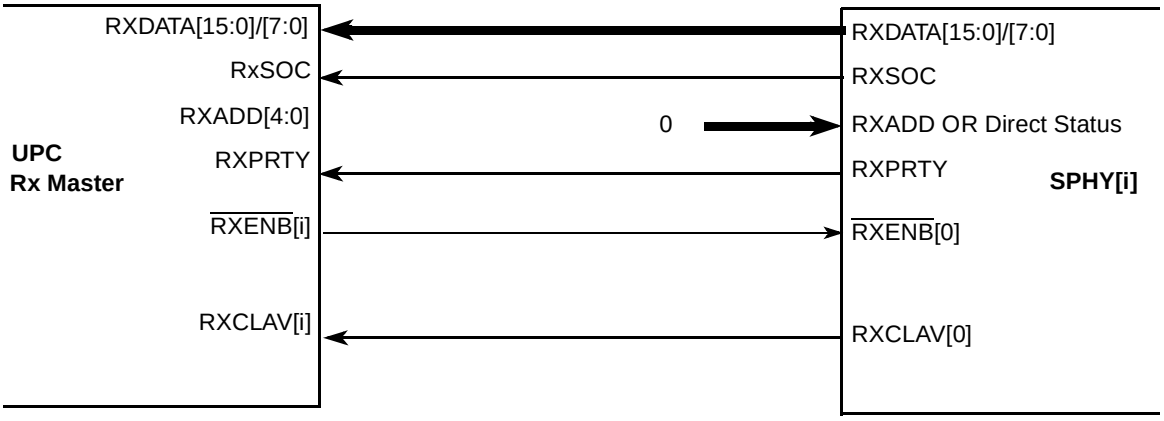

Figure 33-7. UPC with Rx UTOPIA SPHY System

33.3.4.3 Device with Direct Status Polling Indication

The UPC supports direct status polling with simple external glue logic. The user can route a single device with up to 4 internal ports and direct status polling indication to 4 UCCs and handle each port as a SPHY logical device. The respective Rx and Tx Enb signals must be ANDed on the PCB to form a single logical Enb signal that is connected to the device.

33.3.5 SPHY Modes of Operation

The user can choose between a single-port or multi-port setting for a SPHY device. This mode affects how the user configures the transmit shaping for this device.

Table 33-1. SPHY related Modes

Field Setting	Description	Meaning
UPDC[TMP]	0: Transmit Single PHY	A dedicated FIFO is assigned for the device routed to UCC
UPDC[TSP]	0: Single Port PHY 1: Multi Ports PHY	Single Port: The QUICC Engine block de-queues FIFO as a leaky bucket at internal rate. Single Scheduler for all channels. Multi Ports: The QUICC Engine block en-queues FIFO from multiple leaky buckets of different rates. Each port has its own scheduler. The FIFO is de-queued at the PHY request rate, so this mode can be considered as PHY's FIFO Full mode.
UPDC[RMP]	0: Receive Single PHY	The PHY is polled using an always-valid Clav/PRPA or a direct status Clav/ DRPA
UPDC[TB2B]	0: Switch to the next UCC in cyclic order. 1: Attempt to transmit in B2B	TB2B should be set for a SPHY with a rate higher then 50% of the bus bandwidth. If TSP=0, A B2B is conditional of a positive credit; if TSP=1, a B2B transmit is attempted as long as the PHY request data.

Table 33-1. SPHY related Modes (continued)

Field Setting	Description	Meaning
UPDC[RB2B]	0: Switch to the next Device in cyclic order. 1: Attempt B2B receive	RB2B should be set for a SPHY with a high bit rate in order to prevent PHY overrun.
UPDC[TPM]	1: Round robin (Fair) selection among pending qualified ports	Recommended if UPUC[TSP]=1

33.3.5.1 Single Port

In Single-Port mode, the PHY is configured through port-0, and it must be enabled in the port enable register. The PHY has a single internal rate which should be set to the required transmit rate, and this controls the actual transmit rate. The UPC will attempt to transmit a cell/packet on each expiration of the internal rate counter, and if a time lag has been accumulated it will attempt to transmit cells at a faster rate until the time lag has been compensated for. In ATM protocol, as a single PHY there is a single APC (multi-priority) transmit scheduling table for all the channels of this PHY.

This mode is recommended when the line rate exceeds the required transmit rate, as it provides the least jitter on inter-cell/packet arrival time.

33.3.5.2 Multiple Port

In Multi-Port mode, the PHY is represented by any number of ports (0-31), by enabling them in the respective port-enable register. Each port is a logical transmit end-point, with an internal rate and scheduler. Some users may want to direct traffic of different QOS and origin to different ports. This mode is recommended when channels with similar QOS are bundled together, especially if the channels in each bundle have the same order bit-rate, but channels of different bundles have very high bit rate ratios.

33.3.6 Loop-Back Mode

The UPC supports loop-back mode. In this mode, the Rx and Tx UTOPIA signals are cross-connected internally. Output pins are driven; input pins are ignored.

In loop-back mode, the transmitter and receiver must operate in complementary modes. If the transmitter is master, the receiver is slave and vice versa.

Device1 has to be configured as the Tx or Rx slave, and can be routed to any one of the 4 UCCs. On the opposite direction, the master can be configured to work with more than one device. Each device on the master side can be routed to any of the 4 UCCs. In Loop-Back mode the devices Enb outputs on the master side are shorted to device1 Enb input at the slave side. Device1 Clav/PxPA outputs on the slave side are split, and they become the input to all devices on the master side. Note that only one slave address can be configured in the MPHY system. However, there is a restriction. When Loop-back mode is set and the slave is configured to MPHY mode, all UCCs on the master side must also be configured to MPHY mode. This restriction is due to the multiplexing of the Clav/PxPA signals between the master and the slave (see Figure 33-8, Figure 33-9, Figure 33-10, and Figure 33-11). If the slave is configured to SPHY mode, there

is no similar restriction on the master side, and UCCs on the master side can be configured to either MPHY or SPHY mode.

The master can be configured to work in 6-bit addressing mode. The extra msb address signal is unconnected in loop-back mode, and the slave responds to an address driven on ADDR[4:0] only. The slave address should be between 0–15 if extended address mode is selected in a loop-back system.

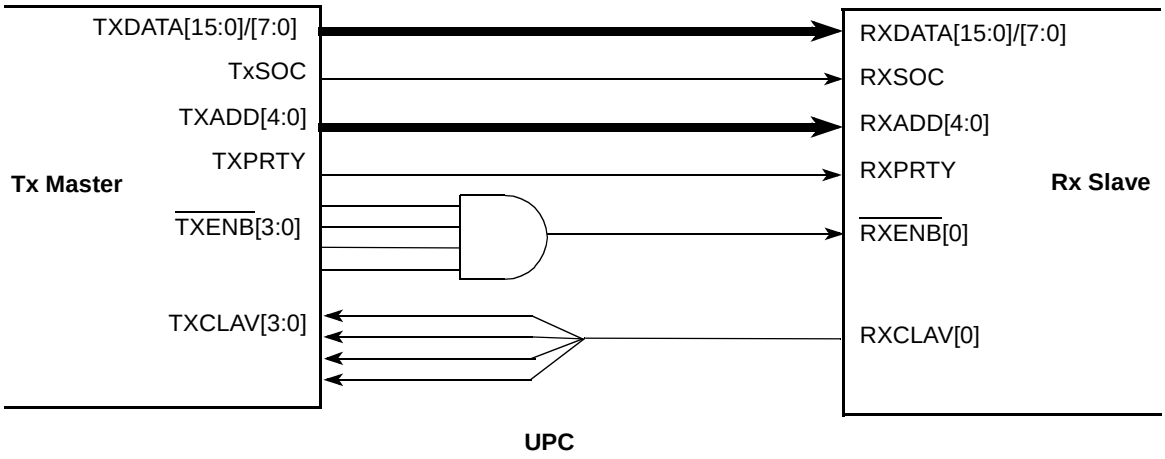

Figure 33-8. UTOPIA Tx Master to Rx Slave Internal Loop-Back System

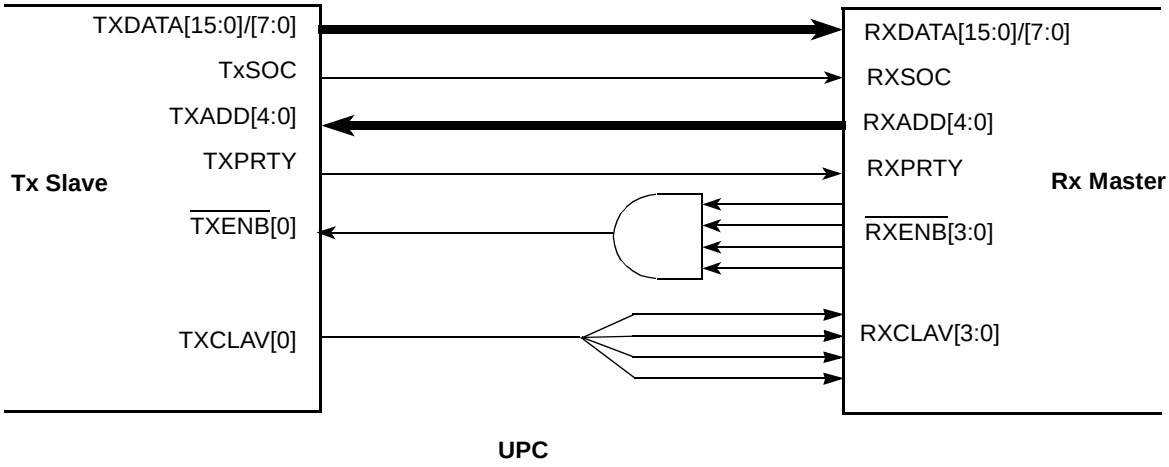

Figure 33-9. UTOPIA Tx Slave to Rx Master Internal Loop-Back System

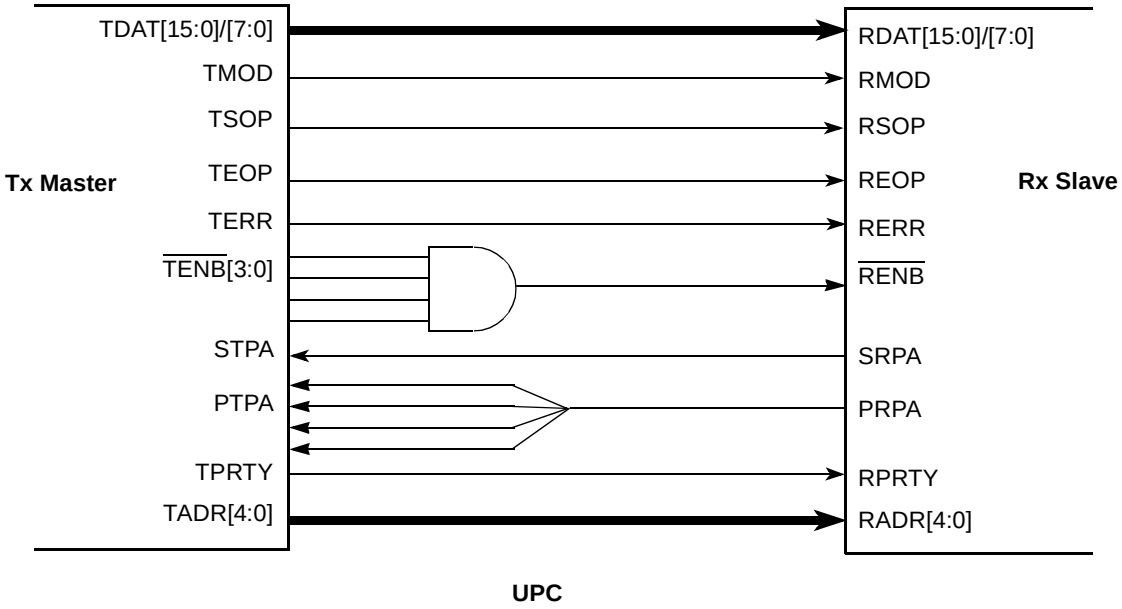

Figure 33-10. POS Tx Master to Rx Slave Internal Loop-Back System

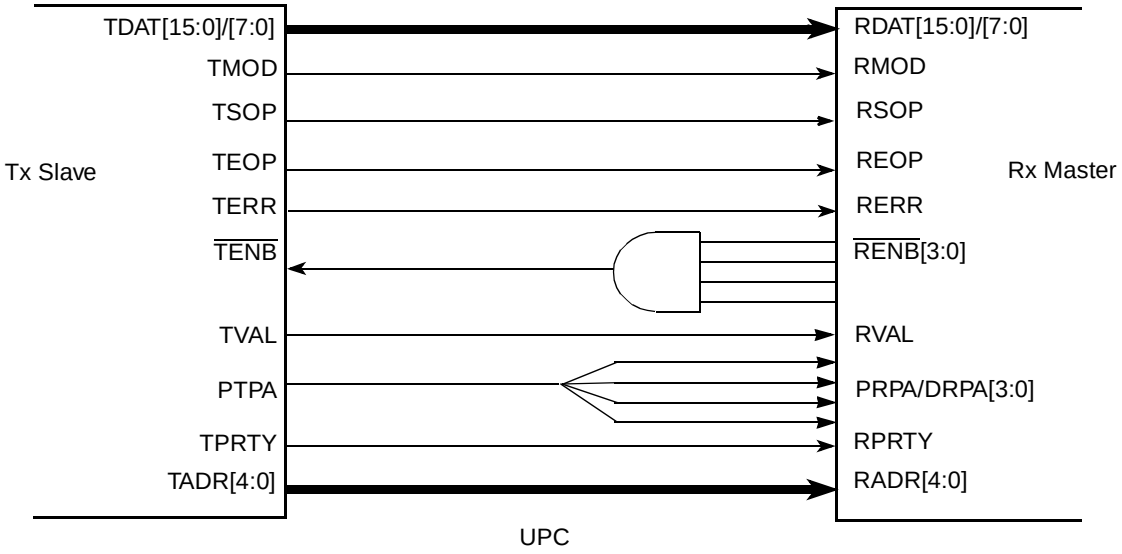

Figure 33-11. POS Tx Slave to Rx Master Internal Loop-Back System

33.3.6.1 Loop-Back Mode Programming Model Example

The example discussed in this section consists of a system with a Tx Master connected to three devices (1, 2, 3) and an Rx slave on device1. The Tx master devices 1 and 2 are routed to UCC1, and device 3 is routed to UCC2. The Rx slave device1 is routed to UCC2. This system can check several features of the UPC. If an Rx slave device is configured as an SPHY, it can respond to all addresses and simulate a full MPHY system. Therefore, configuring Tx Device 3 as a fast SPHY and devices 1 and 2 as MPHY allows features such as IR and B2B to be examined. The programing model for the system is shown in Table 33-2.

Table 33-2. Configurations for Loop-Back Example

Configuration	Bit Value	Description
UPC configurations	UPGCR[DIAG] = 01	Loop-Back mode
	UPGCR[ADDR] = 0	Default address multiplexing
	UPGCR[TMS] = 0	Tx master mode
	UPGCR[RMS] = 1	Rx slave mode
	UPLPA[Tx LAST PHY/PHY ID] = 31	Last PHY for MPHY Tx devices (for example)
UCC configurations	UPUC1[TMP] = 1	MPHY mode
	UPUC2 [TMP] = 0	SPHY mode
	UPUC2[TMP] = 0	SPHY mode
	UPUC2[TB2B] = 1	UCC2 Tx B2B enabled
Device Configurations	UPDC1[Device Tx Routing] = 00	Route Tx device 1 to UCC1
	UPDC2 [Device Tx Routing] = 00	Route Tx device 2 to UCC1
	UPDC3[Device Tx Routing] = 01	Route Tx device 3 to UCC2
	UPDC1[Device Rx Routing] = 01	Route Rx device 1 to UCC3

33.4 External Signal Descriptions

NOTE: Slave Mode Signal Naming

Users familiar with the UTOPIA interface of the CPM in MPC82xx and MPC85xx should know that the external signal naming convention of the QUICC Engine block follows the UTOPIA standard and therefore have different naming in master and in slave modes. The naming convention in the CPM retains the master mode signal naming for slave mode. For example, the QUICC Engine block transmit SOC in slave mode is named RSOC but the CPM transmit SOC in slave mode is named TSOC.

In the QUICC Engine block, users should connect signals between master and slave by name. In the preceding example, the user should connect the master TSOC with the QUICC Engine block TSOC.

33.4.1 Overview

This section describes the UPC external signals. The description is divided into UTOPIA mode and POS mode signal groups. There are several bus configurations, depending on the implemented protocol (UTOPIA/POS), the polling method, number of devices in the UTOPIA/POS configuration, and the data bus width. For example, one UTOPIA device configuration requires a total of 36 I/O ports for 8-bit mode and 52 bits in 16-bit mode. Multi devices configuration requires additional 4 control signals (Clav+Enb, for Tx and Rx) for each additional device. 6-bit addressing MPHY mode requires a total of 50 I/O ports for 8-bit mode and 66 bits in 16-bit mode. Table 33-3 summarizes all possible I/O pins assignments combinations.

Table 33-3. UCC UTOPIA/POS I/O Pin Count

	UTOPIA 31 PHYs	UTOPIA 124 PHYs	POS 31 PHYs	POS 124 PHYs	UTOPIA 128 PHYs
8 bit Data	16	16	16	16	16
16 bit Data	32	32	32	32	32
parity	2	2	2	2	2
Address	10	10	10	10	12
Clav/xPTA	2	8	4[1]	10	8
Clock	2	2	2	2	2
Framing	2	2	8[2]	8	2
Enable	2	8	2[3]	8	8
Total for 8 bit	36	48	42[4]	54	50
Total for 16 bit	52	64	60	72	66

1 PTPA, STPA, RVAL, PRPA
2 TSOP, TEOP, RSOP, REOP, TMOD, RMOD, TERR, RERR
3 TENB, RENB
4 Non standard solution. RMOD, TMOD not needed

33.4.1.1 UTOPIA Interface Master Mode

UTOPIA master signals are shown in Figure 33-12.

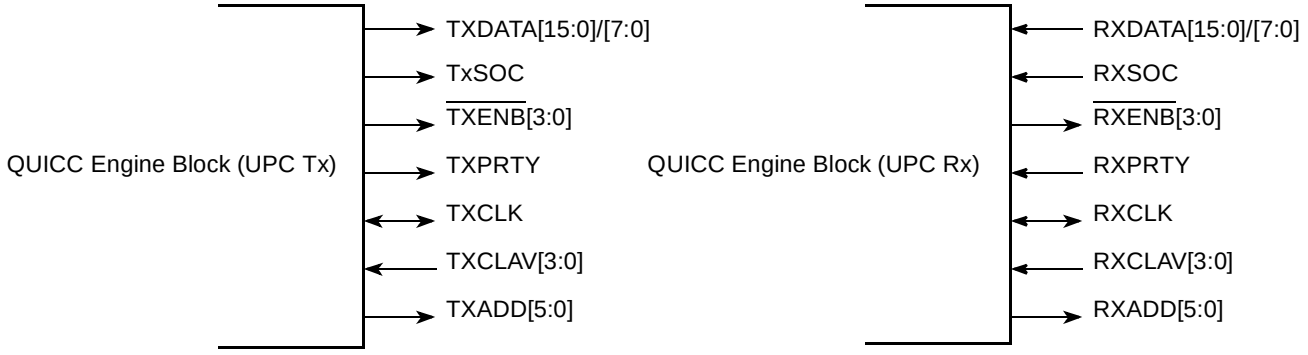

Figure 33-12. UTOPIA Master Mode Signals

Table 33-4 lists the I/O pins in UTOPIA Master mode.

Table 33-4. UTOPIA Master mode Signal Properties

Name	Function	I/O	Tri-State[1]	Pull[2]
TxDATA[15-0]/[7-0]	Transmit data from link layer to PHY	O	Y	Y
TxSOC	Transmit start of cell	O	Y	Y

Table 33-4. UTOPIA Master mode Signal Properties (continued)

Name	Function	I/O	Tri-State[1]	Pull[2]
$\overline{\text{TxENB}}$[3-0]	Transmit enable	O	N	N
TxCLAV[3-0]	Transmit cell available	I		Down
TxPRTY	Transmit parity	O	Y	Y
TxCLK	Transmit clock (up to 50MHz)	I		
TxCLKO	Transmit clock out (up to 50MHz). Output to PHY.	O	N	N
TxADD[5-0]	Transmit address, TxADD[5] is the extra msb (TxAddr[4] for device B)	O	N	N
RxDATA[15-0]/[7-0]	Receive data from PHY to link layer	I		Y
RxSOC	Receive start of cell	I		Down
$\overline{\text{RxENB}}$[3-0]	Receive enable	O	N	N
RxCLAV[3-0]	Receive cell available	I		Down
RxPRTY	Receive parity	I		Y
RxCLK	Receive clock (up to 50MHz)	I/O	N	N
RxADD[5-0]	Receive address, RxADD[5] is the extra msb (RxAddr[4] for device B)	O	N	N

1 Outputs tri-State by UPC as UL2 Master.

2 Pull resistors are required.

33.4.1.2 UTOPIA Interface Slave Mode

UTOPIA slave signals are shown in Figure 33-13.

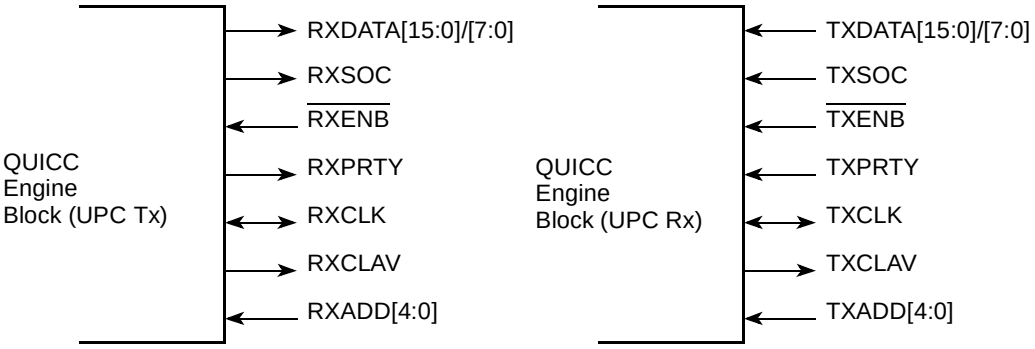

Figure 33-13. UTOPIA Slave Mode Signals

Table 33-5 lists the I/O pins in UTOPIA Slave mode.

Table 33-5. UTOPIA Slave Mode Signal Properties

Name	Function	I/O	Tri-State[1]
TxDATA[15–0]/ [7–0]	Transmit data from PHY to link layer	I	
TxSOC	Transmit start of cell	I	
$\overline{\text{TxENB}}$[0]	Transmit enable	I	
TxCLAV[0]	Transmit cell available	O	Y
TxPRTY	Transmit parity	I	
TxCLK	Transmit clock at 50MHz	I	
TxCLKO	Transmit clock at 50MHz	O	N
TxADD[4–0]	Transmit address	I	
RxDATA[15–0]/ [7–0]	Receive data from link layer to PHY	O	Y
RxSOC	Receive start of cell	O	Y
$\overline{\text{RxENB}}$[0]	Receive enable	I	
RxCLAV[0]	Receive cell available	O	Y
RxPRTY	Receive parity	O	Y
RxCLK	Receive clock at 50MHz	I/O	N
RxADD[4–0]	Receive address	I	

1 Outputs tri-State by UPC as UL2 Slave.

33.4.1.3 POS Interface Master Mode

POS master signals are shown in Figure 33-14.

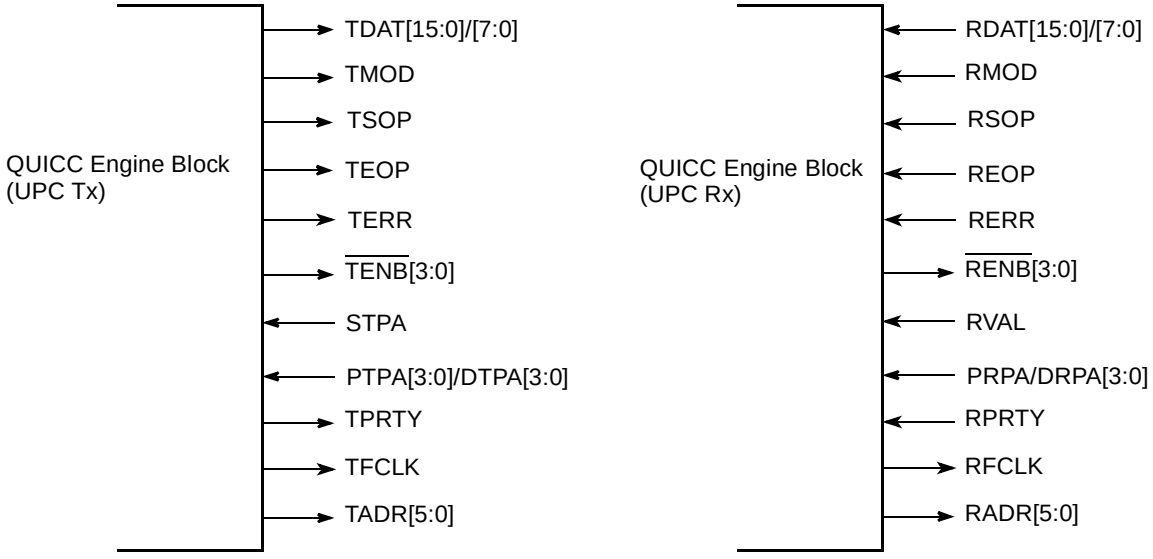

Figure 33-14. POS Master Mode Signals

Table 33-6 lists the I/O pins in POS Master mode.

Table 33-6. POS Master mode Signal Properties

Name	Function	I/O	Tri-State[1]	Pull[2]
TDAT[15:0]/[7:0]	Transmit data from link layer to PHY	O	Y	Y
TMOD	Transmit word modulo	O	Y	Down
TSOP	Transmit start of packet	O	Y	Down
TEOP	Transmit end of packet	O	Y	Down
TERR	Transmit error	O	Y	Down
$\overline{\text{TENB}}$[3:0]	Transmit multi-PHY write enable	O	N	N
STPA	Transmit selected PHY packet available	I		Down
PTPA/DTPA[3:0]	MPHY Transmit polled PHY packet available SPHY Transmit direct PHY packet available	I		Down
TPRTY	Transmit parity	O	Y	Y
TFCLK	Transmit clock from link layer to PHY at 50MHz	I		N
TFCLKO	Transmit clock from link layer to PHY at 50MHz	O	N	N
TADR[5:0]	Transmit address, TADR[5] is the extra msb (TADR[4] for device B)	O	N	N
RDAT[15:0]/[7:0]	Receive data from PHY to link layer	I		Y
RMOD	Receive word modulo	I		Down
RSOP	Receive start of packet	I		Down
REOP	Receive end of packet	I		Down
RERR	Receive error	I		Down
$\overline{\text{RENB}}$[3:0]	Receive multi-PHY read enable	O	N	N
RVAL	Receive data valid	I		Down
PRPA/DRPA[3:0]	MPHY Receive polled PHY packet available SPHY Receive direct PHY packet available	I		Down
RPRTY	Receive parity	I		Y
RFCLK	Receive clock from link layer to PHY at 50MHz	O	N	N
RADR[5:0]	Receive address, RADR[5] is the extra msb (RADR[4] for device B)	O	N	N

1 Outputs tri-State by UPC as POS Master

2 Pull resistors are required.

33.4.1.4 POS Interface Slave Mode

POS slave signals are shown in Figure 33-15.

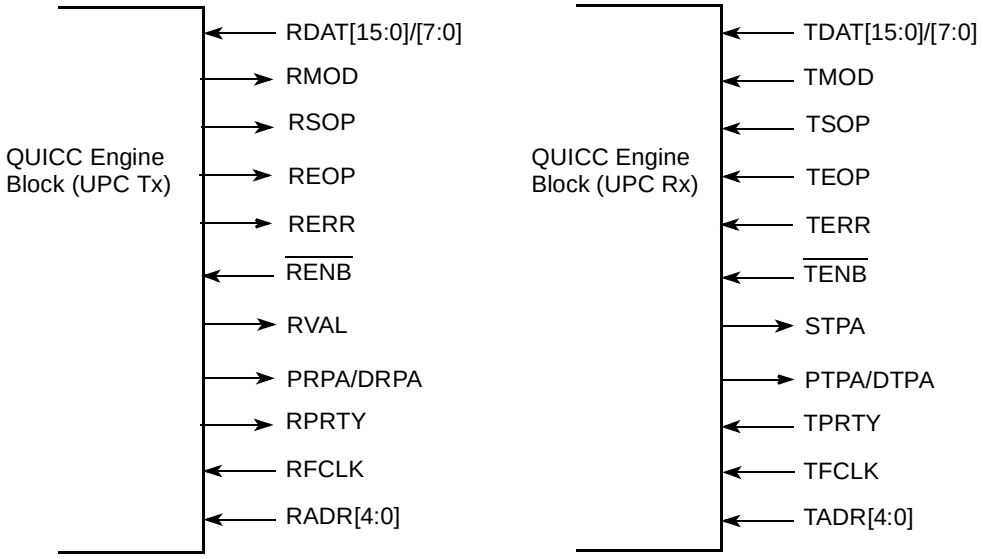

Figure 33-15. POS Slave Mode Signals

Table 33-7 lists the I/O pins in POS Slave mode.

Table 33-7. POS Slave mode Signal Properties

Name	Function	I/O	Tri State[1]
RDAT[15:0]/[7:0]	Receive data from link layer to PHY	O	Y
RMOD	Receive word modulo	O	Y
RSOP	Receive start of packet	O	Y

Field: R																
W																
Reset	0000_0000															

Figure 33-16. UPC General Configuration Register (UPGCR)

The UPGCR is an 8 bit read/write register. Table 33-9 describes the UPGCR fields

Table 33-9. UPGCR Register Field Descriptions

Bits	Name	Description
0	Protocol	0 UL2 1 PL2
1	TMS	Transmit master/slave mode 0 Transmit master mode is selected. 1 Transmit slave mode is selected.
2	RMS	Receive master/slave mode 0 Receive master mode is selected. 1 Receive slave mode is selected.
3	ADDR	Master MPHY Addr multiplexing: (Ignored for slave) 0 5-bit addressing MPHY device operation (default). 31 addresses with separate Clav/Enb for each device. Parallel polling in multi device system. 1 6-bit addressing MPHY device operation. Two 16-port physical devices (A,B) multiplexed on each Clav/Enb pairs for 32 addresses per Clav/Enb. Parallel polling among 4 pairs in multi device system.
4-6	Reserved	Must be cleared.
7	DIAG[1]	Diagnostic mode 0 Normal mode 1 Loop-back mode In Loop-back, UTOPIA/POS Rx and Tx signals are shorted internally. Output pins are driven, input pins are ignored.
8-31	-	Not in use

1 Note on backwards compatibility: the programing model regarding the LPB mode have changed, instead of programing the GUMR[DIAG] as in the 8260, it is done in through UPGCR[DIAG].

33.6.2 UPC Last PHY Address Register (UPLPA)

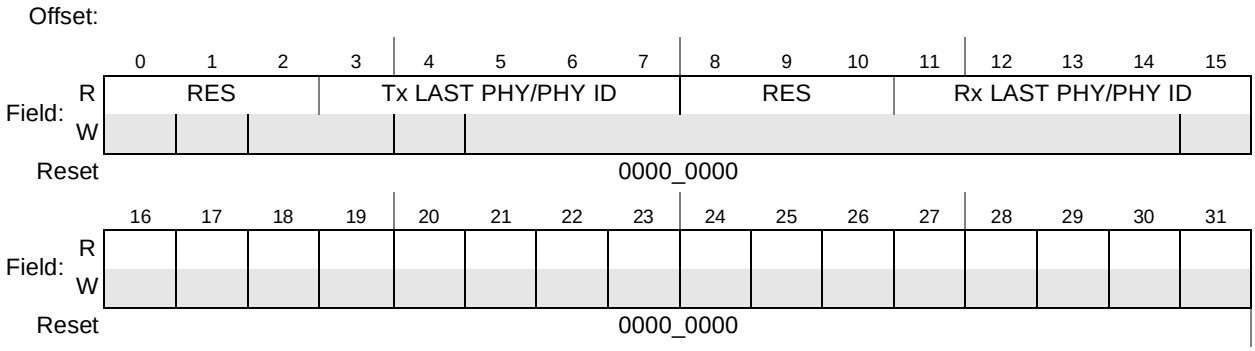

Figure 33-17. UPC Last PHY Address Register (UPLPA)

Table 33-10 describes the UPLPA fields.

Table 33-10. UPLPA Register Field Descriptions

Bits	Name	Description
0-2	—	Reserved, should be cleared.
3-7	Tx LAST PHY/PHY ID	Master mode: Tx Last PHY. This is the last polled PHY addr (MPHY Master mode only) 5 lsb. The interface polls all PHYs starting from PHY address 0 and ending with the PHY address specified in LAST PHY. (The number of active PHYs are LAST PHY+1). Default MPHY mode: Maximal value = 31 6-bit addressing MPHY mode: Maximal value = 15 (Addr[4] is not valid). Common value for device pairs A,B. Slave mode: Tx PHY address
8-10	—	Reserved, should be cleared.
11-15	Rx LAST PHY/PHY ID	Master mode: Rx Last PHY. This is the last polled PHY addr (MPHY Master mode only) 5 lsb. The interface polls all PHYs starting from PHY address 0 and ending with the PHY address specified in LAST PHY. (The number of active PHYs are LAST PHY+1). Default MPHY mode: Maximal value = 31 6-bit addressing MPHY mode: Maximal value = 15 (Addr[4] is not valid). Common value for device pairs A,B. Slave mode: Rx PHY address
16-31	—	Not in use

33.6.3 UPC HEC Register (UPHEC)

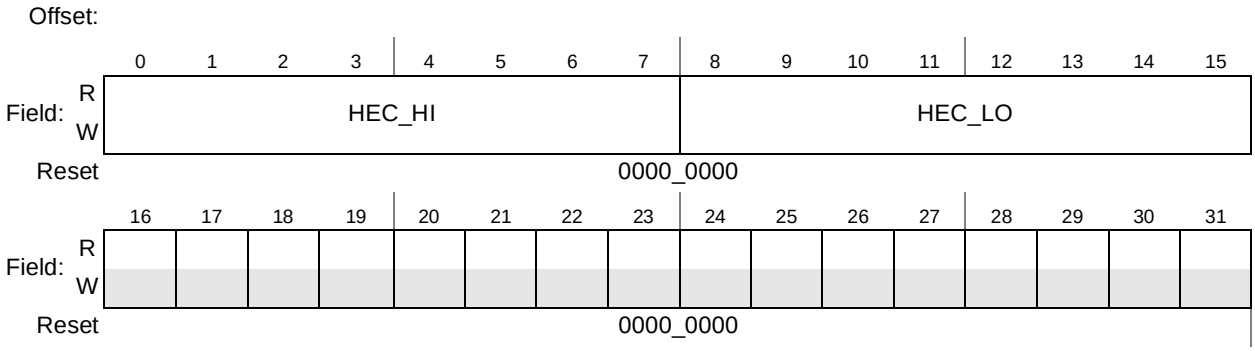

Figure 33-18. UPC HEC Register (UPHEC)

Table 33-11 describes the UPHEC fields.

Table 33-11. UPHEC Register Field Descriptions

Bits	Name	Description
0-7	HEC_HI	UTOPIA: For 8 bit UTOPIA, the value of this field is sent instead of the HEC on TxData[7:0]. For 16 bit UTOPIA, the value of this field is sent instead of the HEC on TxData[15:8]. Note: HEC_HI is a constant byte for the HEC. It does not generate the HEC; instead it only outputs this constant byte as a ‘placeholder’ for the HEC. This byte is then replaced by the ATM PHY with the actual value.
8-15	HEC_LO	For 8 bit UTOPIA this field is ignored. For 16 bit UTOPIA, the value of this field is sent with HEC_LO on TxData[7:0]. POS (Rx Master): segment size in bytes (must be an even number, greater than 8). Will attempt to switch to a different port after transfer of a segment with the specified size.
16-31	-	Not in use

33.6.4 UPC UCC Configuration Register (UPUC)

Figure 33-19. UPC UCC Configuration Register (UPUC)

Table 33-12 describes the UPUCx fields.

Table 33-12. UPUC Register Field Descriptions

Bits	Name [1]	Description
0, 8, 16, 24	TMP_x	Transmit Multiple PHY mode. This mode should be set when several devices or a device with several PHYs are routed to this UCC. UPC Tx Master mode: 0 SPHY mode: Transmit to SPHY device (Tx FIFO is attempted to be filled. Clav/PTA is always assumed valid[2], PHY address must be 0. No other device can be routed to the UCC specified in the routing field. 1 MPHY mode: Transmit to MPHY device/s UPC Tx Slave mode: 0 SPHY system (Output Clav is a direct status, do not tri-state outputs) 1 MPHY system (Output Clav is a response for polling, Tri-state outputs)
1, 9, 17, 25	TSP_x	Transmit Single PHY mode. This mode is valid only if TMP=0: 0 Single EP: Internal address of this PHY must be 0. As Master, the Internal rate pace the de-queuing of the FIFO. As slave, the internal rate enable the assertion of Clav when the FIFO is not empty. 1 Multi EP: Internally behaves as a multi-port PHY (multiple End Points): the Internal rate pace the request.rate for each EP. As master, FIFO is de-queued based on Clav status from the PHY. As slave, Clav reflect the FIFO condition (negated when FIFO is empty).
2, 10, 18, 26	$TB2B_x$	Transmit back to back (valid only in master mode). 0 Do not attempt Transmit B2B from this UCC. 1 Attempt Transmit B2B from this UCC. Can be used in order to enable a PHY back to back (FIFO emptying mode), priorities a group of MPHY devices on the UCC or to simulate Ethernet like operation in POS. See Section 33.7.2, “Transmit and Receive Priority among devices.”
3-7, 11-15, 19-23, 27-31	Reserved	Reserved, should be cleared.

[1] x is the UCC index. For UPC1, x=0-3 for UCC1,3,5,7. For UPC2, x=0-3 for UCC2,4,6,8 respectively.
[2] Either direct status or the address lines of the PHY are hard wired fixed to the PHY's address.

33.6.5 UPC Device X Configuration Register (UPDCx)

33.6.5.1 UPDCx in ATM Protocol

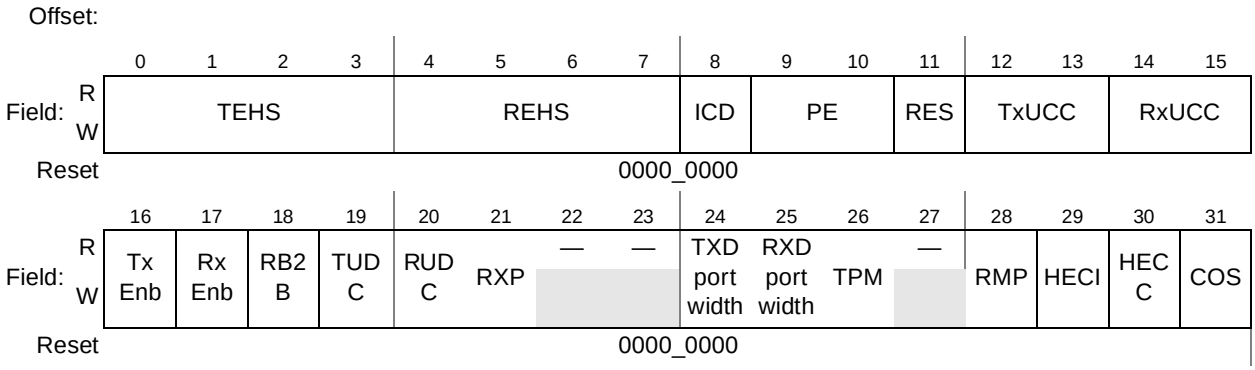

Figure 33-20. UPC Device X Configuration Register in ATM protocol (UPDCx)

Table 33-13 describes the UPDCx fields.

Table 33-13. UPDCx in ATM Protocol Field Descriptions

Bits	Name	Description
0-3	TEHS	Transmit extra header size. Used only in user-defined cell mode to hold the Tx user-defined cells' extra header size. Values between 0-11 are valid. TEHS = 0 generates 1 byte of extra header; TEHS = 11 generates 12 bytes of extra header.
4-7	REHS	Receive extra header size. Used only in user-defined cell mode to hold the Rx user-defined cells' extra header size. Values between 0–11 are valid. For REHS = 0, the receiver expects 1 byte of extra header; for REHS = 11, it expects 12 bytes of extra header.
8	ICD[1]	Idle cells discard 0 Discard idle cells (GFC, VPI, VCI, PTI =0). 1 Do not discard idle cells.
9-10	PE	Port enable 00 Master: UPER has no affect: All ports are enabled. Slave: UPER has no affect, port0 is enabled regardless of Phy address. 01 UPER masks only Rx 10 UPER masks only Tx 11 UPER masks both Rx and Tx
11	—	Reserved. Must be cleared
12-13	TxUCC	00 UCC1 (UPC1) or UCC2 (UPC2) 01 UCC3 (UPC1) or UCC4 (UPC2) 10 UCC5 (UPC1) or UCC6 (UPC2) 11 UCC7 (UPC1) or UCC8 (UPC2)

Table 33-13. UPDCx in ATM Protocol Field Descriptions (continued)

Bits	Name	Description
14-15	RxUCC	00 UCC1 (UPC1) or UCC2 (UPC2) 01 UCC3 (UPC1) or UCC4 (UPC2) 10 UCC5 (UPC1) or UCC6 (UPC2) 11 UCC7 (UPC1) or UCC8 (UPC2)
16	Tx Enb	0 Tx Disabled 1 Tx Enabled
17	Rx Enb	0 Rx Disabled 1 Rx Enabled
18	RB2B	Receive back to back (valid only in master mode). 0 Do not attempt Receive B2B from this device. 1 Attempt B2B receive from this device. Can be used in order to enable a PHY back to back on an SPHY, or to prioritize a device. See Section 33.7.2, “Transmit and Receive Priority among devices.”
19	TUDC	Transmit user-defined cells 0 Regular 53-byte cells. 1 User-defined cells.
20	RUDC	Receive user-defined cells 0 Regular 53-byte cells. 1 User-defined cells.
21	RXP	Receive parity check. 0 Check Rx parity line. 1 Do not check Rx parity line.
22–23	—	Reserved
24	TXD port width	Transmit data bus width Device/SPHY 0 8-bit data bus width 1 16-bit data bus width Note: For POS 16-bit must be used.
25	RXD port width	Receive data bus width Device/SPHY 0 8-bit data bus width 1 16-bit data bus width Note: For POS 16-bit must b used.
26	TPM	Tx Selection Priority Mode. This controls the priority by which PHYs are serviced. 0 Round Robin. After a PHY has been selected, the selection resumes from the next PHY. 1 Fixed. For each selection PHY0 has the highest priority and PHY31 the lowest priority. (The internal rate prevents starvation of high ID PHYs).
27	—	Reserved. Must be cleared
28	RMP	Receive Multiple PHY mode UPC Rx Master mode: 0 Receive from SPHY device (Clav/PTA is always assumed valid[2], PHY address must be 0) 1 Receive from MPHY device/s UPC Rx Slave mode: 0 SPHY system 1 MPHY system

Table 33-13. UPDCx in ATM Protocol Field Descriptions (continued)

Bits	Name	Description
29	HECI[3]	HEC included. Used in UDC mode only. 0 HEC octet is not included when UDC mode is enabled. 1 HEC octet is included when UDC mode is enabled.
30	HECC[4]	HEC Check 0 Do not check Rx HEC 1 Check Rx HEC
31	COS[5]	Coset mode on the HEC

1 Discard Rx Idle Cell

2 Either direct status or the address lines of the PHY are hard wired fixed to the PHY's address.

3 UDC HEC include (Rx and Tx)

4 HEC Check (HW HEC check)

5 Coset mode on the HEC (HW HEC XOR with 0x55)

33.6.5.2

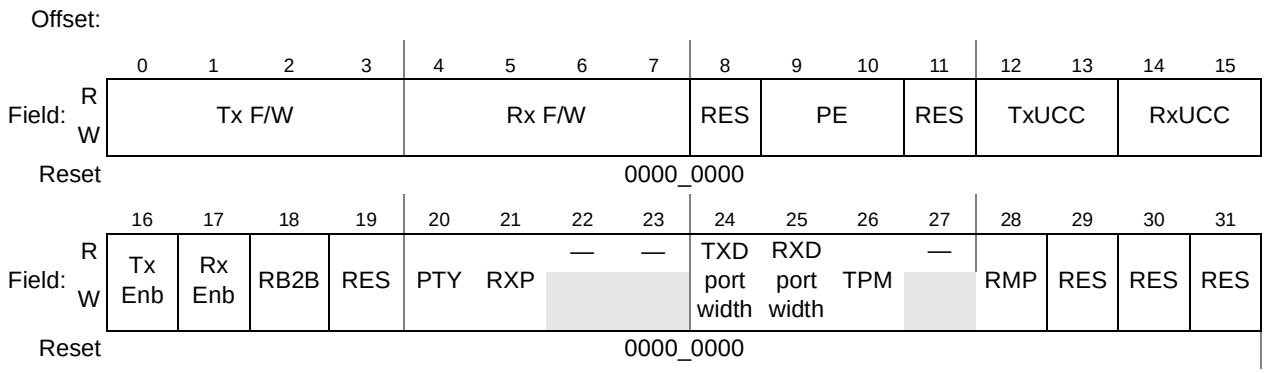

Figure 33-21. UPC Device X Configuration Register in POS protocol (UPDCx)

33.6.5.3 UPC Device X Internal Rate Configuration Register (UPRPx)

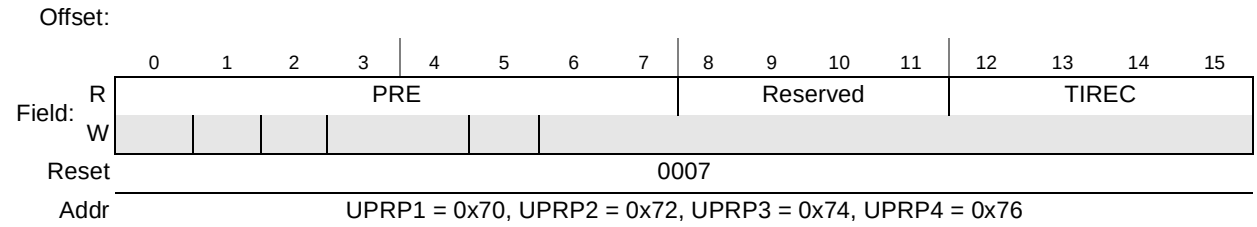

Figure 33-22. Device X Internal Rate Configuration Register (UPRPx)

Table 33-14 describes the UPRPx fields.

Table 33-14. UPRP Field Descriptions

Bits	Name	Description
0-7	PRE	Prescalar divider value. Prescalar divider value is PRE+1 00x: Divide by 1 0xFF: Divide by 256
8-11	Reserved	Must be cleared
12-15	TIREC	Transmit Internal/External Rate Expiration Counter for device X. Values: 0 - External Rate: Tranmsit rate is limited by Clav, polling and selection priorities. (Idle cells are discarded and not transmitted). 1- PPS mode. No burst and no underrun error indication. Recommended for POS Credit is not expired until the end of packet. Useful also for PON. 2-15 - Internal rate with burst and underrun indication. 7 - Default value (82xx internal rate compatible) This field sets the maximal allowed cell credit for the PHYs. An internal rate expiration counter holds the credit balance per PHY. It is incremented every time the internal rate expires. It is decremented every time a cell is transmitted to the PHY (including idle cells, which are not actively transmitted). While the credit is positive (non zero), the UPC will transmit cells to that PHY. When the credit reaches the value of the TIREC, a transmit underrun event is set in registers UPDEx.

33.6.6 UPC Device X Transmit Internal Rate Register (UPTIRRx)

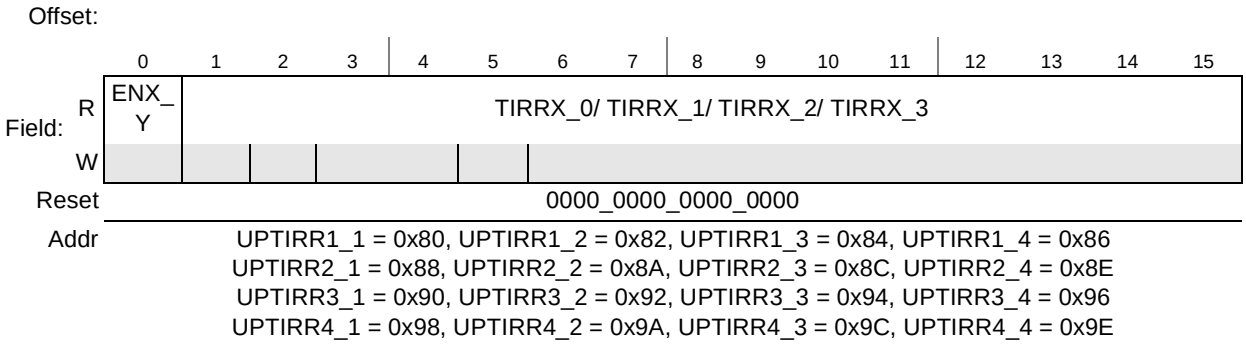

Figure 33-23. UPC Device X Transmit Internal Registers (UPTIRRx_y)

Table 33-15 describes the UPTIRRx fields

Table 33-15. UPTIRR Register Field Descriptions

Bits	Name	Description
0	ENX_Y	0: Device X, Sub Rate Divider is disabled 1: Device X, Sub Rate Divider is enabled
1-15	TIRRX_Y	Device X, Sub rate divider Y is prescaled clock divided by <TIRRX_Y>+1

33.6.7 UPC Device X Port Enable Register (UPERx)

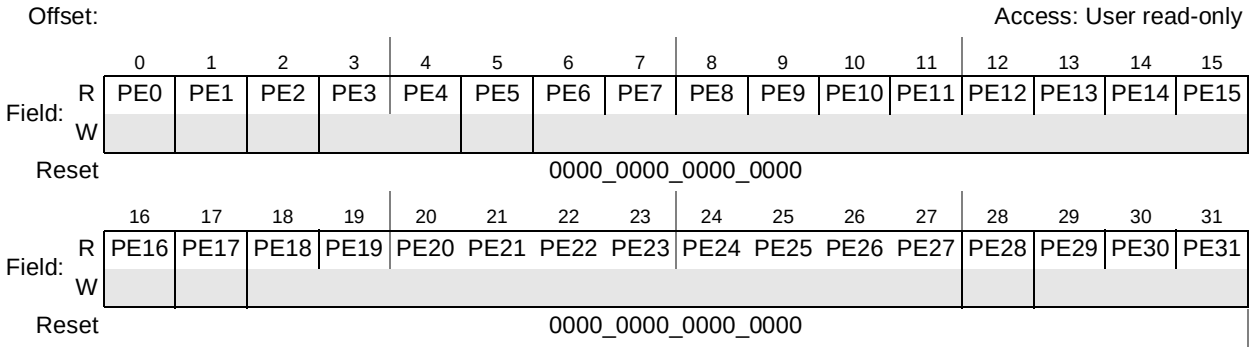

Figure 33-24. UPC Device X Port Enable Register (UPERx)

Table 33-16 describes UPERx fields.

Table 33-16. UPC Device X Port Enable Register (UPER)

Bits	Name	Description
0	PE0	Port0 Enable: The port enable option depends on UPDC[PE] field. 0 Port0 is disabled. Clav/PxPA from this port is internally masked. 1 Port is enabled. For slave single end-point (UPUC[TSP] = 0), the meaning of PE0 depends on UPDC[PE]: • UPDC[PE] = 0: Port0 is always enabled and this field have no impact. • UPDC[PE]! = 0: PE0 enable/disables the slave.
1-31	PE<n>	Port <n> Enable. The port enable option depends on the UPDC[PE] field. 0 Port is disabled. Clav/PxPA from this port is internally masked. 1 Port is enabled. For a slave, these fields have no impact except for multi end-point (UPUC[TSP]=1).

33.6.8 UPC Device X Transmit Rate Select Register (UPDRSx)

Table 33-19 describes UPDEx fields.

Table 33-19. UPDE Register Field Descriptions

Bits	Name	Description
<n>	EV<n>	Port <n> Event[1], as configured by UPGCR[Status] mode. The event is a sticky bit, set by the UPC and cleared when the host writes a value of 1 to it. Writing 0 has no effect. Transmit IR Underrun: The transmit internal rate expiration counter has reached the threshold set by TIREC. TIRU can be set only when using TIREC value larger then 1. 0 No underrun 1 Underrun occurred TVCPA: Transmit Valid Cell/Packet Available: 0 A valid TxClav or PTPA from Port <n> was not detected since the last time this bit was cleared. 1 A valid TxClav or PTPA from Port <n> was detected since the last time this bit was cleared. RVCPA: Receive Valid Cell/Packet Available: 0 A valid RxClav or PRPA from Port <n> was not detected since the last time this bit was cleared. 1 A valid RxClav or PRPA from Port <n> was detected since the last time this bit was cleared.

1 In 6-bit addressing MPHY mode, Ports 0 to 15 correspond to Ports of device A, Ports 16 to 31 correspond to Ports 0 to 15 of device B.

33.6.11 UPC POS STPA/DTPA Threshold Register (UPSTPA)

In POS Tx Master mode, the UPSTPA register holds the PHY FIFO threshold on which the STPA/DTPA signal is negated. At negation of STPA, the POS master continues the transfer of UPSTPA[STPAT] additional bytes or until last indication. If the last indication is reached, the master ends the packet normally. Otherwise, the master enters an idle state in which it parks the polling address on the current PHY ID and waits for assertion of the PTPA to reselect it. Note that on Rx, the POS master acts in the same manner, and on the negation of RVAL with no EOP, it enters an idle state in which it parks the polling address on the current PHY ID and waits for assertion of the PTPA to reselect it.

As slave, this register is not used. The STPA threshold of the UPC is 64 bytes. This is a number smaller than recommended for a PHY (256 bytes). However, since the VFIFO is usually set for at least 256 bytes, the total FIFO size of the UPC exceeds the recommendation.

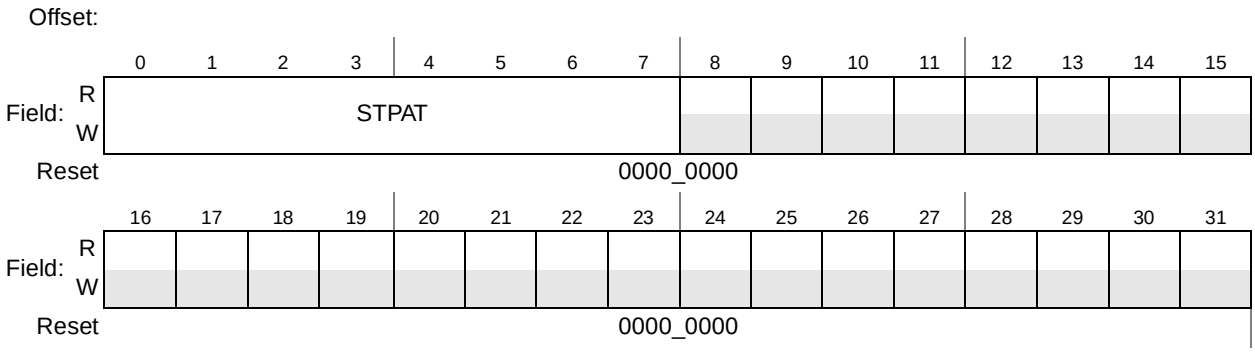

Figure 33-29. UPC STPA Threshold Register (UPSTPA)

Table 33-20 describes UPSTPA fields.

Table 33-20. UPSTPA Register Field Descriptions

Bits	Name	Description
0-7	STPAT	STPA (Selected Transmit Packet Available) Threshold Master mode only: When STPA is asserted, the selected PHY can receive at least <STPAT>+1 bytes or EOP
8-31	—	Not in use

33.6.12 UCCx Event/Mask Registers (UCCEx, UCCMx)

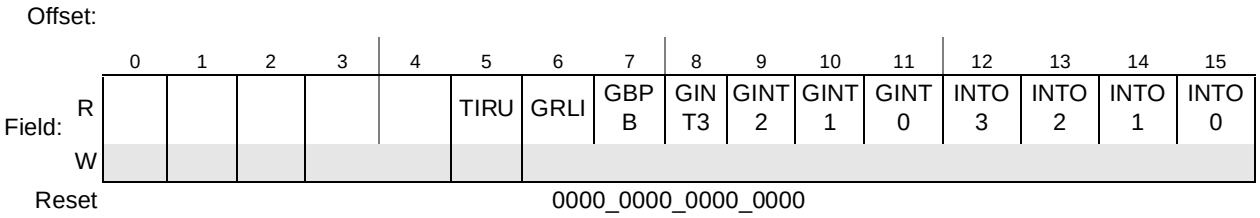

Figure 33-30. UCCEx/UCCMx in ATM protocol

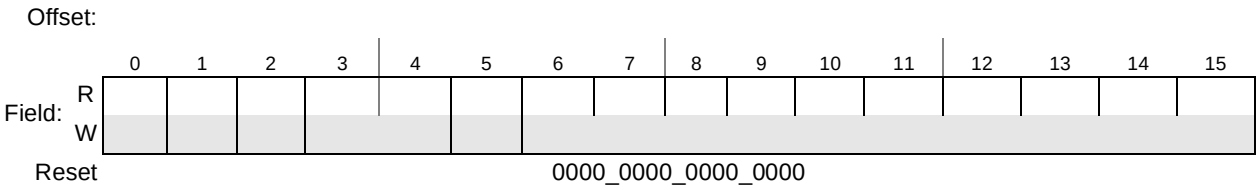

Figure 33-31. UCCEx/UCCMx in POS protocol

33.7 Functional Description

33.7.1 Receive Priority among pending PHYs

This section describes how priority selection is handled in the receiver. This feature is required in addition to policing to allocate enough BW to fast PHYs over slow PHYs.

Polling address generation is always done in a periodic order.

The user can assign a weight to different PHYs in the Rx scheduling to prevent overrun of fast PHYs by multiple slow PHYs.

Each PHY is assigned to one of 2 priority levels. A round robin selection scheme is used among all the pending PHYs of the same priority. The priority is selected by register UPDRPx. Set UPDRPx[RPP]=0 for fast PHYs, and UPDRPx[RPP]=1 for slow PHYs.

33.7.2 Transmit and Receive Priority among devices

Selection between devices is always in a round robin and cyclic order, with the exception of back to back selection in a UCC level. This mode can also be described as a PHY TxFIFO fill mode, RxFIFO empty mode.
The user can require that there will be an attempt to do a back to back transfer from a specified UCC. This is required for a master transmitting to a SPHY or a MPHY device with accumulated internal rate that exceeds 50% of the bus bandwidth. There will be an attempt to conduct a burst of cell transfers to the PHY as long as the expiration counter is positive. In such a case the PHY responds with Clav/PxPA and there is a ready cell or packet for the PHY (Tx). For Rx, a back to back transfer will be attempted as long as there is a valid Clav in the cycle following the cell transfer and there is room for one. In general, using this option gives a higher priority to the devices routed to the UCC for which the B2B option is set.

The user can use this option, to allow a fast PHY the required bandwidth. This is done by assigning the devices for which a back to back transfer is required for a UCC different from the rest of the devices, and assigning the back to back transfer option for this UCC. The BW per PHY will be limited by the PHY itself. Otherwise, there is only a round robin based selection among the devices.

33.8 Initialization

The following list is a set of recommendations for efficient management of the bus bandwidth (The UPC is designed to provide sufficient flexibility in allocation of bus bandwidth among the PHYs such that it does not become the bottleneck):

- In a system where one of the PHYs is allocated more then 50 percent of the bus, route that PHY to a separate device on a dedicated UCC in SPHY mode, and set the back to back transfer option for that device. The other PHYs should be routed to other UCCs.
- In a system with one or two fast PHYs (single PHY devices) it is recommended to route each one to a different UCC as SPHY to optimize the use of the transmit FIFOs (each SPHY has a dedicated transmit FIFO). Use the MPHY device option only when assigning more than two PHYs. The reason is that at a given time the FIFO can hold a maximum number of cells equal to the number of PHYs routed to it. Use the Tx internal rate and transmit the back to back transfer option to control the actual rate for both PHYs.
- In general, design the system so that PHYs with slow rates are sharing a device, fast PHYs are assigned to a dedicated FIFO (SPHY mode).
- In POS level 2, it is recommended to use an IR mechanism if the packet size is fixed (cell like packets). That can help managing the bus utilization and it allows transmit underrun errors to be reported. In MPHY mode, set to ER-like mode (UPRP[TIREC]=0) if the packet size can be larger or is variable (max value expiration counter is 1) in order to limit a PHYs credit to only one packet (avoid back to back packet transfers).
- In POS level 2, it is recommended to use B2B option on the transmitter for SPHY Ethernet like devices. For SPHY ATM like devices, use the IR mechanism in the same way as for UL2.

33.9 Glossary[1]

- *Device*. A group of PHYs or ports (could be also a single PHY) controlled by common control signal pair (xADDR[5], xCLAV/PxPA and xEnb).
- *Expiration counter*. Holds the state of the jitter buffer per PHY (counts the credit for a PHY). This counter controls the transmit shaping. It must be positive to fetch a cell/packet to the transmit queue. A PHY CLAV/xPTA is qualified only when the expiration counter of the PHY is positive. It is incremented on each expiration of the matching internal rate timer while there is a valid request from the PHY, and it is decremented each time a cell/packet is dequeued. An overflow of the counter causes a Transmit Internal Rate Underrun event to be generated.
- Extended address. A 6-bit xADDR master bus that can be connected to standard 5 bit xADDR slave bus. Up to 4 devices use xADDR[4] as the most significant address line, and another 4 devices use xADDR[5] as the most significant address line (ADDR[MSB]). This option is used for 128 PHY addresses (8 devices of 16 PHYs each).
- *Interleaving*. The term used for handling segments of different packets in sequence.
- *Internal rate*. The scheduling of transmit request per PHY. Shapes traffic by allocating a maximal bus bandwidth per PHY. This is the lowest level of traffic shaping.
- *Internal rate underrun*. An underrun event of a conceptual transmit jitter buffer. This event is a mismatch of up to 16 cells/packets[2] over any interval between the number of PHY transmit requests (which are polled at the internal rate) and the actual number of transmitted cells/packets (per PHY). See also Expiration Counter.
- *Multi-Devic*e. Multiple devices on the bus controlled by separate Clav/Enb signals and optionally by a separate xADDR[MSB] (see Extended address).
- *PHY*. A physical bus endpoint, usually with a line connection. A PHY can be represented by several ports, for example in ADSL fast and interleaved paths. The UPC does not distinguish between a PHY and a port.
- *Polling*. The mechanism that allows the master to poll the PHYs to know if there is a cell/packet available for Rx or if the PHY can accept another cell/packet for Tx.
- *Port*. A logical bus endpoint, which has a unique PHY address (see also PHY)
- *Rx*. Receive operation, master transfer cell/packet from the PHY.
- *Routing*. Usually the assignment of devices to UCCs. UPC1 Can be routed to UCC1, UCC3, UCC5, UCC7. UPC2 can be routed to UCC2, UCC4, UCC6, UCC8.
- *Segment*. Part of a packet, usually with fixed size unless it contains the end of the packet.
- *Segmentation*. The process of breaking up the transfer of packets to segments. To optimize for bus performance packets are not transferred continuosuly from start to end, but in segments.Segment: Part of a packet, usually with fixed size unless it contains the end of the packet.
- *Selection*. The mechanism which selects a specific PHY (from those that were successfully polled) for Tx or Rx.
- *Single PHY (SPHY)*. A device with a single PHY (and a single port). In this mode it is assigned a dedicated FIFO (recommended for fast PHYs - e.g. an uplink PHY).

1.Applicable to UTOPIA and POS-PHY Level 2.

2.Could be less then 16, the size of the jitter window is configurable.

Sub rate counter - The mechanism to pace the Internal Rate. Each device has 4 Transmit Internal rate timers (The UPC support a total of 16 different internal rates). Each PHY can use a different timer.

Switching: The process of de-selecting and re-selecting PHYs for segmentation.

Tx - Transmit operation, master transfer cell/packet to the PHY.

UCC - Unified Communication Controller, which defines the protocol and control the data and status FIFOs of the UPC. The UPC can be connected to up to 4 UCCs.

Chapter 34
Multi-Channel Controller (MCC)

34.1 Introduction

The multi-channel controller (MCC) supports up to 256 separate time-division serial channels. It is paired with a serial interface (SI), allowing the MCC to communicate over any of the SI's 8 time-division multiplexed streams (TDM).

Proper programming of the SI and SIRAM is necessary for routing the timeslots within a TDM stream to the appropriate MCC channel at the desired time. Users should be familiar with programming the SI and parallel I/O ports before proceeding.

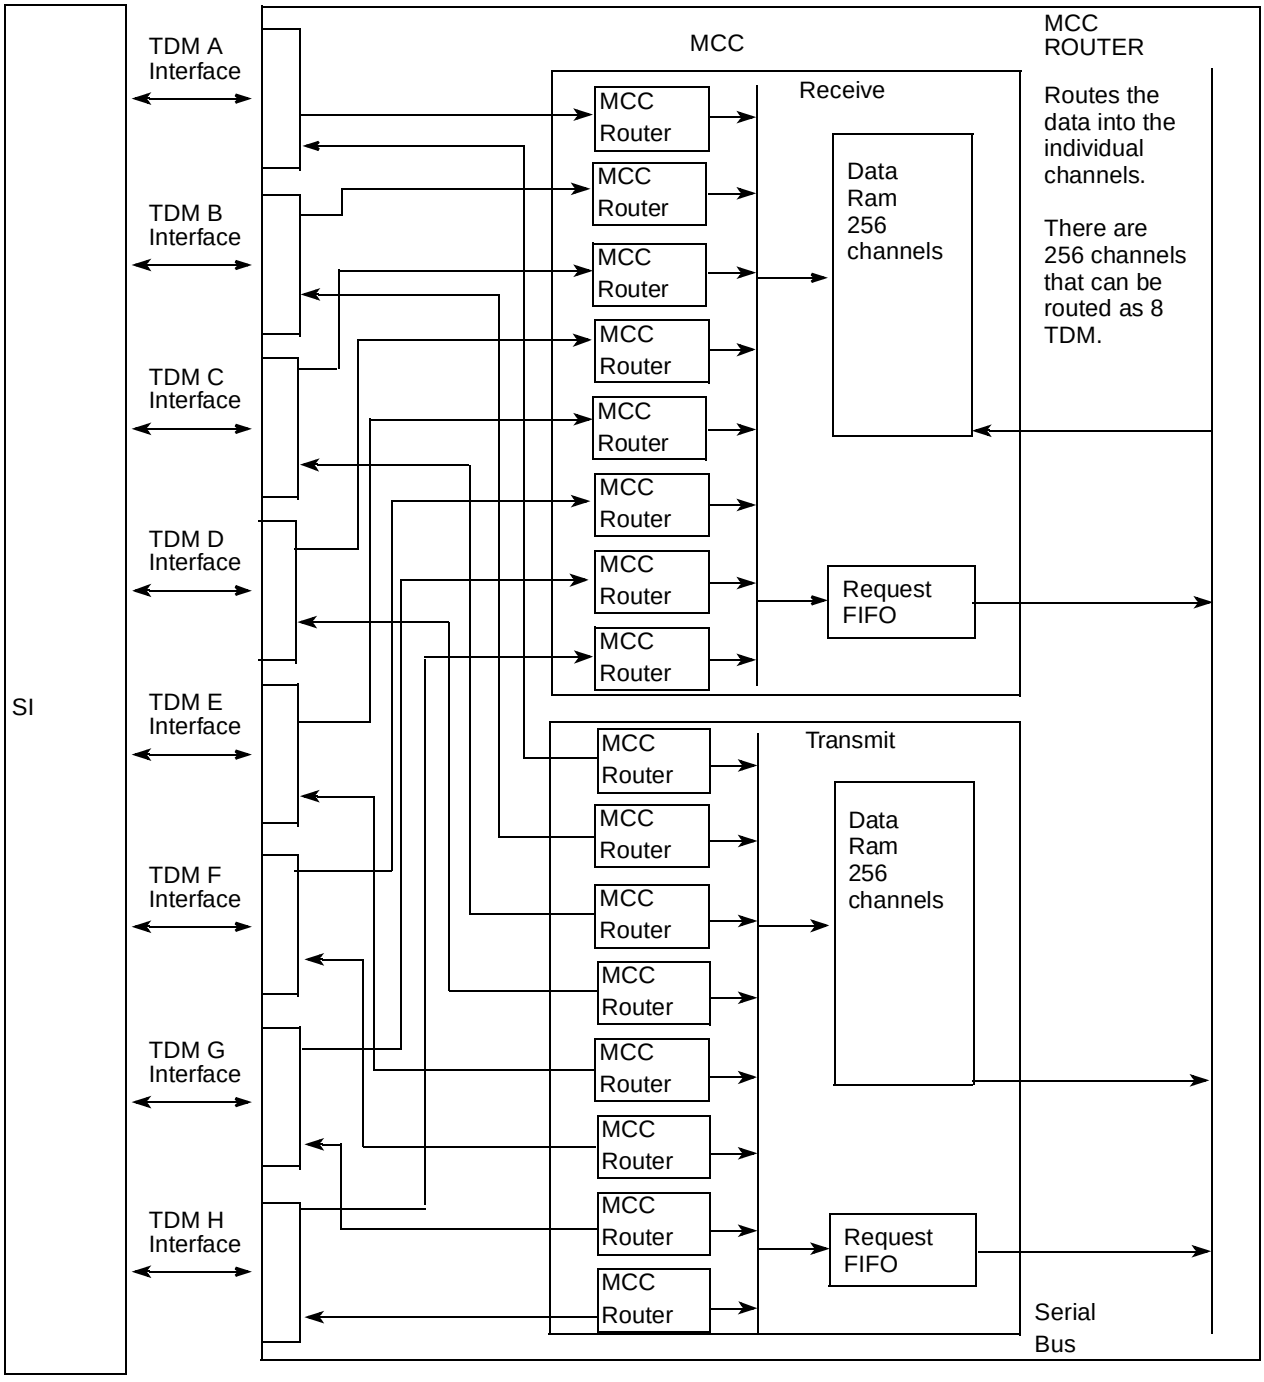

Figure 34-1. MCC Block Diagram

34.1.1 Features

- Supports up to eight TDM lines.
- Up to 256 independent communication channels (up to 8 E1).
- Up to 256 independent communication channels on a single link.

- Independent mapping for receive/transmit.
- Each TDM has 32 channel resolution packers.
- Supports HDLC, transparent, or SS7 protocols on a per-channel basis.
- Supports additional circuit emulation service functionality when used in conjunction with ATM AAL1.
- Supports interworking with AAL0.
- Up to 512 DMA channels (Rx/Tx) with independent buffer descriptor (BD) tables.
- Five interrupt circular tables with programmable size and overflow identification. One for transmit and four for receive.
- Efficient bus usage (no bus usage for inactive channel or for active channels with nothing to transmit).
- Efficient control of the interrupts to the core.
- Supports external BD tables.
- Uses on-chip multi-user RAM (MURAM) for parameter storage.
- Uses 64-bit data transactions for reading and writing data in BDs.
- Supports automatic routing in transparent mode using negative empty polarity.
- Supports inverted data per channel.
- Supports superchannel synchronization in transparent mode (slot synchronization).
- Supports in-line synchronization in transparent mode (synchronization on a pattern of 1 or 2 bytes).
- Provides a processor interrupt on transmit underrun or receive overflow.
- Individual CHANNEL Underrun capability.
- Up to 32 Mbps sustainable aggregated throughput (for HDLC/Transparent) for normal channels and 16-bits super channels. Up to 16 Mbps for other super channels settings.

34.1.2 Comparison with MPC82xx CPM MCC

- Superchannel support—The CPM MCC handled only 1 byte time slots. The QUICC Engine MCC supports 5-, 6-, 7-, 8-, and 16-bit entries.
- The QUICC Engine MCC supports 8 TDMs with 256 channels instead of 4 TDMs with 128 channels.
- The QUICC Engine MCC has the possibility for a channel underrun instead of a global underrun. It means that only the channel that has no data will be affected and not the whole TDM or MCC.
- The QUICC Engine MCC has a programmable Emergency level so the User can alter the service level to the MCC according to the system load it is working in.
- Enhanced debug capabilities.

34.1.3 Modes of Operation

The MCC relies upon its corresponding SI block as its physical interface to a TDM. Once the SI's TDM has been programmed to contain MCC-related timeslots (accomplished via SIRAM programming) and has been enabled, the SI clocks data out of the MCC transmitter, or clocks data into the MCC Receiver. Note

that the SI contains no data buffering, data moving to or from the MCC is clocked directly through the SI, to or from the TDM data lines.

The QUICC Engine block uses a variety of MCC-related data structures to handle that channel's traffic. The QUICC Engine intervention is triggered by requests from the MCC.

The MCC global parameters govern the overall state of the MCC block and also contain some threshold settings and base pointers used by all channels for their operation. There is also one set of channel-specific parameters and channel-extra parameters per MCC channel, containing protocol state information for that channel and pointers to that particular channel's receive and transmit buffer descriptors. These parameter RAM areas are described in more detail in the following sections.

Note that the channel-specific parameter area may be interpreted differently depending on what protocol is being used on that particular channel, whether it is HDLC, transparent, or SS7. If an MCC channel is being used in conjunction with AAL1 CES, there are additional programming model changes that take place. Also, if a TDM is programmed to make use of superchanneled MCC timeslots, a structure called the Superchannel Table is also used. All these parameter RAM areas are described in more detail in the following sections.

34.1.3.1 Transparent

When using this mode, the individual channel in the frame will be in transparent mode. There is an option on the receive side for acquiring synchronization in order to byte or half word alignment.

34.1.3.2 HDLC

When using this mode, the individual channel in the frame will be in HDLC mode. An internal framer will provide standard HDLC features:

- Flag/Abort/Idle generation/detection
- Zero insertion/deletion
- 16-bit CRC-CCITT generation/checking
- Detection of non-octet aligned signal units
- Programmable number of flags between signal units

More details can be found under Section 34.2.2.1, "Channel-Specific HDLC Parameters."

34.1.3.3 Signaling System #7 (SS7)

Based on the HDLC protocol, the signaling system #7 (SS7) protocol is used to manage public service networks. The SS7 protocol operates on signal units (SU), which are analogous to HDLC frames. The physical, data link, and network layer functions of the SS7 protocol are called the message transfer part (MTP). Implementing the MTP layer 2 (data link) functions in host software is difficult with multiple performance issues.

The SS7 controller is implemented using the MCC hardware with microcode running on the RISC. The MCC implements the following layer 2 portions of the MTP:

- Signal unit (SU) retransmission
- Automatic fill-in signal unit (FISU) transmission
- Short SU filtering
- Duplicate fill-in and link-status signal unit (FISU/LSSU) filtering
- Octet counting
- Signal unit error rate monitoring
- Good frame counter and bad frame counter
- Initial alignment (supports alignment error rate monitoring)

Additional host software is needed to handle the following higher-level functions of the MTP layer 2 not supported by the SS7 controller:

- Link state control
- Flow control

SS7 features are as follows:

- Up to 128 independent communication channels
- Independent mapping for receive and transmit
- Standard HDLC features
- Maintenance of signal unit error monitor (SUERM)
- Maintenance of alignment error rate monitor (AERM)
- Maintenance of separate counters for error-free and bad frames
- Detection and stripping of long signal units
- Discard of short signal units (less than 5 octets)
- Transmission of signal units with a programmable delay (applies to JT-Q.703 standard)
- Automatic transmission of fill-in signal units (FISU)
- Automatic retransmission of signal units (for link-status signal unit (LSSU) retransmission)
- Automatic discard of identical FISUs and LSSUs using a user-defined mask
- Octet counting mode in case of long signal units and receiver overrun
- Five circular interrupt tables with programmable size and overflow identification—one for transmit and four for receive.
- Global or individual channel loop modes
- Efficient bus usage (no bus usage for inactive channels or for active channels with nothing to send)
- Efficient control of interrupts to the QUICC Engine block
- Supports external BD tables
- Uses on-chip multi-port RAM for parameter storage
- Uses 64-bit data transactions for reading and writing data in BDs

34.1.3.4 AAL1 Circuit Emulation Service (CES)

When using AAL1 CES, the structured and unstructured data are transferred between the ATM and MCC automatically without QUICC Engine block intervention. This chapter will only describe the modifications required for the MCC. For the AAL1 CES configuration, see Chapter 35, "ATM AAL1 Circuit Emulation Service."

34.1.3.5 Superchannel

Superchannel is not a protocol dependant mode, rather a performance enhancing mode.

Superchanneling is used for sending multiple back-to-back timeslots from the same MCC channel. TX MCC SI entry is not recommended to be more than 2 bytes, due to the increase in required performance. So in every place that such frame structure is needed the superchannel scheme can be used. A single MCC channel is the combination of one MCC channel and one set of related channel parameters and buffer descriptors. A superchannel is the combination of multiple MCC TX channels and one set of MCC channel's parameters and buffer descriptors to manage this group of channels. This provides the ability to construct a larger overall channel than that of a single normal MCC TX channel. Superchannel makes use of HW resources of unused channels to enhance its performance, the user may NOT use the channels in the superchannel for any other purpose nor use the same channel twice in the construction of a superchannel.

The length of superchanneled timeslot may be one of the following sizes 5, 6, 7, 8 or 16 bits.

Note that in the same superchannel all the channels must be the same size.

34.2 Memory Map/Register Definition

The MCC uses the following data structures:

- Global MCC parameters (common to all 256 channels) placed in the MURAM from the offset (relative to the MURAM base address).
- Channel-specific parameters. Each channel uses 64 bytes of specific parameters placed in the MURAM at offset 64*CH_NUM (relative to the MURAM base address). In SS7 mode each channel uses 128 bytes of specific parameters placed in Multi-user RAM. However still the channel specific parameters are placed at offset 64*CH_NUM. Consequently only even channel number can be used with SS7.

  Channel-specific parameters are described in the following sections:

  — Section 34.2.2.1, "Channel-Specific HDLC Parameters"

  — Section 34.2.2.2, "Channel-Specific Transparent Parameters"

  — Section 34.2.2.4, "Channel-Specific SS7 Parameters"

  Note that the MURAM memory corresponding to the inactive channels can be used for other purposes.
- Channel extra parameters. Each channel uses 8 bytes of extra parameters placed in the MURAM at offset XTRABASE + 8*CH_NUM (relative to the MURAM base address). XTRABASE is one of the global MCC parameters.

Channel extra parameters as used in octet counting mode applies only to the ITU-T and ANSI standards. The SS7 microcode will not work if both the Japanese standard and OCM features are selected. Note that the MURAM memory corresponding to inactive channels can be used for other purposes.

- Superchannel table (used only if superchanneled timeslots are defined in SIRAM programming). This table is placed in the MURAM from the offset SCTPBASE (relative to the MURAM base address). SCTPBASE is one of the global MCC parameters. The superchannel table is described in Section 34.2.4, "Superchannel Table."
- BD tables placed in the external memory. All the BD tables associated with the MCC must reside in a 512-KByte segment. The absolute base addresses of a channel BD table is MCCBASE + 8*RBASE (for the receiver) and MCCBASE + 8*TBASE (for the transmitter). MCCBASE is one of the global MCC parameters and RBASE/TBASE are channel extra parameters. Each BD table is a circular queue. One BD includes status bits, start address and length of a data buffer. Figure 34-2 shows the BD structure for the MCC.
- Circular interrupt tables placed in external memory. There is one table for the transmitter interrupts (base address TINTBASE) and from one to four tables for receiver interrupts (base address RINTBASE0–RINTBASE3). TINTBASE and RINTBASE0–RINTBASE3 are global MCC parameters.
- Four registers (MCCE, MCCM, MERL, and MCCF)
  - Section 34.2.6.1, "MCC Event Register (MCCE)/Mask Register (MCCM)
  - Section 34.2.8, "MCC Emergency Request Level (MERL)
  - Section 34.2.5, "MCC Configuration Registers (MCCF)

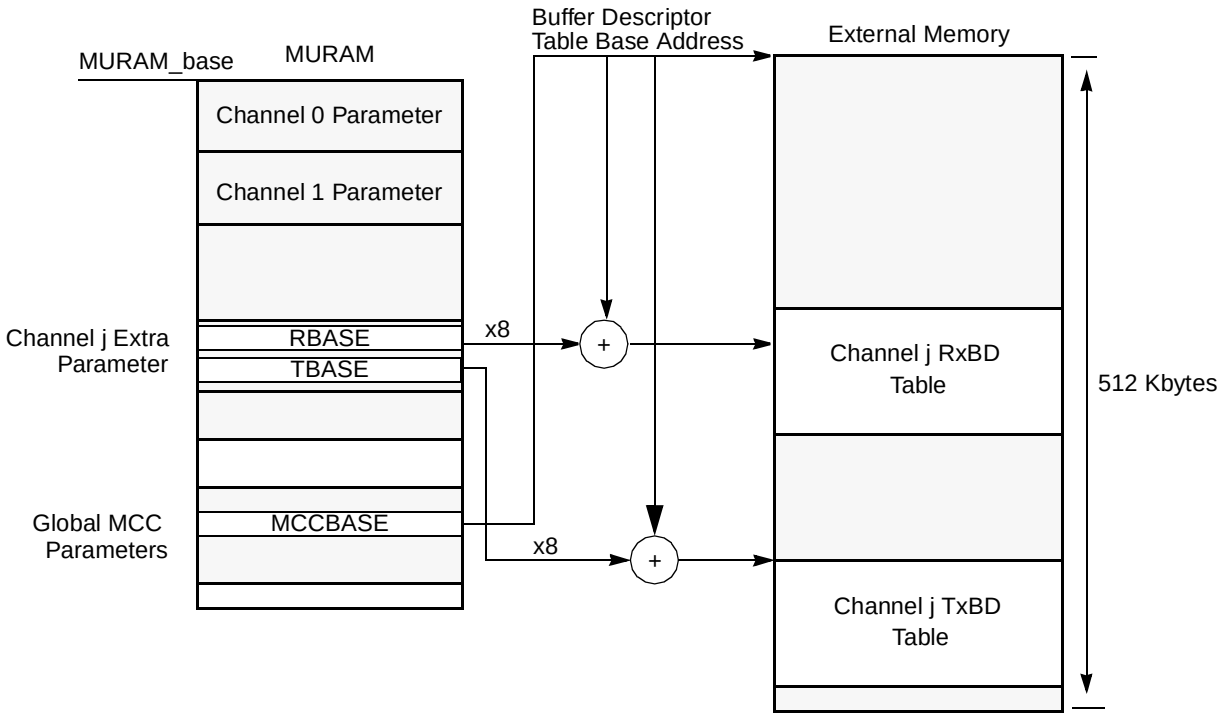

Figure 34-2. MCC BD Structure

Table 34-1. DMA Register Summary

Offset	Register	Access	Reset Value	Section/Page
General Registers				
0x00	MCC event register	R/W	0x0000_0000	34.2.6.1/34-38
0x04	MCC mask register	R/W	0x0000_0000	34.2.6.1/34-38
0x08	MCC configuration register	R/W	0x0000_0000	34.2.5/34-35
0x0C	MCC emergency request level	R/W	0x4000_4000	34.2.8/34-45

34.2.1 Global MCC Parameters

The global MCC parameters are described in Table 34-2.

Table 34-2. Global MCC Parameters

Offset[1]	Name	Width	Description
0x00	**MCCBASE**	Word	MCC base pointer. User-initialized parameter points to the starting address of a 512-Kbyte BD segment in external memory.
0x04	**MCCSTATE**	Hword	MCC state, used by the QUICC Engine block for global state definition. Should be cleared during initialization.
0x06	**MRBLR**	Hword	Maximum receive buffer length (user-initialized). Defines the maximum number of bytes written to a receive buffer before moving to the next buffer for this channel. This value must be a multiple of 8.
0x08	**GRFTHR**	Hword	Global receive frame threshold. Used to reduce interrupt overhead that would otherwise occur when many short HDLC frames arrive, each causing an RXF interrupt. Programming GRFTHR can be used to limit the frequency of RXF interrupts. In normal operation, an unmasked RXF event is written to the interrupt table on each received frame. However, a user may choose to mask the RXF event and instead rely upon the RINTx event written to the interrupt table. This occurs only when the number of RXF events (by all channels) reaches the GRFTHR value. This parameter does not need to be reset after an interrupt.
0x0A	**GRFCNT**	Hword	Global receive frame count. A down counter used to implement the GRFTHR feature. It should be initialized to the GRFTHR value. The QUICC Engine block writes an entry in a circular interrupt table and decrements GRFCNT each time a frame is received. When GRFCNT reaches zero, the QUICC Engine block generates an interrupt and re-initializes GRFCNT with the GRFTHR value. This parameter does not need to be reset after an interrupt.
0x0C	RINTTMP	Word	Temporary location for holding the receive interrupt queue entry, used by the QUICC Engine block (reserved)
0x10	DATA0	Word	Temporary location for holding data, used by the QUICC Engine block (reserved)
0x14	DATA1	Word	Temporary location for holding data, used by the QUICC Engine block (reserved)
0x18	**TINTBASE**	Word	Multi-channel transmitter circular interrupt table base address. The interrupt circular table is a cyclic table (FIFO-like). Each table entry contains information about an interrupt request generated by the MCC to the host.
0x1C	**TINTPTR**	Word	Pointer to the transmitter circular interrupt table. The QUICC Engine block writes the next interrupt information to this entry when an exception occurs. The user must copy the TINTBASE value to TINTPTR before enabling interrupts. Further updates of the TINTPTR are done by the QUICC Engine block.

Table 34-2. Global MCC Parameters (continued)

Offset[1]	Name	Width	Description
0x20	**TINTTMP**	Word	Temporary location for holding the transmit interrupt queue entry, used by the QUICC Engine block. The system initializes this field before initializing the MCC. The user must clear it before enabling interrupts.
0x24	**SCTPBASE**	Hword	Internal pointer for the superchannel transmit table, offset from the MURAM address
0x26	**MCPBASE**	Hword	MCC Channel Pointer Base. Internal pointer for the new channel base address. Must be cleared (Set to 0) if Channel Specific Parameters reside at the beginning of the MURAM.
0x28	**C_MASK32**	Word	CRC constant (user initialized to 0xDEBB20E3). Used for 32-bit CRC-CCITT calculation if HDLC mode is chosen for a selected channel. (This option is programmable. For each HDLC channel, one of two CRC-CCITTs can be selected through the CHAMR, see Section 34.2.2.1.3, “Channel Mode Register (CHAMR)—HDLC Mode.”)
0x2C	**XTRABASE**	Hword	Pointer for the beginning of the extra parameters information, offset from the MURAM address
0x2E	**C_MASK16**	Hword	CRC constant (user initialized to 0xF0B8). Used for 16-bit CRC-CCITT calculation if HDLC mode is chosen for a selected channel. This option is programmable. For each HDLC channel, one of two CRC-CCITT can be selected through the CHAMR.
0x30	**RINTTMP0**	Word	RINTTMPx. Temporary location for holding a receive circular interrupt circular table entry (for tables 0–3), used by the QUICC Engine block. The user must clear it before enabling interrupts.
0x34	**RINTTMP1**	Word	
0x38	**RINTTMP2**	Word	
0x3C	**RINTTMP3**	Word	
0x40	**RINTBASE0**	Word	RINTBASEx—Multi-channel receiver circular interrupt table base address. The interrupt circular table is a cyclic table (FIFO-like). Each table entry contains information about an interrupt request generated by the MCC to the host. RINTPTRx—Pointer to the receiver circular interrupt table. The RISC writes the next interrupt information to this entry when an exception occurs. The user must copy the RINTBASEx value to RINTPTRx before enabling interrupts. Further updates of the RINTPTRx are done by the QUICC Engine block.
0x44	**RINTPTR0**	Word	
0x48	**RINTBASE1**	Word	
0x4C	**RINTPTR1**	Word	
0x50	**RINTBASE2**	Word	
0x54	**RINTPTR2**	Word	
0x58	**RINTBASE3**	Word	
0x5C	**RINTPTR3**	Word	
0x60	TS_TMP	Word	Temporary place for time stamp

1 Offset to MCC Base

34.2.2 Channel-Specific Parameters

Each MCC ROUTER in the MCC is managed by a set of channel-specific parameters. These parameters can change based upon what protocol is being used on that channel. The following sections describe the various programming models used for an MCC channel.

34.2.2.1 Channel-Specific HDLC Parameters

Table 34-3 describes channel-specific parameters for HDLC.

Table 34-3. Channel-Specific Parameters for HDLC

Offset[1]	Name	Width	Description
0x00	**TSTATE**	Word	Tx internal state. To start a transmitter channel the user must write to TSTATE 0x*HH*80_0000. HH is the TSTATE high byte described in Section 34.2.2.1.1, "Internal Transmitter State (TSTATE)—HDLC Mode"
0x04	**ZISTATE**	Word	Zero-insertion machine state. User-initialized to one of the following values: 0x10000207 for regular channel transmitting all 1s before first frame of data 0x00000207 for regular channel transmitting flags before first frame of data 0x30000207 for inverted channel transmitting all 1s before first frame of data 0x20000207 for inverted channel transmitting flags before first frame of data **Note:** Used in conjunction with ZIDATA0 and ZIDATA1.
0x08	**ZIDATA0**	Word	Zero-insertion high word data buffer. User-initialized to one of the following values: 0xFFFFFFFF allows transmission of all 1s before first frame of data 0x7E7E7E7E allows transmission of flags before first frame of data **Note:** Used in conjunction with ZISTATE and ZIDATA1.
0x0C	**ZIDATA1**	Word	Zero-insertion low word data buffer. User-initialized to one of the following values: 0xFFFFFFFF allows transmission of all 1s before first frame of data 0x7E7E7E7E allows transmission of flags before first frame of data **Note:** Used in conjunction with ZISTATE and ZIDATA0.
0x10	TBDFlags	Hword	TxDB flags, used by the QUICC Engine block (read-only for the user)
0x12	TBDCNT	Hword	Tx internal byte count. Number of remaining bytes in buffer, used by the QUICC Engine block (read-only for the user)
0x14	TBDPTR	Word	Tx internal data pointer. Points to the current absolute data address of channel, used by the QUICC Engine block (read-only for the user)
0x18	**INTMSK**	Hword	Channel's interrupt mask flag. See Section 34.2.2.3.3, "Interrupt Circular Table Entry and Interrupt Mask (INTMSK)—AAL1 CES"
0x1A	**CHAMR**	Hword	Channel mode register. See Section 34.2.2.1.3, "Channel Mode Register (CHAMR)—HDLC Mode"
0x1C	TCRC	Word	Temp transmit CRC. Temp value of CRC calculation result, used by the QUICC Engine block (read-only for the user)
0x20	**RSTATE**	Word	Rx internal state. To start a receiver channel the user must write to RSTATE 0x*HH*80_0000. *HH* is the value of the RSTATE high byte described in Section 34.2.2.1.4, "Internal Receiver State (RSTATE)—HDLC Mode"
0x24	**ZDSTATE**	Word	Zero-deletion machine state (User-initialized to 0x00FFFFE0 for regular channel and 0x20FFFFE0 for inverted channel)
0x28	**ZDDATA0**	Word	Zero-deletion high word data buffer (User-initialized to 0xFFFFFFFF)
0x2C	**ZDDATA1**	Word	Zero-deletion low word data buffer (User-initialized to 0x8000FFFF)
0x30	RBDFlags	Hword	RxBD flags, used by the QUICC Engine block (read-only for the user)
0x32	RBDCNT	Hword	Rx internal byte count. Number of remaining bytes in buffer, used by the QUICC Engine block (read-only for the user)

Table 34-3. Channel-Specific Parameters for HDLC (continued)

Offset[1]	Name	Width	Description
0x34	RBDPTR	Word	Rx internal data pointer. Points to current absolute data address of channel, used by the QUICC Engine block (read-only for the user)
0x38	**MFLR**	Hword	Maximum frame length register. Defines the longest expectable frame for this channel. (64-Kbyte maximum). The remainder of a frame that is larger than MFLR is discarded and the LG flag is set in the last frame's BD. An interrupt request might be generated (RXF and RXB) depending on the interrupt mask. A frame's length is considered to be everything between flags, including the CRC. No more data is written into the current buffer when the MFLR violation is detected.
0x3A	MAX_CNT	Hword	Max_length counter, used by the QUICC Engine block (read-only for the user)
0x3C	RCRC	Word	Temp receive CRC, used by the QUICC Engine block (read-only for the user)

[1] The offset is relative to Multi-User RAM (MURAM) base address +MCPBASE+ 64*CH_NUM

34.2.2.1.1 Internal Transmitter State (TSTATE)—HDLC Mode

The internal transmitter state (TSTATE) is a 4-byte register that provides the transaction parameters associated with SDMA channel accesses (like the bus mode registers). It also starts the transmitter channel.

To start the channel, write 0x*HH*800000 to TSTATE, where *HH* is the TSTATE high byte (see Figure 34-3). When the channel is active, the QUICC Engine block changes the value of the three LSBs, hence these 3 bytes must be masked if the user reads back the TSTATE.

Access: User read-write

	0	1	2	3	4	5	6	7
R W	—t		**GBL**	**BO**		**CETM**	**DTB**	**BDB**
Reset:	0	0	0	0	0	0	0	0

Figure 34-3. TSTATE High Byte

TSTATE high byte fields are described in Table 3-6.

Table 34-4. TSTATE High-Byte Field Descriptions

Bits	Name	Description
0–1	—	Reserved, should be cleared.
2	**GBL**	Global. Setting GBL activates snooping (only the coherent system bus can be snooped, this parameter is ignored for secondary bus transactions). To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
3–4	**BO**	Byte ordering. Set BO to select the required byte ordering for the buffer. If BO is changed on-the-fly, it takes effect at the beginning of the next frame or at the beginning of the next BD. 00, 01, 11 Reserved 10 Big-endian

Table 34-4. TSTATE High-Byte Field Descriptions (continued)

Bits	Name	Description
5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.
6	**DTB**	Data bus indicator. Selects the bus that handles transfers to and from data buffers. 0 Coherent system bus SDMA 1 QUICC Engine block secondary bus SDMA
7	**BDB**	BD bus. Selects the bus that handles transfers to/from BD and interrupt circular tables. 0 Coherent system bus SDMA used for accessing BDs 1 QUICC Engine block secondary bus SDMA used for accessing BDs

34.2.2.1.2 Interrupt Mask (INTMSK)—HDLC Mode

The interrupt mask (INTMSK) provides bits for enabling/disabling the reporting of each possible event defined in the interrupt circular table entry. For descriptions of each event bit, refer to Section 34.2.6.2, "Interrupt Circular Table Entry."

	0–5	6	7	8	9	10	11	12	13	14	15
Interrupt Entry	—	UN	TXB	—		NID	IDL	MRF	RXF	BSY	RXB
INTMSK	—	**Mask Bits**		—		**Mask Bits**					

Figure 34-4. INTMSK Mask Bits

To enable an interrupt, set the corresponding bit. If a bit is cleared, no interrupt request is generated and no new entry is written in the circular interrupt table. The user must initialize INTMSK prior to operation. Reserved bits should remain cleared.

34.2.2.1.3 Channel Mode Register (CHAMR)—HDLC Mode

The channel mode register (CHAMR) is a user-initialized register, shown in Figure 3-5. For a descriptions of CHAMR in transparent and SS7 modes, refer to Section 3.2.2.3 and Section 3.2.4.1 respectively. For channels that are used in conjunction with CES functionality, the user should refer to Section 34.2.2.3.4, "Channel Mode Register (CHAMR)—AAL1 CES," for additional information.

Reset	0	0	0	0	0	0	0 0	0	0	0	0	0 0	0 0

Figure 34-5. Channel Mode Register (CHAMR)—HDLC Mode

CHAMR fields are described in Table 34-5.

Table 34-5. CHAMR Field Descriptions

Bits	Name	Description
0	**MODE**	This mode bit determines whether the HDLC or transparent mode is used. It also determines how other CHAMR bits are interpreted. 0 Transparent mode. See Section 34.2.2.2.3, "Channel Mode Register (CHAMR)—Transparent Mode" 1 HDLC mode. See Section 34.2.2.1.3, "Channel Mode Register (CHAMR)—HDLC Mode"
1	**POL**	Enable polling. POL enables the transmitter to poll the TxBDs. 0 Polling is disabled (The QUICC Engine block does not access the external bus to check the R bit in the TxBD). 1 Polling is enabled. POL is used to optimize the use of the external bus. Software should always set POL at the beginning of a transmit sequence of one or more frames. The QUICC Engine block clears POL when no more buffers are ready in the transmit queue, i.e. when it finds a BD with R = 0 (for example, at the end of a frame or at the end of a multi-frame transmission). To minimize useless transactions on the external bus, software should always prepare the new BD, or multiple BDs, and set BD[R] before enabling polling.
2	**1**	Must be set.
3	**IDLM**	Idle mode. 0 No idle patterns are sent between frames. After sending NOF+1 flags, the transmitter starts sending the data of the frame. If the transmission is between frames and the frame buffers are not ready, the transmitter sends flags until it can start transmitting the data. 1 At least one idle pattern is sent between adjacent frames. The NOF value shall be no smaller than the PAD setting, see Section 34.2.7.2, "Transmit Buffer Descriptor (TxBD)." If NOF = 0, this is identical to flag sharing in HDLC. Mode flags precede the actual data. When IDLM = 1, at least one idle pattern is sent between adjacent frames. If the transmission is between frames and the frame buffer is not ready, the transmitter sends idle characters. When data is ready, the NOF+1 flags are sent followed by the data frame. If IDLE mode is selected and NOF = 1, the following sequence is sent: .....init value, FF flag data,..... The init value before the idle will be ones.
4	—	This bit must be cleared.
5	**RD**	0 Normal bit order (transmit/receive the lsb of each octet first) 1 Reversed bit order (transmit/receive the msb of each octet first)
6–7	—	These bits must be cleared.
8	**CRC**	Selects the type of CRC when HDLC channel mode is used. 0 16-bit CCITT-CRC 1 32-bit CCITT-CRC
9	—	This bit must be cleared.
10	**TS**	Receive time stamp. If this bit is set, a 4 byte time stamp is written at the beginning of every data buffer pointed to by the BD. Also, the data buffer must start from an address equal to 8*n-4 (n is any integer larger than 0).

Table 34-5. CHAMR Field Descriptions (continued)

Bits	Name	Description
11–12	**RQN**	Receive queue number. Specifies the receive interrupt queue number. 00 Queue number 0. 01 Queue number 1. 10 Queue number 2. 11 Queue number 3.
13–15	**NOF**	Number of flags. NOF defines the minimum number of flags before frames: 000 At least 1 flag 001 At least 2 flags .... 111 At least 8 flags

34.2.2.1.4 Internal Receiver State (RSTATE)—HDLC Mode

Internal receiver state (RSTATE) is a 4-byte register that provides transaction parameters associated with SDMA channel accesses (like the bus mode registers) and starts the receiver channel.

To start the channel the user must write 0x*HH*800000 to RSTATE, where *HH* is the RSTATE high byte (see Figure 3-6). When the channel is active, the QUICC Engine block changes the value of the 3 LSBs, hence these 3 bytes must be masked if the user reads back the RSTATE.

Offset: 0x20 Access: User read-write

	0	1	2	3	4	5	6	7
R W	—		**GBL**	**BO**		**CETM**	**DTB**	**BDB**
Reset:	0	0	0	0	0	0	0	0

Figure 34-6. Rx Internal State (RSTATE) High Byte

RSTATE high byte fields are described in Table 34-6.

Table 34-6. RSTATE High Byte Field Descriptions

Bits	Name	Description
0–1	—	Reserved, should be cleared.
2	**GBL**	Global. Setting GLB activates snooping (only the coherent system bus can be snooped, this parameter is ignored for secondary bus transactions). To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”
3–4	**BO**	Byte ordering. Set BO to select the required byte ordering for the buffer. If BO is changed on-the-fly, it takes effect at the beginning of the next frame or at the beginning of the next BD. 00, 01, 11 Reserved 10 Big-endian
5	CETM	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.

Table 34-6. RSTATE High Byte Field Descriptions (continued)

Bits	Name	Description
6	**DTB**	Data bus indicator. The transfers to data buffers are handled by the: 0 Coherent system bus SDMA 1 QUICC Engine block secondary bus SDMA
7	**BDB**	BD and interrupt circular tables bus indicator. The transfers to/from BD and interrupt circular tables are handled by the: 0 Coherent system bus SDMA 1 QUICC Engine block secondary bus SDMA **Note:** The following restrictions result from the fact that there is a common bus selection bit for BDs and interrupt circular tables: • The RxBDs of all the channels that use a particular interrupt table must reside on the same bus (memory or secondary). • All TxBDs must reside on the same bus (memory or secondary).

34.2.2.2 Channel-Specific Transparent Parameters

Table 34-7 describes channel-specific parameters for transparent operation.

Table 34-7. Channel-Specific Parameters for Transparent Operation

Offset[1]	Name	Width	Description
0x00	**TSTATE**	Word	Tx internal state. To start a transmitter channel the user must write to TSTATE 0x*HH*80_0000. *HH* is the TSTATE high byte described in Section 34.2.2.1.1, "Internal Transmitter State (TSTATE)—HDLC Mode"
0x04	**ZISTATE**	Word	Zero-insertion machine state. (User-initialized to 0x10000207 for regular channel, or 0x30000207 for inverted channel)
0x08	**ZIDATA0**	Word	Zero-insertion high word data buffer (User-initialized to 0xFFFFFFFF)
0x0C	**ZIDATA1**	Word	Zero-insertion low word data buffer (User-initialized to 0xFFFFFFFF)
0x10	TBDFlags	Hword	TxDB flags, used by the QUICC Engine block (read-only for the user)
0x12	TBDCNT	Hword	Tx internal byte count. Number of remaining bytes in buffer, used by the QUICC Engine block (read-only for the user)
0x14	TBDPTR	Word	Tx internal data pointer. Points to current absolute data address of channel, used by the QUICC Engine block (read-only for the user)
0x18	**INTMSK**	Hword	Channel's interrupt mask flag. See Section 34.2.2.2.2, "Interrupt Mask (INTMSK)—Transparent Mode"
0x1A	**CHAMR**	Hword	Channel mode register. See Section 34.2.2.2.3, "Channel Mode Register (CHAMR)—Transparent Mode"
0x1C	—	Word	Reserved
0x20	**RSTATE**	Word	Rx internal state. To start a receiver channel the user must write to RSTATE 0x*HH*80_0000. *HH* is the RSTATE high byte described in Section 34.2.2.1.4, "Internal Receiver State (RSTATE)—HDLC Mode"

[1] The offset is relative to Multi-user RAM address +MCPBASE+64*CH_NUM

34.2.2.2.1 Internal Transmitter State (TSTATE)—Transparent Mode

In transparent mode, TSTATE functions the same as in HDLC mode. For a description, refer to Section 34.2.2.1.1, “Internal Transmitter State (TSTATE)—HDLC Mode.”

34.2.2.2.2 Interrupt Mask (INTMSK)—Transparent Mode

In transparent mode, INTMSK functions the same as in HDLC mode. For a description, refer to Section 34.2.2.1.2, “Interrupt Mask (INTMSK)—HDLC Mode.”

34.2.2.2.3 Channel Mode Register (CHAMR)—Transparent Mode

Figure 3-7 shows the user-initialized channel mode register, CHAMR, for transparent mode. For channels that are used in conjunction with CES functionality, the user should refer to Section 34.2.2.3.4, “Channel Mode Register (CHAMR)—AAL1 CES,” for additional information.

Figure 34-7. Channel Mode Register (CHAMR)—Transparent Mode

CHAMR fields are described in Table 34-8.

Table 34-8. CHAMR Field Descriptions—Transparent Mode

Bits	Name	Description
0	**MODE**	Channel mode. Selects either HDLC or transparent mode. 0 Transparent mode. 1 HDLC mode
1	**POL**	Enable polling. POL enables the transmitter to poll the TxBDs. 0 Polling is disabled (The QUICC Engine block does not access the external bus to check the R bit in the TxBD). 1 Polling is enabled. POL is used to optimize the use of the external bus. Software should always set POL at the beginning of a transmit sequence of one or more frames. The QUICC Engine block clears POL when no more buffers are ready in the transmit queue, i.e. when it finds a BD with R = 0 (for example, at the end of a frame or at the end of a multi-frame transmission). To prevent a significant number of useless transactions on the external bus, software should always prepare the new BD, or multiple BDs, and set BD[R] before enabling polling.
2–3	**0b11**	Must be set.
4	**EP**	Empty polarity and enable polling. 0 The E bit in the RxBD is handled in positive logic (1 = empty; 0 = not empty). Polling occurs only if POL is set. 1 The E bit in the RxBD is handled in negative logic (0 = empty, 1 = not empty). Polling occurs disregarding the value of POL.
5	**RD**	0 Normal bit order (transmit/receive the lsb of each octet first) 1 Reversed bit order (transmit/receive the msb of each octet first)

Table 34-8. CHAMR Field Descriptions—Transparent Mode (continued)

Bits	Name	Description			
6–7	**SYNC**	Synchronization. SYNC controls synchronization of multi-channel operation in transparent mode.			
		SYNC	**Receive**	**Transmit**	**Description**
		00	None	None	Transmitter and receiver operate with no synchronization algorithm. RCV SYNC should be cleared or received data may be shifted.
		01	Slot	Slot	The first data is sent/received in the slot defined in the slot assignment table (for superchannels only). RCV SYNC should be cleared or received data may be shifted.
		10	8-bit	None	Receive data synchronization uses an 8-bit pattern specified by the 8 msb of RCV SYNC. The sync bytes are not written to the receive buffer.
		11	16-bit	None	Receive data synchronization uses a 16-bit pattern specified by RCV SYNC. The first byte of the sync pattern will not be written to the receive buffer. The second byte of the sync pattern will be written to the receive buffer (first and second represent the order in which the two bytes of the sync pattern are received on the serial channel).
8–9	—	Reserved, must be cleared.			
10	**TS**	Receive time stamp. If this bit is set, a 4 byte time stamp is written at the beginning of every data buffer that the BD points to. Also, the data buffer must start from an address equal to 8*N-4 (N is any number larger than 0).			
11–12	**RQN**	Receive queue number. Specifies the receive interrupt queue number. 00 Queue number 0. 01 Queue number 1. 10 Queue number 2. 11 Queue number 3.			
13–15	—	Reserved, must be cleared.			

34.2.2.2.4 Internal Receiver State (RSTATE)—Transparent Mode

In transparent mode, RSTATE functions the same as in HDLC mode. For a description, refer to Section 34.2.2.1.4, “Internal Receiver State (RSTATE)—HDLC Mode.”

34.2.2.3 MCC Parameters for AAL1 CES Usage

When using AAL1 circuit emulation service (CES), the structured and unstructured data are transferred between the ATM and MCC automatically without QUICC Engine block intervention. Refer to Chapter 35, “ATM AAL1 Circuit Emulation Service.” The following subsections describe the additional parameters required for AAL1 CES.

34.2.2.3.1 MCC Global Parameters—AAL1 CES

The global MCC parameters specific to AAL1 CES operation are described in Table 34-9.

Table 34-9. CES-Specific Global MCC Parameters

Offset[1]	Name	Width	Description
0x00	**CATB**	Hword	CES adaptive threshold tables base address. Points to the multi-user RAM area containing the CES slip control thresholds and the adaptive counterl, see Section 35.5, "ATM-to-TDM Adaptive Slip Control." Should be 8-byte aligned (8 octets for each AAL1-MCC channel). User-defined and should match the CATB value programmed in the AAL1 parameter RAM; see Section 35.8.1, "AAL1 CES Parameter RAM."
0x02	—	Hword	Reserved, should be cleared during initialization.
0x04, 0x08, 0x0C, 0x10, 0x14, 0x18, 0x1C, 0x20	**UTA1, UTA2, UTA3, UTA4, UTA5, UTA6, UTA7, UTA8**	Hword	Underrun template address for Group*X*. Points to the multi-user RAM area containing the user-defined template to be sent during an MCC transmitter pre-underrun condition.
0x06, 0x0A, 0x0E, 0x12, 0x16, 0x1A, 0x1E, 0x22,	**UTS1, UTS2, UTS3, UTS4, UTS5, UTS6, UTS7. UTS8**	Hword	Underrun template size for Group*X*. This is the size in bytes of the underrun template buffer.

[1] The offset to the CES-specific global MCC parameter RAM is +0x0080 from regular offset.

34.2.2.3.2 Channel-Specific Parameters—AAL1 CES

The following are changes that occur in the channel-specific parameter RAM when using AAL1 CES.

34.2.2.3.3 Interrupt Circular Table Entry and Interrupt Mask (INTMSK)—AAL1 CES

Interrupt circular table entries contain information about channel-specific events. The interrupt mask (INTMSK) provides bits for enabling/disabling the reporting of each possible event defined in the interrupt circular table entry. Note that two CES-related interrupts provide slip indications for the MCC transmitter. They are reflected in both the interrupt circular table entries and the INTMSK fields, as described in Table 34-19. Figure 34-8 shows the INTMSK mask bits.

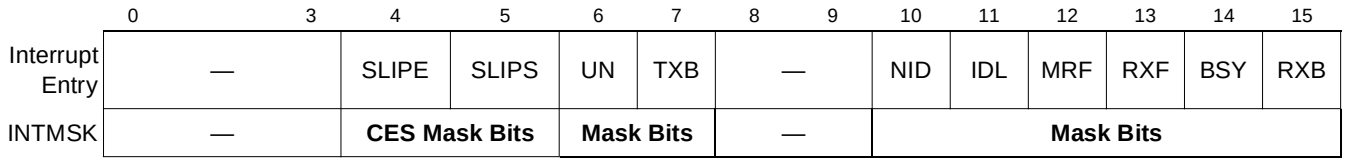

Figure 34-8. INTMSK Mask Bits

To enable an interrupt, set the corresponding bit. If a bit is cleared, no interrupt request is generated and no new entry is written in the interrupt circular table. The user must initialize INTMSK prior to operation. Reserved bits are cleared.

34.2.2.3.4 Channel Mode Register (CHAMR)—AAL1 CES

Figure 3-9 shows the user-initialized channel mode register, CHAMR, for CES operation. It is the same as the CHAMR in transparent mode with three extra CES fields in bits 13–15.

Offset: 0x1A Access: User read-write

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

34.2.2.4 Channel-Specific SS7 Parameters

Table 34-11 describes channel-specific parameters for SS7. Note that a given parameter location may have a different definition depending on the standard used (ITU-T/ANSI or Japanese standard).

Table 34-11. Channel-Specific Parameters for SS7

Offset[1]	Name	Width	Description
0x00	TSTATE	Word	Tx internal state. The user must write to TSTATE 0x*HH*80_0000. *HH* is the TSTATE High Byte. Refer to Section 34.2.2.1.1, "Internal Transmitter State (TSTATE)—HDLC Mode"
0x04	ZISTATE	Word	Zero-insertion machine state. User-initialized to one of the following values: 0x10000207 for regular channel transmitting all 1s before first frame of data 0x00000207 for regular channel transmitting flags before first frame of data 0x30000207 for inverted channel transmitting all 1s before first frame of data 0x20000207 for inverted channel transmitting flags before first frame of data **Note:** Used in conjunction with ZIDATA0 and ZIDATA1.
0x08	ZIDATA0	Word	Zero-insertion high word data buffer. User-initialized to one of the following values: 0xFFFFFFFF allows transmission of all 1s before first frame of data 0x7E7E7E7E allows transmission of flags before first frame of data **Note:** Used in conjunction with ZISTATE and ZIDATA1.
0x0C	ZIDATA1	Word	Zero-insertion low word data buffer. User-initialized to one of the following values: 0xFFFFFFFF allows transmission of all 1s before first frame of data 0x7E7E7E7E allows transmission of flags before first frame of data **Note:** Used in conjunction with ZISTATE and ZIDATA0.
0x10	TBDFlags	Hword	TxBD flags, used by the QUICC Engine block (read-only for the user)
0x12	TBDCNT	Hword	Tx internal byte count. Number of remaining bytes in buffer, used by the QUICC Engine block (read-only for the user)
0x14	TBDPTR	Word	Tx internal data pointer. Points to current absolute data address of channel, used by the QUICC Engine block (read-only for the user)
0x18	ECHAMR	Word	Extended channel mode register. See Section 34.2.2.4.1, "Extended Channel Mode Register (ECHAMR)—SS7 Mode"
0x1C	TCRC	Word	Temporary transmit CRC. Temporary value of CRC calculation result, used by the QUICC Engine block (read-only for the user)
0x20	RSTATE	Word	Rx internal state. To start a receiver channel the user must write to RSTATE 0x*HH*80_0000. *HH* is the RSTATE High Byte. Refer to Section 34.2.2.1.4, "Internal Receiver State (RSTATE)—HDLC Mode"
0x24	ZDSTATE	Word	Zero-deletion machine state (User-initialized to 0x00FFFFE0 for regular channel, or 0x20FFFFE0 for reversed bit order channel)
0x28	ZDDATA0	Word	Zero-deletion high word data buffer (User-initialized to 0xFFFFFFFF)
0x2C	ZDDATA1	Word	Zero-deletion low word data buffer (User-initialized to 0x8000FFFF)
0x30	RBDFlags	Hword	RxBD flags, used by the QUICC Engine block (read-only for the user)
0x32	RBDCNT	Hword	Rx internal byte count. Number of remaining bytes in buffer, used by the QUICC Engine block (read-only for the user)
0x34	RBDPTR	Word	Rx internal data pointer. Points to current absolute data address of channel, used by the QUICC Engine block (read-only for the user)

Table 34-11. Channel-Specific Parameters for SS7 (continued)

Offset[1]	Name	Width	Description
0x38	MFLR	Hword	Maximum frame length register. Defines the longest expected frame for this channel. (64-Kbyte maximum). The remainder of a frame that is larger than MFLR is discarded and the LG flag is set in the last frame's BD. An interrupt request might be generated (RXF and RXB) depending on the interrupt mask. A frame's length is considered to be everything between flags, including CRC. No more data is written into the current buffer when the MFLR violation is detected.
0x3A	MAX_cnt	Hword	Max_length counter, used by the QUICC Engine block (read-only for the user)
0x3C	RCRC	Word	Temporary receive CRC, used by the QUICC Engine block (read-only for the user)
0x40	N	Hword	Applies to ITU-T/ANSI SS7 only. Interrupt threshold in octet counting mode (N=16). See Section 34.2.2.4.2, "Signal Unit Error Monitor (SUERM)—SS7 Mode"
	N_cnt	Hword	Applies to ITU-T/ANSI SS7 only. Temporary down counter for N (user initialized to the value of N).
	JTSTTmp	Word	Applies to Japanese SS7 only. Temporary storage for Time-Stamp Register Value. Used by the QUICC Engine block to implement a 24-ms delay before sending FISU.
0x44	D	Hword	Signal unit to signal unit error ratio (SUERM parameter, user initialized to 256). See Section 34.2.2.4.2, "Signal Unit Error Monitor (SUERM)—SS7 Mode"
0x46	D_cnt	Hword	Applies to ITU-T/ANSI SS7 only. Temporary down-counter for D (user initialized to the value of D). D_cnt is decremented only when receive buffers are available.
	JTTDelay		Applies to Japanese SS7 only. FISU retransmission delay (specified in units of 512¨µs). According to the Japanese SS7 standard, the delay should be 24 ms and thus JTTDelay should be programmed to 24 ms/512 µs = 46.875 (approximately 47). Therefore, the user should program JTTDelay to 0x2F and the CETSCR to generate a 1 µs time stamp period. Refer to "QUICC Engine Time-Stamp Control Register (CETSCR)".
0x48	Mask1	Word	Mask for SU filtering, bytes 0-3. See Section 34.2.2.4.8, "SU Filtering—SS7 Mode"
0x4C	Mask2	Hword	Mask for SU filtering, byte 4. See Section 34.2.2.4.8, "SU Filtering—SS7 Mode"
0x4E	SS7_OPT	Hword	SS7 configuration register. See Section 34.2.2.4.4, "SS7 Configuration Register—SS7 Mode"
0x50	LRB1_Tmp	Word	Temporary storage, used by QUICC Engine block for SU filtering.
0x54	LRB2_Tmp	Hword	Temporary storage, used by QUICC Engine block for SU filtering.
0x56	SUERM	Hword	Signal unit error rate monitor counter (user initialized to 0). See Section 34.2.2.4.2, "Signal Unit Error Monitor (SUERM)—SS7 Mode"
0x58	LRB1	Word	Four first bytes of last received signal unit. Used by CP for SU filtering. See Section 34.2.2.4.8, "SU Filtering—SS7 Mode."
0x5C	LRB2	Hword	Fifth byte of last received signal unit. Used by QUICC Engine block for SU filtering. See Section 34.2.2.4.8, "SU Filtering—SS7 Mode"
0x5E	T	Hword	SUERM threshold value (user initialized to 64). See Section 34.2.2.4.2, "Signal Unit Error Monitor (SUERM)—SS7 Mode"
0x60	LHDR	Word	The BSN, BIB, FSN, FIB fields of last transmitted signal unit and result of CRC. Used by QUICC Engine block for automatic FISU transmission.
0x64	LHDR_Tmp	Word	Temporary storage, used by QUICC Engine block for automatic FISU transmission.

Table 34-11. Channel-Specific Parameters for SS7 (continued)

Offset[1]	Name	Width	Description
0x68	EFSUC	Word	Error-free signal unit counter, user initialized to 0. The counter is incremented whenever an error-free (no CRC error, no non-octet aligned error, no short or long frame errors) signal unit is received.
0x6C	SUEC	Word	Signal unit error counter, user initialized to 0. Incremented each time an SU is received that contains an error. These errors are: short frame, long frame, CRC error, and non-octet aligned error.
0x70	SS7STATE	Word	Internal state of SS7 controller, user initialized to 0.
0x74	JTSRTmp	Word	Temporary storage for time-stamp register value. Applies to Japanese SS7 only; otherwise should be cleared. Used by the CP to implement the 24-ms delay for signal unit error rate monitoring in Japanese SS7.
0x78	JTRDelay	Hword	FISU transmit delay (specified in units of 512us). Applies to Japanese SS7 only; otherwise should be cleared. According to the Japanese SS7 standard, the delay should be 24 ms and thus JTRDelay should be programmed to 24 ms/512 µs = 46.875 (approximately 47). Therefore the user should program JTRDelay to 0x2F and the CETSCR to generate a 1 µs time stamp period. Refer to “QUICC Engine Time-Stamp Control Register (CETSCR)”.
0x7A	M	Hword	ITU threshold for AERM. If M_cnt reaches M, an AERM interrupt is generated. Note that M is normally programmed to 5.
0x7C	M_cnt	Hword	Up-counter for M. Should be cleared during initialization.

1 The offset is relative to the multi-port RAM address +MCPBASE+ 64*CH_NUM. SS7 channel specific parameters require twice the amount of multi-port RAM required for HDLC or Transparent channel specific parameters. Therefore for SS7 even channel numbers (0, 2, 4, etc.) must be used and odd channel number must be left unused.Items in **boldface** must be initialized by the user. Unless otherwise stated, all other items are managed by microcode and should be initialized to zero.

34.2.2.4.1 Extended Channel Mode Register (ECHAMR)—SS7 Mode

The extended channel mode register (ECHAMR) is a user-initialized register, shown in Figure 34-10 It includes both the interrupt mask bits and channel configuration bits.

The interrupt mask provides bits for enabling/disabling each event defined in the interrupt circular table entry. Other bits provide various channel configuration options.

Offset: 0x18 Access: User read-write

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
R W	MODE0	—	OCT	SUERM	FISU	—	UN	TXB	—	AERM	NID	IDL	MRF	RXF	BSY	RXB

Reset	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Figure 34-10. Extended Channel Mode Register (ECHAMR) - SS7 Mode

ECHAMR fields are described in Table 34-12.

Table 34-12. ECHAMR Fields Description

Bits	Name	Description
0,16	MODE0 MODE1	00 Transparent mode 01 HDLC mode 10 Reserved 11 SS7 mode (This is the required bit setting for an MCC to perform SS7.)
1, 5, 8	0	Reserved, should be cleared during initialization.
2–4 6–7 9–15	INTMSK	Interrupt mask bits. These bits are used for enabling/disabling the reporting of each possible event defined in the interrupt circular table entry. See Section 3.6.1.1, “Interrupt Circular Table Entry.” 0 Disabled 1 Enable
17	POL	Enable polling. POL enables the transmitter to poll the TxBDs. 0 Polling is disabled (The QUICC Engine block does not access the external bus to check the R bit in the TxBD). 1 Polling is enabled. POL is used to optimize the use of the external bus. Software should always set POL at the beginning of a transmit sequence of one or more frames. The CP clears POL when no more buffers are ready in the transmit queue, i.e. when it finds a BD with R = 0 (for example, at the end of a frame or at the end of a multi-frame transmission). To prevent a significant number of useless transactions on the external bus, software should always prepare the new BD, or multiple BDs, and set BD[R] before enabling polling.
18	1	Reserved, must be set.
19	IDLM	Idle mode. 0 No idle patterns are transmitted between frames. After transmitting NOF+1 flags, the transmitter starts sending the data of the frame. If the transmission is between frames and the frame buffers are not ready, the transmitter sends flags until it can start transmitting the data. 1 At least one idle pattern is sent between adjacent frames. The NOF value shall be no smaller than the PAD setting, see TxBD. If NOF = 0, this is identical to flag sharing in SS7. Mode flags precede the actual data. When IDLM = 1, at least one idle pattern is sent between adjacent frames. If the transmission is between frames and the frame buffer is not ready, the transmitter sends idle characters. When data is ready, the NOF+1 flags are sent followed by the data frame. If IDLE mode is selected and NOF = 1, the following sequence is sent: .....init value, FF flag data,..... The init value before the idle will be ones.
20–25	—	Reserved, should be cleared during initialization.
10	TS	Receive time stamp. If this bit is set, a 4 byte time stamp is written at the beginning of every data buffer that the BD points to. Also, the data buffer must start from an address equal to 8*n-4 (n is any integer larger than 0).
11–12	RQN	Receive queue number. Specifies the receive interrupt queue number. 00 Queue number 0 01 Queue number 1 10 Queue number 2 11 Queue number 3

Table 34-12. ECHAMR Fields Description (continued)

Bits	Name	Description
13–15	NOF	Number of flags. NOF defines the minimum number of flags before frames: 000 - at least 1 flag 001 - at least 2 flags .... 111 - at least 8 flags

34.2.2.4.2 Signal Unit Error Monitor (SUERM)—SS7 Mode

The microcode maintains the signal unit error rate monitor as described in ITU-T Q.703 paragraph 10, and ANSI T1.111-1996 paragraph 10.

The microcode uses SUERM, N, N_cnt, D, D_cnt and T parameters for the leaky-bucket implementation of the SU error monitor.

- After every N octets received while in octet counting mode, SUERM is incremented and an interrupt request can be generated (SUERM) depending on the interrupt mask.
- After D error-free frames have been received, SUERM is decremented. SUERM will not be decremented below zero.
- If SUERM reaches T, the SUERM is cleared and an interrupt is generated.

34.2.2.4.3 SUERM in Japanese SS7

The Japanese SS7 uses a time interval to monitor errors. If an error is present, it checks every 24 ms.

- An error flag is set that indicates whether current frame is errored or not.
- For every JTRDelay an error flag is checked.
- If there is no error, decrement the counter SUERM by 1 (not below zero).
- If there is an error, increment the counter SUERM by D.
- If SUERM reaches T, the counter SUERM is cleared and a “signal unit error rate monitor” interrupt is generated.

Table 34-13. Parameter Values for SUERM in Japanese SS7

Parameter	Definition	Value
T	Threshold	285
D	Upcount	16
JTRDelay	Length of interval (24ms)	0x2F

34.2.2.4.4 SS7 Configuration Register—SS7 Mode

The SS7 configuration register, shown on Figure 34-11 contains additional SS7 parameters.

Offset: 0x4E Access: User read-only

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
R	—				AERM	SUERM_DIS	STD	SF_DIS	SU_FIL	SEN_FIS	O_ORN	O_ITUT	FISU_PAD			
W																
Reset																

Figure 34-11. SS7 Configuration Register (SS7_OPT)

Table 34-14 describes SS7 configuration register fields.

Table 34-14. SS7 Configuration Register Fields Description

Bits	Name	Description
0-3	—	Reserved, should be cleared during initialization.
4	**AERM**	Alignment error rate monitor enable. See Section 34.2.2.4.5, “AERM Implementation” 0 Do not enable AERM. 1 Enable AERM.
5	**SUERM_DIS**	Disable the SU error rate monitor. See Section 34.2.2.4.7, “Disabling SUERM” 0 Enable SUERM. 1 Disables both SUERM and AERM.
6	**STD**	Standard compliance 0 ITU-T/ANSI compliant 1 Japanese SS7 compliant
7	**SF_DIS**	Discard short frames (less than 5 octets) 0 Do not discard short frames. 1 Discard short frames.
8	SU_FIL	SU Filtering 0 Disable SU filtering. 1 Enable SU filtering.
9	**SEN_FIS**	Send FISU if first BD of frame is not ready. 0 Flags are sent if the current BD, which is the first BD of the frame, does not have its ready bit set. 1 FISUs are automatically sent if the current BD, which is the first BD of the frame, does not have its ready bit set.
10	**O_ORN**	Enter octet counting mode (OCM) on overrun. Should be cleared if using the Japanese standard. 0 Disable entering OCM if there are no receive BDs available. 1 Enter OCM if there are no receive BDs available. Note that when STD = 1, O_ORN = 1, and no receive buffers are ready, any received signal unit is treated as an errored signal unit.
11	**O_ITUT**	Enter octet counting mode (OCM) on ITU-T conditions (after an abort sequence or when an SU is too long). Should be cleared if using the Japanese standard. 0 Disable entering OCM on ITU-T conditions. 1 Enable entering OCM on ITU-T conditions.
12-15	**FISU_PAD**	Padding of the automatically transmitted FISUs. If the SEN_FISU bit is set, the CP will use the value of FISU_PAD as a number of pad character. Please refer to PAD parameter in Section 34.2.7.2, “Transmit Buffer Descriptor (TxBD)”

34.2.2.4.5 AERM Implementation

The SS7 microcode implements the ITU Q.703 alignment error rate monitor (AERM). The microcode uses the T, SUERM, M and M_cnt parameters. The M_cnt parameter is incremented for every T errored frames. If M_cnt reaches M, an AERM interrupt is generated to layer 3.

Note that in AERM mode no SUERM interrupt is generated. Also, the algorithm associated with D and D_cnt is disabled as per the ITU specification.

34.2.2.4.6 AERM in Japanese SS7

To meet the Japanese AERM requirements the user must change the parameters T and D. Note that the interrupt generated is not AERM but SUERM.

During proving, do the following:

1. Set SS7_OPT register to 0b0000 001X XX00 XXXX. The value of X doesn’t matter because these bits do not affect the operation of the error counter.
2. Clear JTRdelay parameter to'0.'
3. Set parameters T (threshold) and D (up counter) to'1.'
4. Clear parameter SUERM (error counter) to'0.'
5. Set JTTDelay to value required to generate 24ms delay.

These settings allow FISU or LSSU transmission to be delayed by the required 24ms (JTTDelay). They also allow the correct operation of the JT Q703 error counter and ensure that an SUERM interrupt is generated on the first SU received in error.

After proving period, set the parameters (T and D) to values according to the Japanese SUERM. See section Table 34-13.

To disable AERM and enter SUERM, do the following:

1. Set SUERM_DIS bit in SS7_OPT.
2. Set parameters (T, D & SUERM) for Japanese SUERM.
3. Clear SUERM_DIS bit in SS7_OPT.

34.2.2.4.7 Disabling SUERM

When SS7_OPT[SUERM_DIS] is set, the N_cnt and D_cnt parameters are not decremented and no SUERM interrupt is generated. This allows these parameters to be updated, for example, at the end of the proving period in alignment error monitoring.

Note: If the SS7 controller is in the octet counting mode (OCM) when SUERM_DIS is set, and consequently if no idles (only flags/data) are received, then after the host updates N_cnt and D_cnt and clears SUERM_DIS, the receiver will start in OCM. However if SUERM_DIS is set while in OCM and consequently idles are received, then the OCM state is left as-is.

34.2.2.4.8 SU Filtering—SS7 Mode

To reduce the overhead to the user software, a filtering algorithm has been adopted to allow superfluous frames to be discarded. This algorithm compares the first 3–5 bytes (depending on the type) of the current FISU or LSSU to the last SU received and discards the current SU if it has already been received.

34.2.2.4.9 Comparison Mask

A user programmable 5-byte mask exists in the parameter RAM map. When an SU is received, the controller checks the contents of the LI field. If LI is between 0 and 2, the SU (except for the CRC portion) will be masked according to the user programmable mask and will then be compared to the last SU received. The state machine for the matching algorithm is in Section 34.2.2.4.10, "Comparison State Machine."

The Mask1 and Mask2 channel-specific parameters construct the 5-byte user mask. The exact format and byte ordering are shown on Figure 34-12 and Figure 34-13.

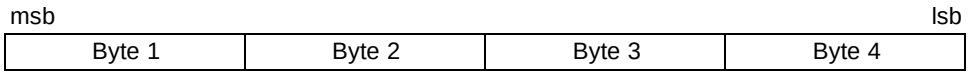

Figure 34-12. Mask1 Format

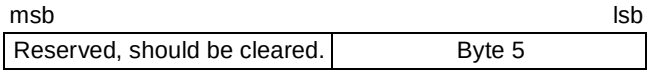

Figure 34-13. Mask2 Format

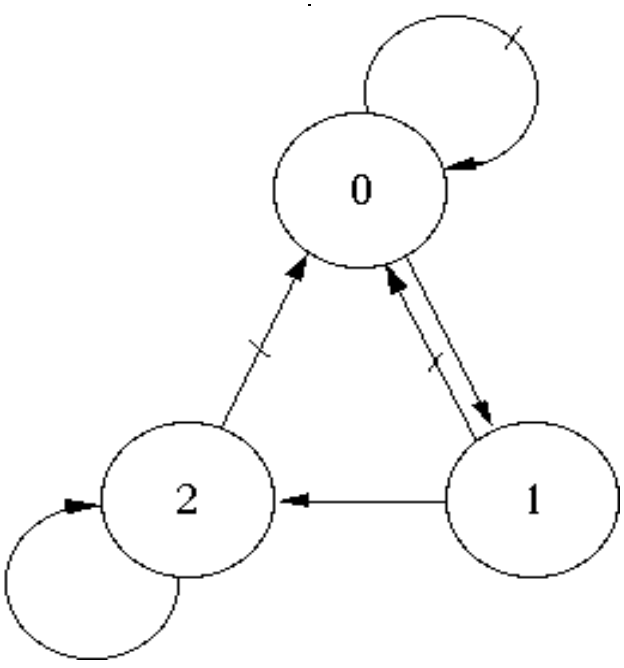
34.2.2.4.10 Comparison State Machine

The following state machine exists for filtering.



- State 0—The first 3-5 bytes (depending on the contents of the LI field) are masked and then compared with the first 3-5 bytes of the last SU. If there is a match, go to State 1, else remain in State 0. The current SU will be received into a buffer descriptor.
- State 1—The first 3-5 bytes (depending on the contents of the LI field) are masked and then compared with the first 3-5 bytes of the last SU. If there is a match, go to State 2, else go to State 0. The current SU will be received into a buffer descriptor.
- State 2—The first 3-5 bytes (depending on the contents of the LI field) are masked and then compared with the first 3-5 bytes of the last SU. If there is a match, the current SU will be discarded (unless there is an error), the channel will remain in state 2 and SU error monitor will be adjusted accordingly. If the frames do not match, the current SU will be received into a buffer descriptor and the channel will return to State 0.

34.2.2.4.11 Filtering Limitations

Because the algorithm is purely checking identical SUs, two FISUs will be received after each MSU rather than merely one, even though they have the same sequence numbers.

Reception of an MSU resets the filtering algorithm. Also, reception of a short frame resets the filtering algorithm when SS7_OPT[SF_DIS] = 0; however, when SS7_OPT[SF_DIS] = 1 (short frames are discarded), the filtering algorithm remains unchanged.

34.2.2.4.12 Resetting the SU Filtering Mechanism

This command resets the filtering algorithm to ensure that the next SU will be received, even if it would normally have been filtered. This command could be issued periodically so that the CPU can check to make sure that the link is really up and not simply receiving flags.

To issue this MCC command, refer to Section 20.3.1, “QUICC Engine Command Register (CECR).” Use opcode 0b01_0001.

NOTE

For the MPC82*xx*, the opcode command for the RESET SU FILTER is 0b1110 (0xE). The QUICC Engine opcode command for the RESET SU FILTER is opcode 0b01_0001.

34.2.2.4.13 Octet Counting Mode—SS7 Mode

When entering the octet counting mode (OCM), the QUICC Engine block will load the user defined N register to its internal octet counter. While in the octet counting mode the RISC will decrement its internal counter for every unstuffed octet received. When the internal counter is decremented to zero, the QUICC Engine block will increment the SUERM register and reload the N register into the internal count register. In addition an interrupt (OCT) might be generated depending on the interrupt mask. The SS7 controller will enter octet counting mode under the following circumstances:

- An ABORT character is received at any time and SS7_OPT[O_ITUT] is set.
- The SU currently being received has exceeded the length programmed in the MFLR register and SS7_OPT[O_ITUT] is set.

- The receiver overruns and SS7_OPT[O_ORN] is set. Note that when no receive buffers are available, only octets are counted; that is, D_cnt is not decremented after receiving the frame.

The SS7 controller will leave octet counting mode when a valid signal unit is detected (with a valid CRC and a length less than MFLR and greater than 4).

NOTE

Octet counting mode applies only to the ITU-T and ANSI standards. The SS7 microcode will not work if both the Japanese standard and OCM features are selected.

34.2.3 Channel Extra Parameters

In addition to the information kept in the channel-specific parameter ram, a channel also has a set of pointers used to index its transmit and receive buffer descriptors. This information is kept in a set of channel-extra parameters. Table 34-15 describes the channel-extra parameters. These parameters are indexed using the channel number, as described in the table.

Table 34-15. Channel Extra Parameters

Offset[1]	Name	Width	Description
0x00	**TBASE**	Hword	TxBD base address. Offset of the channel's TxBD table relative to the MCCBASE (The base address of the BD table for this channel MCCBASE+8*TBASE)
0x02	**TBPTR**	Hword	TxBD pointer. Offset of the current BD relative to the MCCBASE. TBPTR is user-initialized to TBASE before enabling the channel or after a fatal error before reinitializing the channel. (The address of the BD in use for this channel MCCBASE+8*TBPTR)
0x04	**RBASE**	Hword	RxBD base address. Offset of the channel's RxBD table relative to the MCCBASE. (The base address of the BD table for this channel MCCBASE+8*RBASE)
0x06	**RBPTR**	Hword	RxBD pointer. Offset of the current BD relative to the MCCBASE. RBPTR is user-initialized to RBASE before enabling the channel or after a fatal error before reinitializing the channel. (The address of the BD in use for this channel MCCBASE+8*RTBPTR)

[1] The offset relative to multi-port RAM base address + XTRABASE + 8*CH_NUM

34.2.4 Superchannel Table

The SCT serves as a mapping between the hardware resources being used as part of a superchannel (as programmed in SIRAM) and which channel's parameters are being used to manage that superchannel. When the SI encounters an SIRAM entry that is programmed to be part of a superchannel, the channel number in that SIRAM entry indicates to the MCC which hardware to use during that timeslot. However, when that hardware requires service (more data or request handling) from the QUICC Engine block, a lookup occurs using the Superchannel Table (SCT). As a result, there are multiple channels inside the MCC hardware to enhance performance, but a single channel as far as the user is concerned. This single high performance channel is what is defined as a "superchannel."

The MCC channel number used in the MCSEL field of the superchanneled SIRAM entry is used as an offset to a superchannel table entry that contains the MCC channel number whose parameters and buffer descriptors are being used to control that superchannel (see Figure 34-14). The only entries in the

superchannel table which must be initialized are those whose numbers appear in superchanneled entries in the SIRAM.

Note that no SCT is used for the receive side and the channel numbers used when programming receive SIRAM timeslots should always be that of the actual intended MCC receive channel FIFO.

	0	1	2 … 9	10	11	12	13	14	15
Field	0	0	**SuperChannel Number**	0	0	0	0	0	0
Addr	**MURAM_base_address+SCTPBASE**+2*(associated MCC channel_number) (MCC_channel _number is the number written in the MCSEL field of the corresponding SIRAM entry)								

Figure 34-14. Superchannel Table Entry

34.2.4.1 Transparent Slot Synchronization

Transparent slot synchronization (TSS) is used to ensure that data transmission and reception for a transparent superchannel begins on the intended timeslot of that superchannel. It is not required that the first timeslot that appears in the SIRAM programming for a transparent superchannel be the first to send or receive when the superchannel begins operation. The user indicates which timeslot in a superchannel should be the first to send or receive by programming the CNT and BYT fields of the superchanneled timeslots as described in “Programming SIx RAM Entries.”

34.2.4.2 Superchannelling Programming Examples

The example in Figure 34-15 shows the SI RAM programming and the super-channel table for two different transmitter superchannels running on the same TDM interface. One superchannel includes TDM timeslots 1, 6, and 7, which also happen to be programmed to use MCC channel numbers 1, 6, and 7. The second superchannel in this example is comprised of timeslots 2, 3, and 4 using MCC channels 2, 3, and 4. This approach of using a channel number which is the same as the timeslot number is arbitrary and not a requirement.

Note that entries in the superchannel table for MCC channels 1, 6 and 7 all are programmed to point to the channel-specific and channel-extra parameters for channel 1. Superchannel table entries for MCC channels 2, 3 and 4 are programmed such that these channels are managed by the parameters of channel 2.

The superchannel BD tables are associated with channels 1 and 2 (no BD tables are necessary for channels 3, 4, 6, and 7)

Figure 34-15. Transmitter Superchannel Example

In this example, data is expected to be sent on the first timeslots allocated for each superchannel. Thus for the first superchannel, timeslot 1 has CNT=0 and BYT=1, the “first byte” condition and the remaining timeslots that are part of this superchannel—timeslots 6 and 7, have CNT=0x7 and BYT=0. This indicates to the MCC that when this transparent superchannel becomes active it should begin sending data on timeslot 1. If the application required that data not be sent on this superchannel until timeslot 7, for example, then timeslots 1 and 6 have CNT=0x7 and BYT=0 and timeslot 7 would be programmed with CNT=0 and BYT=1.

Similarly, the second superchannel in this example sends data beginning with its first timeslot, timeslot 2. It contains the “first byte” condition of CNT=0 and BYT=1. If the application required a different timeslot in this superchannel, either timeslot 3 or 4, that channel could be programmed to have the “first byte” condition instead.

Figure 34-16 shows the SIRAM programming for transparent receiver superchannels which use slot synchronization. This example assumes a timeslot configuration similar to the transmit example in Figure 34-15. For this receive example, to guarantee that reception begins on the first timeslots for each superchannel, all timeslots that correspond to superchannels are programmed as superchanneled timeslots and the first timeslot for each superchannel is programmed with the “first byte” CNT and BYT conditions.

Note that the receive examples do not include a superchannel table because a superchannel table is only used on the transmit side. Receive SIRAM entries should always be programmed using the channel number of the managing MCC channel for that superchannel (the same MCC channel number used in the superchannel table entries corresponding to the transmit channels for that superchannel). The MCC does not share the individual data channel's hardware resources on the receive side.

Figure 34-16. Receiver Superchannel with Slot Synchronization Example

Figure 34-17 shows the SIRAM programming for the same overall configuration as the previous examples, but in this case it does not matter to the application on which timeslot of a superchannel that reception begins. Thus, slot synchronization is not necessary, the timeslots do not need to be programmed as superchanneled timeslots, and the CNT and BYT fields can be programmed normally.

Note: The superchannel BD tables are associated with channels 1 and 2.

Figure 34-17. Receiver Superchannel without Slot Synchronization Example

34.2.5 MCC Configuration Registers (MCCF)

The MCC configuration register (MCCF), shown in Figure 3-18, defines the mapping of the MCC channels, paired with the serial interface (SI), to the TDM channels. For the MCC-SI, each of the four 32-channel subgroups can be connected to one of the eight TDM highways (TDMA, TDMB, TDMC, TDMD,TDME, TDMF, TDMG, TDMH).

Figure 34-18. SI MCC Configuration Register (MCCF)

NOTE_on backward compatibility

The configuration register is not backward compatible. The QUICC Engine MCC supports 8 TDMs whereas the CPM supports 4 TDMs. As a result, the number of bits needed for the QUICC Engine MCCs configuration was increased from 2 to 4.

Table 34-16 describes MCCF fields.

Table 34-16. MCCF Field Descriptions

Bits	Name	Description
0–2, 4–6, 8–10 12–14, 16–18, 20-22, 24–26,28-30	**GROUP *x***	Group x of channels is used by TDM y as shown in Table 3-19. 000 Group x is used by TDM A. 001 Group x is used by TDM B. 010 Group x is used by TDM C. 011 Group x is used by TDM D. 100 Group x is used by TDM E. 101 Group x is used by TDM F. 110 Group x is used by TDM G. 111 Group x is used by TDM H.

Table 34-17 describes group assignments.

Table 34-17. Group Channel Assignments

Group	Channels
Group1 in MCCF 1	0–31
Group2 in MCCF1	32–63
Group3 in MCCF1	64–95
Group4 in MCCF1	96–127
Group5 in MCCF 1	128–159
Group6 in MCCF1	160–191
Group7 in MCCF1	192–223
Group8 in MCCF1	224–255

NOTE

The TDM group channel assignments made in MCCF must be coherent with the SI register programming and SI RAM programming.The user must also program MCCF before enabling the TDM channel in the SIGMR.

34.2.6 MCC Exceptions

The MCC interrupt reporting scheme has two levels. The circular interrupt tables (illustrated in Figure 34-19) report channel-specific events and are masked by each channel's INTMSK field located in channel-specific parameter RAM. The MCCE event register (described in Section 34.2.6.1, "MCC Event Register (MCCE)/Mask Register (MCCM)") reports some global-level events and whether new activity has taken place in any of the MCC's interrupt tables. These events can be masked by the MCCM.

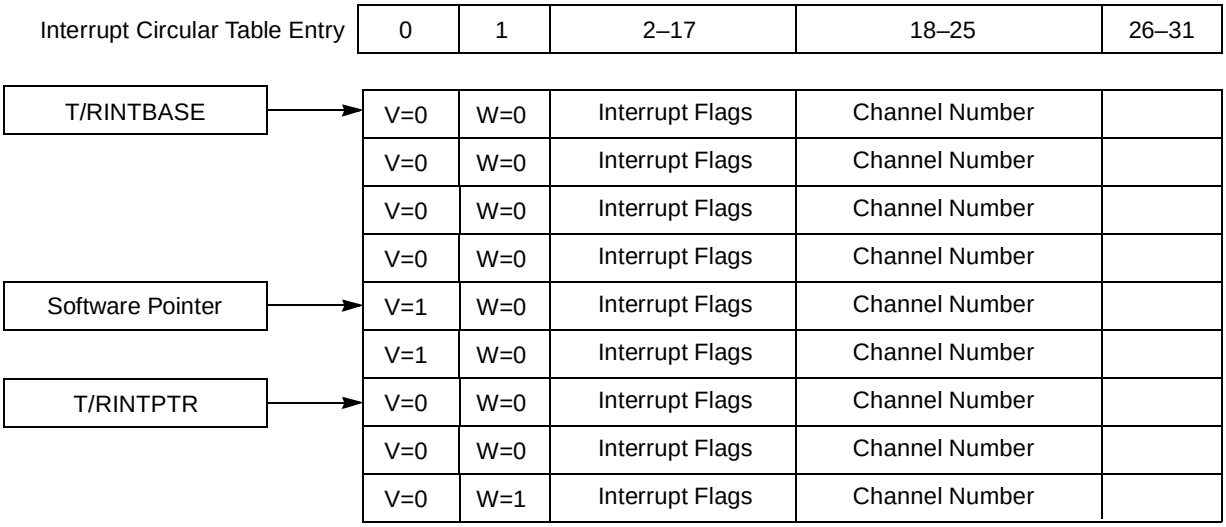

Figure 34-19. Interrupt Circular Table

There is one table for transmitter interrupts and from one to four tables for receiver interrupts. Each channel is programmed to report receiver interrupts in one of the receiver tables. This way receiver interrupts can be sorted, for example, by priority. Each interrupt circular table must be least two entries long.

T/RINTBASE and T/RINTPTR, which are user-initialized global MCC parameters (See Table 34-2"), point to the starting location of the table (in external memory) and the current empty position (initialized at the top of the table) available to the QUICC Engine block. All the entries in the table must be user-initialized with 0x00000000, except for the last one which must be initialized with 0x40000000 (W = 1, thus defining the end of the table). When an MCC channel generates an interrupt request, the QUICC Engine block writes a new entry to the table (with V = 1) and increments T/RINTPTR (if W = 1 for the current entry, T/RINTPTR is loaded with T/RINTBASE).

The circular interrupt tables consist of channel-specific events, with a bit for each possible event as well as the number of the channel reporting that event. Each channel has an INTMSK field that determines which events on that particular channel trigger the creation of a new entry in the interrupt tables. Whenever a new entry is added to an interrupt table, the MCC will set the appropriate TINT or RINTx bit in the MCCE event register, if that bit is properly enabled in MCCM mask register. If there was no room in the interrupt table for a new entry, the corresponding queue overflow bit (QOVx) will be set in the MCCE and the interrupt information is lost, although operation will continue.

After an MCC interrupt reaches the core, the software should read the corresponding MCCE. After clearing the appropriate event bits by writing ones to them, the software may begin processing the table(s) that contain pending events, as indicated by the bits MCCE[RINTx] and MCCE[TINT]. When processing the interrupt tables, the software must clear each entry's valid bit (V) (see Section 34.2.6.2, "Interrupt Circular Table Entry"). The user follows this procedure until it reaches an entry with V = 0. It may not be appropriate for an application to process every new entry of all interrupt tables at once, depending on desired interrupt handler latency or other factors. It is up to the user to determine an interrupt handling scheme that provides desired performance and functionality.

34.2.6.1 MCC Event Register (MCCE)/Mask Register (MCCM)

The MCC event register (MCCE) is used to report events and generate interrupt requests. For each of its flags, a programmable mask/enable bit in MCCM determines whether an interrupt request is generated. The MCC mask register (MCCM) is used to enable/disable interrupt requests. For each flag in the MCCE there is a programmable mask/enable bit in MCCM which determines whether an interrupt request is generated. Setting an MCCM bit enables and clearing an MCCM bit disables the corresponding interrupt.

MCCE bits are cleared by writing ones to them; writing zeros has no effect.

Figure 3-20 shows MCCE and MCCM bits.

Figure 34-20. MCC Event Register (MCCE)/Mask Register (MCCM)

Table 34-18 describes MCCE fields.

Table 34-18. MCCE/MCCM Register Field Descriptions

Bits	Name	Description
0	QOV0	QOVx—Receive interrupt queue overflow. IQOV is set (and an interrupt request generated) by the QUICC Engine block whenever an overflow occurs in the transmit circular interrupt table. This occurs if the QUICC Engine block tries to update an interrupt entry that was not handled by the user (such an entry is identified by V = 1). RINTx—Receive interrupt. When RINT = 1, the MCC generated at least one new entry in the receive interrupt circular table. After clearing it, the user reads the next entry from the receive interrupt circular table and starts processing a specific channel's exception. The user returns from the interrupt handler when it reaches a table entry with V = 0.
1	RINT0	
2	QOV1	
3	RINT1	
4	QOV2	
5	RINT2	
6	QOV3	
7	RINT3	
8–11	—	Reserved, should be cleared.
12	TQOV	Transmit interrupt queue overflow. TQOV is set (and an interrupt request is generated) by the QUICC Engine block whenever an overflow occurs in the transmit circular interrupt table. This condition occurs if the QUICC Engine block attempts to write a new interrupt entry into an entry that was not handled by the user. Such an entry is identified by V = 1.

Table 34-18. MCCE/MCCM Register Field Descriptions (continued)

Bits	Name	Description
13	TINT	Transmit interrupt. When TINT = 1, at least one new entry in the transmit interrupt circular table was generated by MCC. After clearing it, the user reads the next entry from the transmit interrupt circular table and starts processing a specific channel's exception. The user returns from the interrupt handler when it reaches a table entry with V = 0.
14	GUN	Global transmit underrun. This flag indicates whether an underrun occurred inside the MCC's transmit channel array. The user must clear this bit.
15	GOV	Global receiver overrun. This flag indicates whether an overrun occurred inside the MCC's receive channel array. The user must clear this bit.
16–31	—	Reserved, should be cleared.

34.2.6.2 Interrupt Circular Table Entry

Each interrupt circular table entry, shown in Figure 34-19, contains information about channel-specific events. The transmit circular table shows only events caused by transmission; the receive circular tables shows only events caused by reception. The corresponding interrupt mask bits are mode-dependent; refer to the appropriate section:

- Section 34.2.2.1.2, "Interrupt Mask (INTMSK)—HDLC Mode
- Section 34.2.2.2.2, "Interrupt Mask (INTMSK)—Transparent Mode
- Section 34.2.2.3.3, "Interrupt Circular Table Entry and Interrupt Mask (INTMSK)—AAL1 CES
- Section 34.2.2.4.1, "Extended Channel Mode Register (ECHAMR)—SS7 Mode

2 Only used in conjunction with AAL1 CES

Figure 34-21. Interrupt Circular Table Entry

Table 34-19 describes interrupt circular table fields.

Table 34-19. Interrupt Circular Table Entry Field Descriptions

Bits	Name	Description
0	**V**	Valid bit. V = 1 indicates that this entry contains valid interrupt information. Upon generating a new entry, the QUICC Engine block sets V = 1. The user clears V immediately after it reads the interrupt flags of the entry, prior to processing the interrupt. The V bits in the table are user-initialized. During initialization, the user must clear those bits in all table entries.
1	**W**	Wrap bit. W = 1 indicates the last interrupt circular table entry. The next event's entry is written/read (by RISC/user) from the address contained in INTBASE (see Table 34-2). During initialization, the user must clear all W bits in the table except for the last one which must be set.
2	—	Reserved, should be cleared. (If SS7 mode, refer to the following descriptions.)
	OCT	SS7 mode only: N octets received. If the channel is in octet counting, this bit is set when N octets have been received.
3	—	Reserved, should be cleared. (If SS7 mode, refer to the following descriptions.)
	SUERM	SS7 mode only: SU error monitor threshold reached. The SU error monitor has reached the programmed threshold T.
4	FISU	SS7 mode only: FISU transmission started. The CP has started automatic FISU transmission if the first BD of frame does not have its ready bit set and the SEN_FISU bit is enabled in SS7_OPT register. Please refer to SEN_FISU bit in Section 3.2.4.3, "SS7 Configuration Register—SS7 Mode.
	SLIPE	Only used in conjunction with AAL1 CES. Slip End. Set when an MCC channel interworking with an ATM channel exits the slip state (the connection's CESAC falls to the MCC_Start threshold). At this point, the transmitter stops sending the underrun template (or last buffer) and starts sending valid data.
5	—	Reserved, should be cleared.
	SLIPS	Only used in conjunction with AAL1 CES.Slip Start. Set when an MCC channel interworking with an ATM channel enters a slip state (the channel's CESAC reaches the MCC_Stop threshold). At this point the transmitter freezes and begins sending the underrun template (or last buffer) until CESAC falls to the MCC_Start threshold.
6-7	UNTXB	Underrun or Tx Buffer 00 No event 01TXB 10 UN 11 Channel underrun
8	—	Reserved, should be cleared.
9	—	Reserved, should be cleared. (If SS7 mode, refer to the following description.)
	AERM	SS7 mode only: Alignment error rate monitor threshold (M value in SS7 channel-specific parameters) has been reached.
10	NID	Set whenever a pattern that is not an idle pattern is identified.
11	IDL	Idle. Set when the channel's receiver identifies the first occurrence of idle (0xFFFE) after any non-idle pattern.
12	MRF	Maximum receive frame length violation. This interrupt occurs when more bytes are received than the value specified in MFLR. This interrupt is generated as soon as the MFLR value is exceeded; the remainder of the frame is discarded
13	RXF	Rx frame. A complete HDLC frame has been received.
14	BSY	Busy. A frame was received but was discarded due to lack of buffers.

Table 34-19. Interrupt Circular Table Entry Field Descriptions (continued)

Bits	Name	Description
15	RXB	Rx buffer. A buffer has been received on this channel that was not the last buffer in frame. This interrupt is also given for different error types that can happen during reception. Error conditions are reported in the RxBD.
16–17	—	Reserved, should be cleared.
18–25	CN	Channel number. Identifies the requests channel index (0–255).
26–31	—	Reserved, should be cleared.

34.2.7 MCC Buffer Descriptors

Each MCC channel requires two BD tables (one for transmit and one for receive). Each BD contains key information about the buffer it defines. The BDs are accessed by the MCC as needed. BDs can be added dynamically to the BDs chain. The RxBDs chain must include at least two BDs; the TxBD chain must include at least one BDs.

The MCC BDs are located in external memory.

34.2.7.1 Receive Buffer Descriptor (RxBD)

Figure 34-22 shows the RxBD.

Offset + 6																

Figure 34-22. MCC Receive Buffer Descriptor (RxBD)

[1] SS7 mode only. Otherwise, reserved.

RxBD fields are described in Table 34-20.

Table 34-20. RxBD Field Descriptions

Bits	Name	Description
0	**E**	Empty 0 The data buffer associated with this BD has been filled with received data, or data reception has been aborted due to an error condition. The user is free to examine or write to any fields of this RxBD. The QUICC Engine block does not use this BD again while the empty bit remains zero. 1 The data buffer associated with this BD is empty, or reception is in progress. This RxBD and its associated receive buffer are in use by the QUICC Engine block. When E = 1, the user should not write any fields of this RxBD.
1	—	Reserved, should be cleared.

Table 34-20. RxBD Field Descriptions (continued)

Bits	Name	Description
2	**W**	Wrap (final BD in table) 0 This is not the last BD in the RxBD table. 1 This is the last BD in the RxBD table. After this buffer has been used, the QUICC Engine block receives incoming data into the first BD in the table (the BD pointed to by RBASE). The number of RxBDs in this table is programmable and is determined by the wrap bit.
3	**I**	Interrupt 0 The RXB bit is not set after this buffer has been used, but RXF operation remains unaffected. 1 The RXB or RXF bit in the HDLC interrupt circular table entry is set when this buffer has been used by the HDLC controller. These two bits may cause interrupts (if enabled).
4	L	Last in frame (only for HDLC mode of operation). The HDLC controller sets L = 1, when this buffer is the last in a frame. This implies the reception either of a closing flag or of an error, in which case one or more of the CD, OV, AB, and LG bits are set. The HDLC controller writes the number of frame octets to the data length field. 0 This buffer is not the last in a frame. 1 This buffer is the last in a frame.
5	F	First in frame. The HDLC controller sets F = 1 for the first buffer in a frame. In transparent mode, F indicates that there was a synchronization before receiving data in this BD. 0 This is not the first buffer in a frame. 1 This is the first buffer in a frame.
6	**CM**	Continuous mode 0 Normal operation (The empty bit (bit 0) is cleared by the QUICC Engine block after this BD is closed). 1 The empty bit (bit 0) is not cleared by the QUICC Engine block after this BD is closed, allowing the associated data buffer to be overwritten automatically when the QUICC Engine block next accesses this BD. However, if an error occurs during reception, the empty bit is cleared regardless of the CM bit setting.
7	—	Reserved, should be cleared.
8	**UB**	User bit. UB is a user-defined bit that the QUICC Engine block never sets nor clears. The user determines how this bit is used.
9	—	Reserved, should be cleared.
10	LG	Rx frame length violation (HDLC mode only). Indicates that a frame length greater than the maximum value was received in this channel. Only the maximum-allowed number of bytes, MFLR rounded to the nearest higher double word alignment, are written to the data buffer. This event is recognized as soon as the MFLR value is exceeded when data is word-aligned. When data is not word-aligned, this interrupt occurs when the SDMA writes 64 bits to memory. The worst-case latency from MFLR violation until detected is 7 bytes timing for this channel. When MFLR violation is detected, the receiver is still receiving even though the data is discarded. The buffer is closed upon detecting a flag, and this is considered to be the closing flag for this buffer. At this point, LG is set (1) and an interrupt may be generated. The length field for this buffer is everything between the opening flag and this last identifying flag.
11	NO	Rx non octet-aligned frame. A frame of bits not divisible exactly by eight was received. NO = 1 for any type of nonalignment regardless of frame length. The invalid byte is always eliminated from the frame data. Data size reflects only the valid data bytes. A Non octet frame which is smaller than 1 byte is eliminated completely.
12	AB	Rx abort sequence. A minimum of seven consecutive ones was received during frame reception. Abort is not detected between frames. The sequence: Closing-Flag, data, CRC, AB, data, opening-flag... does not cause an abort error. If the abort is long enough to be an idle, an idle line interrupt may be generated. An abort within the frame is not reported by a unique interrupt but rather with a RXF interrupt and the user has to examine the BD.

Table 34-20. RxBD Field Descriptions (continued)

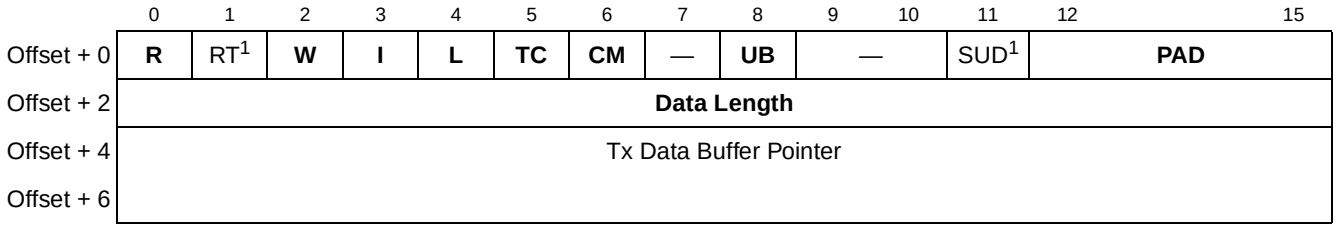
Bits	Name	Description
13	CR	Rx CRC error. This frame contains a CRC error. The received CRC bytes are always written to the receive buffer.
14	—	Reserved, should be cleared.
	SF	SS7 mode only: Short frame indication. Set if the received frame is less than 5 octets.
15	—	Reserved, should be cleared.

The data length and buffer pointer are described as follows:

- Data length. Data length is the number of octets written by the QUICC Engine block into this BD's data buffer. It is written by the QUICC Engine block when the BD is closed. When this is the last BD in the frame (L = 1), the data length contains the total number of frame octets (including two or four bytes for CRC). Note that memory allocated for buffers should be not smaller than the contents of the maximum receive buffer length register (MRBLR). The data length does not include the time stamp.
- Rx buffer pointer. The receive buffer pointer points to the first location of the associated data buffer. This value must be equal to 8*n if CHAMR[TS] = 0 and equal to 8*n - 4 if CHAMR[TS] = 1 (where n is any integer larger than 0).

34.2.7.2 Transmit Buffer Descriptor (TxBD)

Figure 34-23 shows the TxBD.



[1] SS7 mode only. Otherwise, reserved.

Figure 34-23. Transmit Buffer Descriptor (TxBD)

Table 34-21 describes TxBD fields.

Table 34-21. TxBD Field Descriptions

Bits	Name	Description
0	**R**	Ready 0 The buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated data buffer. The QUICC Engine block clears this bit after the buffer has been transmitted or after an error condition is encountered. 1 The data buffer is ready to be transmitted. The transmission may have begun, but it has not completed. The user cannot modify this BD once this bit is set.

Table 34-21. TxBD Field Descriptions (continued)

Bits	Name	Description
1	RT	SS7 mode only: Retransmit. 0 Normal operation 1 The QUICC Engine block repeats transmission of this BD until the RT bit is cleared. After the RT bit is cleared the QUICC Engine block advances to the next BD in the table. This feature is useful for automatic LSSU retransmission. **Note:** This bit is reserved in all other modes of operation.
2	**W**	Wrap (final BD in table) 0 This is not the last BD in the TxBD table. 1 This is the last BD in the TxBD table. After this buffer is used, the RISC receives incoming data into the first BD in the table (the BD pointed to by TBASE). The number of TxBDs in this table is programmable and determines which BD should contain the wrap bit.
3	**I**	Interrupt 0 No interrupt is generated after this buffer has been serviced. 1 TXB in the circular interrupt circular table entry is set when this buffer has been serviced by the MCC. This bit can cause an interrupt, if enabled.
4	**L**	Last 0 This is not the last buffer in the frame. 1 This is the last buffer in the current frame.
5	**TC**	Tx CRC. Valid only when L = 1. Otherwise it is ignored. 0 Transmit the closing flag after the last data byte. This setting can be used for testing purposes by sending an erroneous CRC after the data. 1 Transmit the CRC sequence after the last data byte.
6	**CM**	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear the ready bit after this BD is closed, allowing the associated data buffer to be retransmitted automatically when the QUICC Engine block next accesses this BD. However, the R bit is cleared if an error occurs during transmission, regardless of the CM bit setting.
7	—	Reserved, should be cleared.
8	**UB**	User bit. UB is a user-defined bit that the QUICC Engine block never sets nor clears. The user determines how this bit is used.
9–10	—	Reserved, should be cleared.
11	—	Reserved, should be cleared.
	SUD	SS7 mode only: Signal unit delay 0 This buffer does not have a transmission delay. 1 A time delay of JTTDelay x 512 µs passes before this buffer is transmitted. Can be used for LSSU transmission according to the JT Q.703 Standard which defines a 24 ms delay between back-to-back LSSUs. This bit is only valid when SS7_OPT[STD] is set.
12–15	**PAD**	Pad characters. These four bits indicate the number of PAD characters (0x7E or 0xFF depending on the IDLM mode selected in the CHAMR register) that the transmitter sends after the closing flag.

The data length and buffer pointer are described below:

- Data length. The data length is the number of bytes the MCC should transmit from this BD’s data buffer. It is never modified by the RISC. The value of this field should be greater than zero.

- Tx buffer pointer. The transmit buffer pointer, which contains the address of the associated data buffer, may be even or odd. The buffer must reside in external memory. This value is never modified by the RISC.

34.2.8 MCC Emergency Request Level (MERL)

The MCC offers flexible options to determine when the MCC will go into emergency mode, providing system optimization.

Figure 34-24 shows the MCC Emergency Request Level (MERL) register.

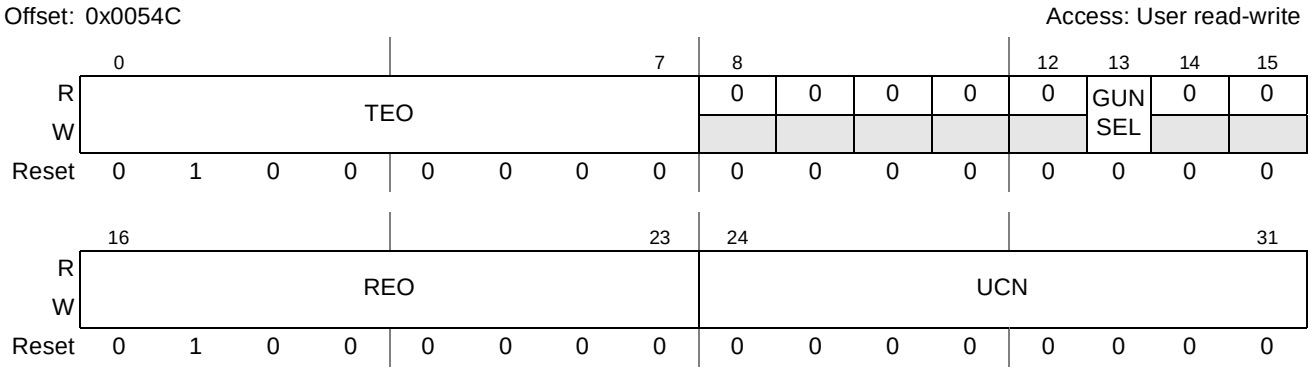


Figure 34-24. MCC Emergency Request Level (MERL)

Table 34-22 describes the MERL register.

Table 34-22. MCC Emergency Request Level (MERL)

Bits	Name	Description
0–7	TEO	Transmit Emergency Offset is an offset from the beginning of the transmitter request FIFO. The offset is actually the amount of data in the request FIFO. Emergency request will be asserted when the amount of data in the request FIFO equals the amount or more. The FIFO has 256 requests. There are 2 special cases. • The TEO is equal to 11111111- The MCC Tx will never work in emergency regime. • The TEO is equal to 00000000 - The MCC Tx will always be in emergency regime.
8–12	Reserved	Must be zero.
13	GUN SEL	GUN SEL- Global Underrun Select 0- GUN - If the transmitter has an underrun in one of it's channels the transmitter will transmit idles until reset. 1- An indication will be given as to the specific channel number that has an underrun. The line may see a period of idles, followed by old data, followed by idles again.
14–15	Reserved	Must be zero.

Bits	Name	Description
16–23	REO	Receive Emergency Offset is an offset from the beginning of the receive request FIFO. The offset is actually the amount of data in the request FIFO. Emergency request will be asserted when the amount of data in the request FIFO equals this amount or less. The FIFO has 256 requests. There are 2 special cases. • The REO is equal to 11111111- The MCC Rx will never work in emergency regime. • The REO is equal to 00000000 - The MCC Rx will always be in emergency regime.
24–31	UCN	Underrun Channel Number - During an underrun, the UCN will contain the most recent channel number that caused an underrun.

NOTE

The MERL provides the capability of raising the priority of the MCC in an application, and may therefore benefit from tweaking these settings with the system fully loaded to discover how to best optimize that specific system. The recommended initial setting values of this register is half the number of active channels in system. The default value is 64 which is the equivalent of a quarter of an E1 line of requests in each TDM.

34.3 MCC Commands

The user starts channels by writing to the TSTATE/RSTATE registers as described in Section 34.2.2.1.4, “Internal Receiver State (RSTATE)—HDLC Mode,” and Section 34.2.2.1.1, “Internal Transmitter State (TSTATE)—HDLC Mode.”

The following commands, used to stop and initialize channels, are issued to the MCC by writing to the CECR as described in “QUICC Engine Command Register (CECR).” All MCC channels must be initialized using one of the following commands before being used in an active TDM.

Table 34-23. MCC Commands

Command	Description
INIT RX AND TX[1]	Performs both INIT RX and INIT TX commands contiguously, using the channel number supplied with the command.
INIT RX[1]	Initializes MCC receive FIFOs in groups of 32 channels, the command initializes the group with the channel number programmed in the CECR[MCN] field when the command is issued. This command should only be issued when the channels are disabled. To initialize more than 32 channels, reissue the command with the appropriate channel numbers. The INIT TX AND RX command may be used to initialize both the receive and transmit sides of an MCC channel at the same time. Note that this command will initialize the first 16 channels to be preloaded to receive 8 bits, and the second set of channels will be preloaded to receive 16 bits. This is done to stagger when channels require servicing and spread out QUICC Engine block loading.
INIT TX[1]	Initializes MCC transmit FIFOs in groups of 32 channels, the command initializes the group with the channel number programmed in the CECR[MCN] field when the command is issued. This command should only be issued when the channels are disabled. To initialize more than 32 channels, reissue the command with the appropriate channel numbers. The INIT TX AND RX command may be used to initialize both the receive and transmit sides of an MCC channel at the same time. Note that this command will initialize the first 8channels to be preloaded with 16 bits of idle, and the second set of channels will be preloaded with 16 bits of idle. This is done to stagger when channels require servicing and spread out QUICC Engine block loading.

Table 34-23. MCC Commands

Command	Description
[2]INIT TX AND RX[1] (16 BITS)	Same as regular INIT RX AND TX, except that all channels are equally preloaded with idle. For applications in which all channels must begin sending or receiving data in the same TDM frame.
INIT TX, ONE[1] CHANNEL	Performs the INIT TX command but only for the channel number programmed in CECR[MCN] as opposed to initializing 32 channels at once.
INIT RX, ONE[1] CHANNEL	Performs the INIT RX command but only for the channel number programmed in CECR[MCN] as opposed to initializing 32 channels at once.
MCC RESET	Initializes the state machine hardware of the MCC indicated in CECR[PAGE] and CECR[SBC]. It has the same effect on the MCC block that a QUICC Engine block reset does. Required after the GUN or GOV MCC event occurs.
STOP TRANSMIT	Disables the transmission on the selected channel and clears CHAMR[POL]. When this command is issued in the middle of a frame, the QUICC Engine block sends an ABORT indication and then idles/flags on the selected channel. If this command is issued between frames, the QUICC Engine block sends only idles or flags (depending on CHAMR[IDLM]). TBPTR points to the buffer that the QUICC Engine block was using when the STOP TRANSMIT command was issued.
STOP RECEIVE	Forces the receiver of the selected channel to terminate reception. After this command is executed, the QUICC Engine block does not change the receive parameters in the multi-port RAM. The user must initialize the channel receive parameters in order to restart reception.

1 The INIT PARAMETERS style commands are also used to reset the MCC channel internal HW and these commands need to be issued to cover any channel number used, whether used normally or as part of a superchannel.

2 This init should be used when working with 16 bit entries for supper channel in order to avoid GUN or CUN.

34.4 MCC Initialization Information

The MCC must be initialized and started/stopped in relation with the corresponding TDMs. The following two sections present the initialization and start/stop sequences which must be followed for single channels and superchannels.

The following is a general sequence for initializing an MCC and its channels after reset:

1. Program the parallel I/O port interface for the TDM to be used, see Section 3.4, “Parallel I/O Ports.”.
2. Program the SIU’s interrupt controller to mask or enable MCC-related interrupts as desired, see Section 19.2, “Interrupt Controller.”
3. Program the SI’s SIRAM and related registers. If the user wishes to enable the TDM at this time, the SIRAM programming cannot yet contain MCC-related timeslots. Those timeslots should be NULL entries and not be programmed for MCC usage until after MCC-related initialization is complete. Refer to Chapter 36, “Serial Interface with Time-Slot Assigner,” for SI programming details.
4. Initialize buffer descriptors and data buffers as needed.
5. Initialize all MCC global parameters.
6. Initialize MCC channel-specific parameters for channels to be used. (Note that TSTATE and RSTATE can be fully programmed here to begin data transmission and reception as soon as the TDM is enabled. If a user wishes to wait until after the TDM is enabled before starting data

transmission and reception, the user may program only the FCR portions of RSTATE and TSTATE; and STOP TX and STOP RX commands should be issued for the appropriate channels before enabling the TDM.)

7. Initialize MCC channel-extra parameters for channels to be used.
8. Initialize Superchannel Table if superchannels are to be used.
9. Issue MCC INIT commands as appropriate to make sure all MCC FIFOs that are to be used are initialized.
10. Enable TDM (or if TDM is already enabled, the user may now reprogram the TDM to include MCC-related timeslots. This programming is done in the SI).
11. If the user did not program a channel's TSTATE and RSTATE in step 6 to begin data transmission and reception immediately upon having an active TDM, the user may program the start conditions at this time.

NOTE

Some steps may be performed out of order. However it is critical, regardless of their relative sequence, that steps 5, 6, 7, 8 and 9 occur before the enabling of the TDM or an active TDM is reprogrammed to include MCC-related timeslots. Failure to properly initialize MCC parameters and issue appropriate INIT commands before MCC-related timeslots are programmed in an active TDM may result in spurious GUN events or other anomalous behavior.

34.4.1 Stopping and Restarting a Single-Channel

The following sequence must be followed to stop a single channel in order to change the SI without using the shadow SI:

1. Issue a STOP command for the respective channel as described in Section 34.3, "MCC Commands," or change the associated SI RAM entry to point to a channel which is not active and wait for two frame periods in order to clear the internal FIFOs.
2. Change the channel parameters.
3. Enable the MCC channel(s) as described in Section 34.2.2.1.1, "Internal Transmitter State (TSTATE)—HDLC Mode," and Section 34.2.2.1.4, "Internal Receiver State (RSTATE)—HDLC Mode." or change the associated SI RAM entry to point to the respective channel.

It is possible to change the SI using the SI shadow while the channel is active. Both the primary and the shadow configuration of the SI RAM must observe the configuration defined in MCCF (see Section 34.2.5, "MCC Configuration Registers (MCCF)")". The MCCF cannot be changed while there are active channels.

The following sequence must be followed to stop a single channel in order to change the MCC parameters of the respective channel:

1. Issue a STOP command for the respective channel as described in Section 34.3, "MCC Commands,".
2. Change the SI.

3. Enable the MCC channel(s) as described in Section 34.2.2.1.1, “Internal Transmitter State (TSTATE)—HDLC Mode,” and Section 34.2.2.1.4, “Internal Receiver State (RSTATE)—HDLC Mode.”

34.4.2 Stopping and Restarting a Superchannel

The following sequence must be followed to stop a superchannel in order to change the SI:

1. Issue a STOP command for the respective channel as described in Section 34.3, “MCC Commands.”
2. Disable the TDM.
3. Change the SI.
4. Enable the TDM.
5. If necessary, change the MCC parameters (in MURAM and external memory).
6. Enable the MCC channel(s) as described in Section 34.2.2.1.1, “Internal Transmitter State (TSTATE)—HDLC Mode,” and Section 34.2.2.1.4, “Internal Receiver State (RSTATE)—HDLC Mode.”

Channels can’t be added dynamically to a Superchannel. The Superchannel must be deactivated, initialized with the new channels and only then reactivated. Shadow RAM maybe used to change the frame dynamically.

34.4.3 Global Underrun and Channel Underrun Recovery Routine

The MCC has 2 ways of handling a transmitter data underrun. The first is global underrun that views the lack of data as a critical error that must result in resetting the whole MCC. This is usually true if the underrun occurs due to performance issues.

The second way is channel underrun that handles only the specific channel that has no data. This is recommended only for systems with stable performance.

During a channel underrun, the Tx data line will be pulled to idles only during that channel’s period in the TDM line. The channel number will appear in MERL[16:23], see Section 34.2.8, “MCC Emergency Request Level (MERL).”

34.4.3.1 GUN RECOVERY

- Issue a RESET HOST command or a total RESET to the Device.
- Execute a full MCC initialization.

34.4.3.2 Channel Underrun RECOVERY

- Issue STOP TX to that channel.
- Execute the MCC initialization for that specific channel.
- Issue RESTART sequence.

34.4.4 Global Overrun Recovery Routine

Global overrun is a situation where there is overflow in the Rx data buffers resulting in data corruption. The recovery routine is similar to that of Global Underrun.

- Issue a RESET HOST command or a total RESET to the Device.
- Execute a full MCC initialization.

Chapter 35
ATM AAL1 Circuit Emulation Service

This chapter describes implementation of circuit emulation service (CES) using ATM adaptation layer type 1 (AAL1) on the QUICC Engine block and should be used as a supplement to Chapter 32, "ATM Controller AAL0, AAL1, and AAL5."

35.1 Features

The AAL1 CES features on the QUICC Engine block are as follows:

- AAL1
  - — Reassembly
    - – Reassembles PDU directly to external memory
    - – Supports partially filled cells (configurable on a per-VC basis)
    - – Sequence number (SN) protection (CRC-3 and parity) check
    - – Implements a 3-step SN algorithm
    - – Detects and handles lost or misinserted cell
    - – Maintains bit count integrity (dummy cell insertion)
    - – Dummy cell contents can be programmed by the user (per UCC)
    - – Pointer verification in structured AAL1 cell format
    - – Automatic synchronization using the structured pointer during reassembly
    - – SRTS (synchronous residual time stamp) gathering on every cycle (8 cells) in unstructured AAL1
    - – Statistics gathering on a per-VC basis:
      - – AAL1 valid cell count
      - – AAL1 lost cell count
      - – AAL1 misinserted cell count
      - – AAL1 pointer mismatch/parity error
      - – AAL1 Rx buffer pre-overflow
  - — Segmentation
    - – Segment PDU directly from external memory
    - – Partially filled cells support (configurable on a per-VC basis)
    - – Sequence number generation
    - – Sequence number protection (CRC-3 and even parity) generation
    - – Pointer generation during segmentation in structure AAL1 cell format

  - Clock recovery using external SRTS logic during reassembly in unstructured AAL1
  - Statistics gathering on a per-VC basis:
    - AAL1 Tx cell count
    - AAL1 Tx buffer underrun

- Circuit emulation service (CES)
  - ATM to TDM
    - Structured and unstructured data are transferred between the ATM and MCC automatically without CPU intervention
    - In case of pre-underrun, the MCC start sending the last frame or the user-defined underrun template. The MCC and ATM controller automatically perform slip control with no CPU intervention.
    - In case of pre-overrun, the ATM receiver discards incoming cells until the MCC transmitter empties enough buffers for the receiver to restart.
    - Supports common channel signaling (CCS)
    - Supports channel associated signaling (CAS)
      - Up to 4 (one per trunk) CAS blocks residing in internal RAM when in automatic CAS mode and up to 8 blocks when in core CAS modify mode
      - Supports Nx64 E1/T1 channels
      - CAS routing table on per-VC basis
      - Automatic un-packing of the CAS information during reassembly and updating of the internal CAS block
  - TDM to ATM
    - Structured and unstructured data are automatically transferred between the MCC and ATM controller without CPU intervention
    - Supports common channel signaling (CCS)
    - Supports channel associated signaling (CAS)
      - Up to 4 (one per trunk) CAS blocks residing in internal RAM when in automatic CAS mode and up to 8 blocks when in core CAS modify mode
      - Support Nx64 E1/T1 channels
      - CAS routing table on per-VC basis
      - Automatic packing of CAS information from internal RAM to AAL1 Tx cells
      - Once per superframe, the QUICC Engine block fetches the CAS information from an external framer and updates each internal CAS block.

35.2 AAL1 CES Transmitter Overview

The QUICC Engine block supports both structured and unstructured AAL1 cell formats. For unstructured format, the transmitter reads 47 bytes from the external buffer and inserts them into the AAL1 user data field. For structured format, the transmitter reads 46 or 47 bytes from the external buffer and inserts them into the AAL1 user data field.

35.2.1 Data Path

The AAL1 PDU header, which consists of the sequence number (SN) and the sequence number protection (SNP) (CRC-3 and parity bit), is generated and inserted into the AAL1 Tx cell, as shown in Figure 35-1.

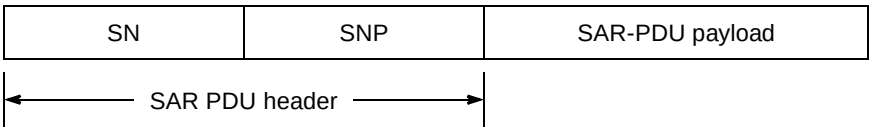

Figure 35-1. AAL1 Transmit Cell Format

When the transmitter operates in structured data transfer (SDT) mode, two types of AAL1 cells are defined: P (pointer) format and non-P format. The two formats are shown below.

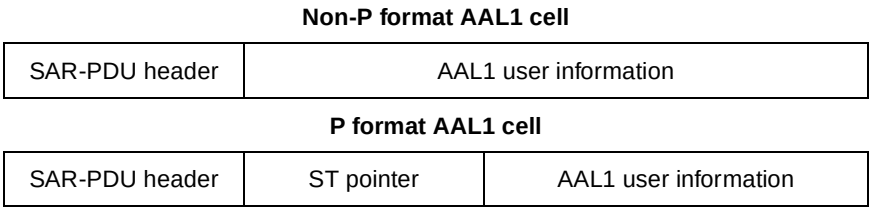

Figure 35-2. AAL1 SDT Cell Types

The transmitter generates the structured pointer according to the I.363.1 ITU standard and inserts the pointer exactly once every cycle (eight successive cells). The transmitter will insert the structured pointer, at the first opportunity, into a cell with an even sequence count (SC). When the end of the structure is not present in the current cycle, a P-format cell with a dummy pointer (127) is inserted into the last cell (SC=6) of the cycle.

The QUICC Engine block supports partially filled cells configured on a per-VC basis. In this mode, only the valid octets are filled with user information; the rest of the cell is filled with padding octets.

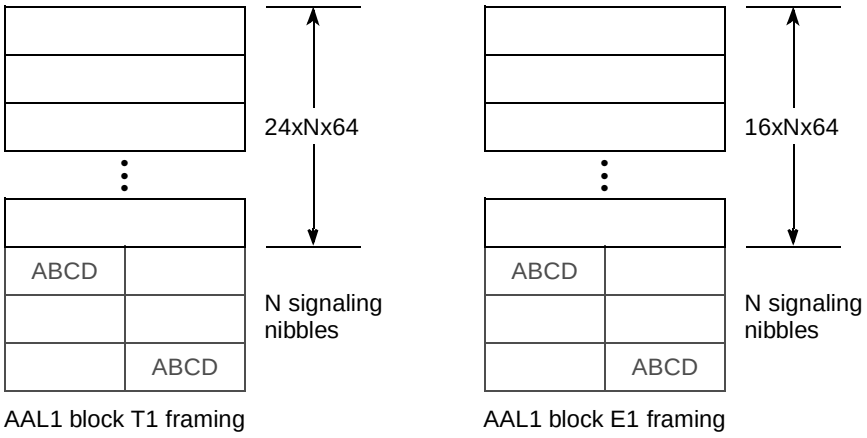
The QUICC Engine block supports synchronous residual time stamp (SRTS) generation using an external PLL. If this mode is enabled, the QUICC Engine block reads the SRTS code from external logic and inserts it into four outgoing cells. See Section 32.2.22.4.1, “SRTS Generation and Clock Recovery Using External Logic.”

35.2.2 Signaling Path

The QUICC Engine block automatically handles the signaling information as part of the interworking function. The ATM transmitter packs the signaling information at the end of each superframe during the data segmentation process. Each VC is associated to one signaling block by an internal routing table; see Section 35.4.6, “Channel Associated Signaling (CAS) Support.” The signaling information that resides in the internal RAM is inserted into the AAL1 cell according to the af-vtoa-0078 specification.

The AAL1 structure is divided into two sections. The first section carries the Nx64 payload, and the second carries the signaling bits that are associated with the payload.

The QUICC Engine block supports two framing modes: one for Nx64 DS1 ESF (extended superframe) framing, and the other for Nx64 E1 G.704 framing. See Figure 35-3. Each of the internal signaling blocks can be used to deliver only one of the framing formats; that is, they cannot be changed dynamically.



Note: The CAS block size is (N+1) nibble if N is an odd number.

Figure 35-3. AAL1 Framing Formats

35.3 AAL1 CES Receiver Overview

The ATM controller supports both AAL1 structured and unstructured formats. For the unstructured format, 47 octets are copied to the current receive buffer and for the structured format, 46 (P format) or 47 (non-P format) octets are copied to the current receive buffer.

The AAL1 PDU header, which consists of the sequence number (SN) and the sequence number protection (SNP) (CRC-3 and parity bit), is checked and the result is delivered to the 3-step-SN algorithm. The 3-step-SN algorithm (see Section 35.6.1, “The Three States of the Algorithm”) handles the lost or misinserted cells. This algorithm can detect one lost or misinserted cell and maintain synchronization. If more than one cell is lost or misinserted, the 3-step-SN algorithm switches to hunt mode where it stays until a cell with a valid SN field is received. After the receiver switches to hunt mode, it closes the RxBD, modifies the receive statistics, generates an optional interrupt to the CPU and performs a restart sequence.

The restart sequence is implemented only when the ATM channel works in CES mode (RCT[CESM]). In CAS mode (RCT[CASM]), the ATM receiver channel begins the restart sequence by dropping all incoming cells and advancing to the beginning of the next super frame, which is the first BD after the one marked with EOSF (end of super frame). When this BD is ready and the adaptive counter reaches the ATM_Start threshold, the receiver’s write pointer is no longer in danger of overrunning the read pointer of the MCC transmitter; that is, it is safe to begin receiving cells again. The ATM receiver then begins the resynchronization process: for unstructured AAL1 type the ATM receiver waits for the first valid cell, and for structured AAL1 type the receiver waits for the first valid cell that contains a valid pointer. The first received octet becomes the first byte of the new BD (new super frame). (See Section 35.5, “ATM-to-TDM Adaptive Slip Control” and Section 35.4, “Interworking Functions.”)

Note that when the ATM channel is not in CES mode, no restart sequence is performed; the ATM receiver immediately starts hunting for the first valid cell. The first received octet becomes the first byte of the next BD.

During reassembly, the ATM receiver channel's 3-step-SN algorithm status is delivered to the pointer verification mechanism. (See Section 35.7, "Pointer Verification Mechanism.") If the receiver operates in unstructured data format, the 3-step-SN algorithm status is delivered directly to the bit count integrity module. When partially filled cells arrive, the bit count integrity module copies only the valid octets from the received cell (or from the dummy cell if that cell is lost) to the current receive buffer.

In unstructured AAL1 format, when the receive process begins, the receiver hunts for the first cell with a valid sequence number (SN field). When one arrives, the receiver leaves the hunt state and begins receiving incoming cells.

In structured AAL1 format, when the receive process begins, the receiver hunts for the first cell with a valid structured pointer (valid pointers range between 0 and 93 inclusive, and the dummy pointer is 127) that points to the start of a new structure. When one arrives, the receiver leaves the hunt state, opens a new buffer and begins receiving. The structured pointer points to the first octet of the structured block, which then becomes the first byte of the new buffer.

During the reassembly process, if the receiver switches to hunt mode (due to the 3-step-SN algorithm or due to receiving two successive mismatched pointers), the ATM receiver closes the current RxBD, discards incoming cells, modifies the receive statistics accordingly and initiates a restart sequence. The receiver then waits for a cell with a valid structured pointer to regain synchronization and start receiving incoming cells again.

The QUICC Engine block supports SRTS clock recovery using an external PLL (SRTS mode applicable only in unstructured mode). The QUICC Engine block tracks the SRTS from the four incoming cells and writes the SRTS code to external logic. See Section 32.2.22.4.1, "SRTS Generation and Clock Recovery Using External Logic." The data flow for an AAL1 CES receiver is summarized in Figure 35-4.

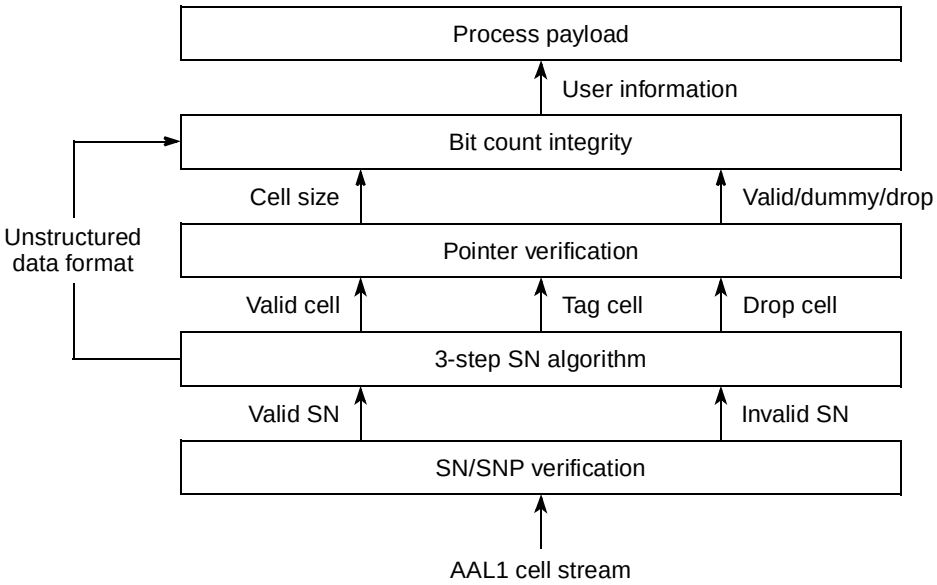


Figure 35-4. AAL1 CES Receiver Data flow

35.4 Interworking Functions

The QUICC Engine block supports the interworking of ATM and TDM. The TDM data processing is done by the MCC and the SI (refer to Chapter 34, "Multi-Channel Controller (MCC)," and Chapter 36, "Serial Interface with Time-Slot Assigner," for further information). The ATM controller processes the ATM data.

Data forwarding between the ATM controller and the MCC can be done in two ways:

- Automatic data forwarding. This mode enables automatic data forwarding between AAL1 and transparent mode over a TDM.
- Core intervention. When an MCC receive buffer is full and its RxBD is closed, the MCC interrupts the core. The core copies the MCC's receive buffer pointer to an ATM TxBD and sets the ready bit (TxBD[R]). Similarly, when an ATM receive buffer is full and its RxBD is closed, the core services the ATM controller's interrupt by copying the ATM receive buffer pointer to an MCC TxBD and setting TxBD[R]. This mode is useful when additional core processing is required.

Possible interworking applications are as follows:

- Circuit emulation service (CES)
- Carrying voice over ATM
- Multiplexing low speed services, such as voice and data, onto one ATM connection

35.4.1 Automatic Data Forwarding

The basic concept of automatic data forwarding is to program the ATM controller and the MCC to process the same BD table (ring).

The MCC and ATM receivers must be programmed to operate in opposite E-bit polarity. That is, both receivers receive into buffers in which RxBD[E] = 0 and then set RxBD[E] when the buffer is full. For the ATM receiver, set RCT[INVE] of the AAL1 CES-specific areas of the receive connection table; see Section 35.9.1, "Receive Connection Table (RCT)." For the MCC receiver, set CHAMR[EP].

35.4.1.1 ATM-to-TDM

When going from ATM to TDM (depicted in Figure 35-5), the ATM receiver reassembles data received from a particular channel to a specific BD table. The MCC transmitter is programmed to operate on the same table. When the ATM controller fills a receive buffer, the MCC controller sends it. The controllers synchronize on the ATM controller's RxBD[E] and the MCC's TxBD[R].

A threshold mechanism for the MCC transmitter is used to synchronize the automatic start of the ATM-to-TDM data forwarding. The transmitter waits until the start threshold is reached (enough cells are received) before sending the valid data. In effect, the MCC start threshold mechanism implements a jitter buffer designed to accommodate the CDV of the ATM network.

In a CES application, software should first initialize the MCC transmitter, then initialize the ATM receiver. This way the MCC transmitter sends idle data (0xFF) until the ATM receiver fills enough buffers to reach the MCC start threshold. (The receiver is effectively filling a jitter buffer.) When the CES_Adaptive_Counter (CESAC) reaches the MCC_Start threshold, the MCC super channel polling CESAC starts sending the received data with the first frame SYNC. (The first octet using the first BD is

sent on the first assigned time slot.) Section 35.5, "ATM-to-TDM Adaptive Slip Control," shows the flow of ATM-to-TDM interworking.

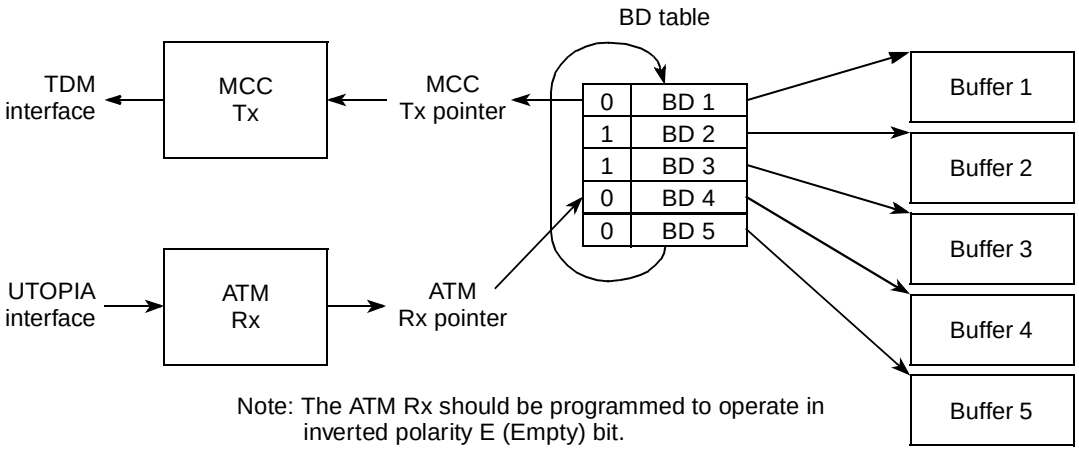

Figure 35-5. ATM-to-TDM Interworking

35.4.1.2 TDM-to-ATM

When going from TDM to ATM (depicted in Figure 35-6), the MCC receiver routes data from the TDM line to a specific BD table. The ATM transmitter is programmed to operate on the same BD table. When the MCC fills a receive buffer, the ATM controller sends it. The two controllers synchronize on the MCC's RxBD[E] and the ATM controller's TxBD[R].

In a CES application, first initialize the ATM transmitter, then initialize the MCC receiver and set CHAMR[EP].

In order to prevent an overrun condition on the MCC receiver, the ATM transmitter should be programmed to work at a faster rate than the MCC super channel. This ensures that the ATM channel polls the common BD table at a higher rate than it is being filled by the MCC. In CES mode, the ATM controller ignores BSY (busy) events when the ATM tries to open a buffer that is not yet full; it continues polling the BD until the buffer is filled by the MCC receiver and then updates the relevant statistics; see Section 35.15, "Internal AAL1 CES Statistics Tables."

Note that if an overrun condition occurs on the MCC, despite the above mechanism, software should restart the MCC and ATM channels in order to recover.

Figure 35-6 shows the flow of TDM-to-ATM interworking.

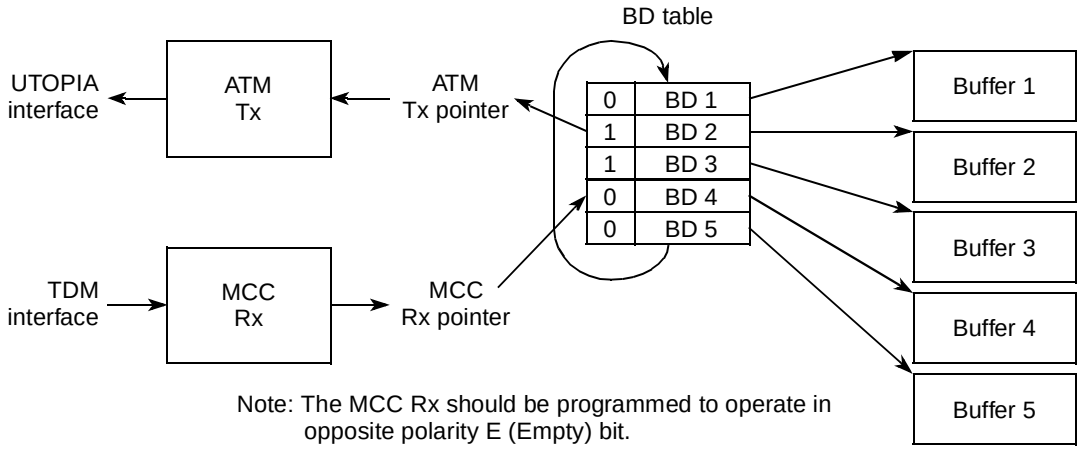

Figure 35-6. TDM-to-ATM Interworking

35.4.2 Timing Issues

Use of the TDM interface assumes that all communicating entities are synchronized; that is, that they are using a synchronized serial clock. If the TDM interfaces are not synchronized, a slip can occur in the reassembly buffer. In order to prevent the overrun and underrun condition, the QUICC Engine block maintains an adaptive slip control using a set of 4 threshold pointers and a counter for each ATM-TDM (VC to super channel) connection.

Before a buffer-not-ready event (ATM-to-TDM data forwarding) occurs at the MCC transmitter, the MCC buffer pointer reaches the MCC_Stop threshold. Consequently, the MCC pointer freezes on the last transmitted BD and starts sending the underrun template (or the last transmitted frame). In the meantime, the ATM receiver continues to write valid data and advance the ATM buffer pointer. When the adaptive counter CESAC reaches the MCC_start threshold and the MCC has finished sending a multiple frame size, the MCC exits the pre-underrun state, advances BD pointer, reads the new BD pointer and starts sending the valid received data. (Refer to Section 35.5, “ATM-to-TDM Adaptive Slip Control.”)

The same mechanism is implemented on the ATM side. When the ATM receiver (ATM-to-TDM data forwarding) reaches the ATM_Stop threshold (pre-overrun), the ATM controller switches to hunt mode and discards the channel’s incoming cells. In the meantime, the MCC transmitter continues to send valid data and advance the MCC buffer pointer. When CESAC falls to the ATM_start threshold, the ATM write pointer is advanced to the first BD after the one marked with EOSF (in CAS mode). When this BD is ready and CESAC reaches the ATM_Start threshold, the receiver’s write pointer is not longer in danger of overrunning the read pointer of the MCC transmitter; that is, it is safe to begin receiving cells again. The ATM receiver then begins the resynchronization process: for unstructured AAL1 type the ATM receiver waits for the first valid cell, and for structured AAL1 type the receiver waits for the first valid cell that contains a valid pointer. The first received octet becomes the first byte of the new BD (new super frame). (Refer to Section 35.5, “ATM-to-TDM Adaptive Slip Control.”)

Note that when the ATM receiver is in hunt mode due to one of the following:

- Sequence number protection error (SNPE)

- Sequence count error (SCE)
- Structured pointer error (SPE)
- Slip condition

The signaling information (CAS) and SRTS information is not updated by the ATM controller until the ATM receiver switches to SYNC mode, that is, a valid cell is received in unstructured cell format or a valid pointer is received in structured cell formats.

Software should distinguish between the two types of overrun and underrun conditions:

7. The MCC and ATM controller can automatically recover from overruns and underruns caused by slips without any CPU intervention. (See Section 35.5, “ATM-to-TDM Adaptive Slip Control.”)
8. Global underrun (MCCE[GUN]) and overrun (MCCE[GOV]) conditions are errors that need CPU intervention because it is not known which channels are affected. The CPU should accordingly reinitialize the transmit parameters and/or the receive parameters to recover.

35.4.3 Clock Synchronization (SRTS, Adaptive FIFO)

Clock synchronization methods, such as SRTS and adaptive FIFO, may be used to prevent reassembly buffer slip. The SRTS method may be implemented using external logic. The QUICC Engine block can read the SRTS from external logic and insert it into outgoing AAL1 cells and conversely, can track the SRTS from incoming AAL1 cells and deliver it to external logic. See Section 32.2.22.4.1, “SRTS Generation and Clock Recovery Using External Logic.”

Alternatively, an adaptive FIFO method can be implemented under core control. Adaptive FIFO is a way to hold the bridging buffer at its mid-level point. One way to implement it is to periodically poll the adaptive counter CESAC (difference between the MCC and ATM data pointers) and use this difference as a pseudo-SRTS; see Section 35.5.1, “CES Adaptive Threshold Tables.” Writing the pseudo-SRTS to the same external PLL logic used in the SRTS method adjusts the TDM clock.

35.4.4 Mapping TDM Time Slots to VCs

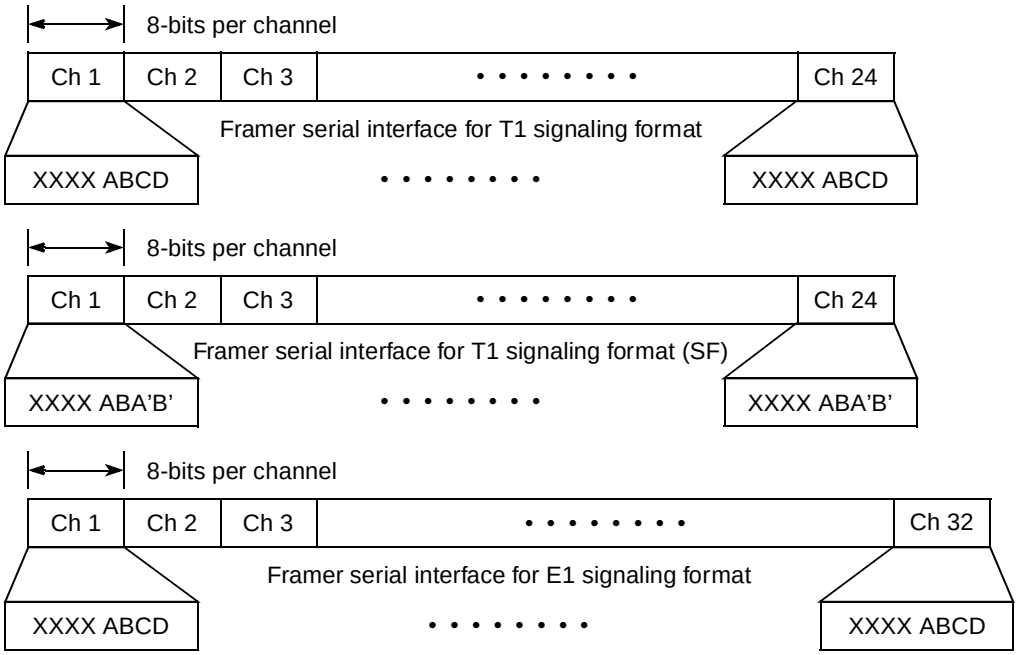
Any TDM time-slot combination can be routed to a specific data buffer using the MCC and its SI. (Refer to Chapter 34, “Multi-Channel Controller (MCC),” and Chapter 36, “Serial Interface with Time-Slot Assigner,” for further information.) A common set of data buffers (one BD table) should be used by the ATM controller to route both the receive and transmit data. For information about ATM buffers see Section 35.11, “Buffer Descriptors.”

35.4.5 Trunk Condition

According to the Bellcore standard, the interworking function should be able to transmit special payloads on both the ATM and TDM channels to signal alarm conditions (bellcore TR-NWT-000170). The trunk condition can be generated under core control. The core may deliver buffers containing special data (trunk condition payload) to the ATM controller or MCC or even overwrite data buffers being used by the channels.

35.4.6 Channel Associated Signaling (CAS) Support

For applications requiring channel associated signaling (CAS) support, the CAS manipulation is done by an external framer. The MCC should be programmed to receive or transmit the internal CAS block transparently through the external framer's serial interface. The internal CAS block (depicted in Figure 35-8) can be adjusted to comply with a specific framer's serial interface. (See Section 35.4.7.1, "CAS Routing Table.")



Note: The MCC should capture the signaling data on the last frame of a super frame. See Section 1.4.7.2, "TDM-to-ATM CAS Support".

Figure 35-7. Mapping CAS Data on a Serial Interface

The MCC and ATM CAS are synchronized with the superframe block boundary. At the ATM side, the structured block size should be set to the superframe block size plus the size of the CAS block so that the structured pointer inserted by the ATM controller points to the start of the structured data block. At the MCC side, the MCC is synchronized with the frame sync signal; the external framer has the ability to place the signaling information at the appropriate place in a superframe. The QUICC Engine block supports an automatic mode for forwarding the signaling information from the TDM to the ATM and vice versa. The ATM controller maintains two CAS blocks per trunk (eight total). One contains the signaling information unpacked from the AAL1 cells (ATM-to-TDM), and the other contains the signaling information fetched from an external framer (TDM-to-ATM). All 8 CAS blocks reside in the internal RAM.

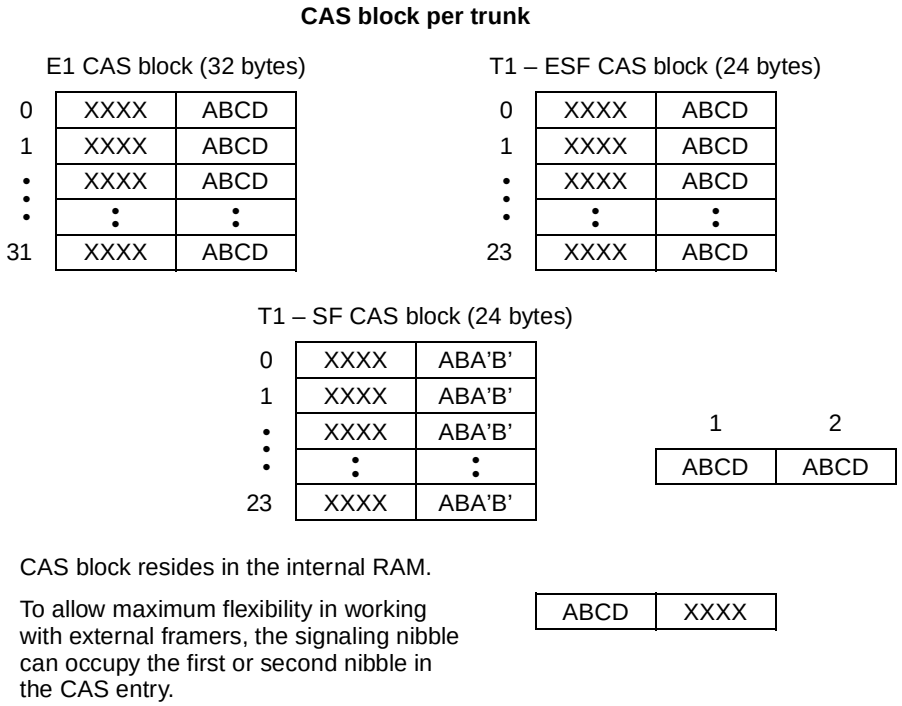


Figure 35-8. Internal CAS Block Formats

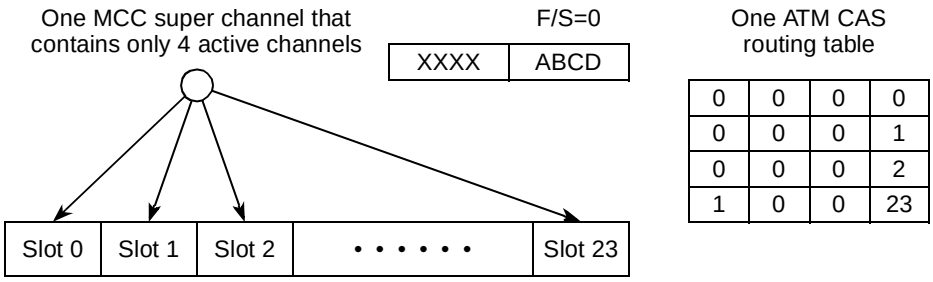
35.4.7 Mapping VC Signaling to CAS Blocks

Each ATM channel is connected to a specific CAS block. The ATM controller implements CAS routing tables (CRT) to maintain the routing of the signaling information from the AAL1 cells to the internal CAS blocks for receiving, and vice versa for transmitting. Each ATM channel has a routing table for the transmitter and one for the receiver. These tables are adjacent, each consists of a 32-byte space. Total size for both tables is 64 bytes with each entry pointing to one signaling nibble. To allow maximum flexibility with external framers, the signaling nibble can occupy the first or second nibble in the internal CAS block (depicted in Figure 35-8).

The CRT entries should be initialized only once before the ATM channel is enabled (receiver or transmitter). The number of entries that should be initialized must be equal to the number of active slots (channels) in the corresponding MCC super channel. Each super channel is mapped to a unique ATM connection (VC). The CRT entries are in ascending order based on the channel slots assigned for the MCC super channel (depicted in Figure 35-9).



Example of one MCC super channel in ESF framing (T1) containing 4 TDM slots connected to an ATM channel with one CAS routing table (CRT). See Section 1.4.7.1, “CAS Routing Table.”

Figure 35-9. Mapping CAS Entry

35.4.7.1 CAS Routing Table

Two CRTs are available per channel. The first is the transmitter table followed by a receiver table. Each table consists of 32 single byte entries. Accessing this table for the transmitter is done using: INT/EXT_RTCRT_BASE + CC * 64 and for a receiver INT/EXT+RTCRT_BASE + CC * 64 + 32.

Figure 35-10 shows the structure of a CAS routing table. The RISC maintains a pointer which steps through the table and wraps back to the beginning of the table after servicing the last entry (W=1).

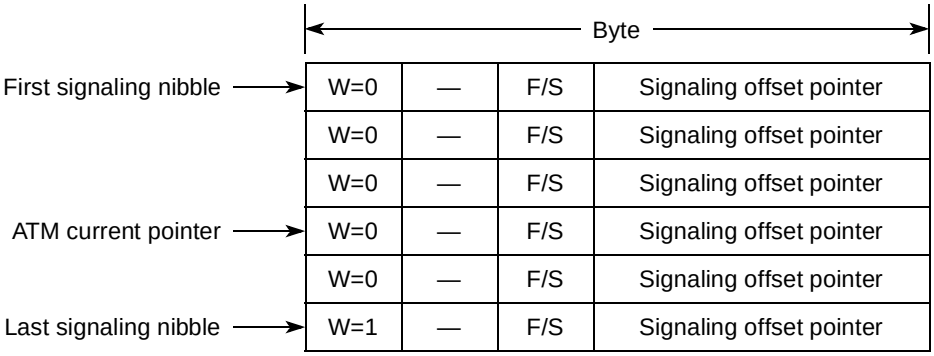


Figure 35-10. AAL1 CES CAS Routing Table (CRT)

Figure 35-11 describes the structure of a CAS routing table entry.

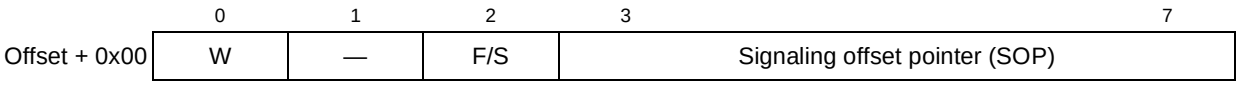

Figure 35-11. AAL1 CES CAS Routing Table Entry

Table 35-1 describes CAS routing table entry fields.

Table 35-1. CAS Routing Table Entry Field Descriptions

Bits	Name	Description
0	W	Wrap bit. When set, this bit indicates the last circular table entry. During initialization, the host must clear all W bits in the table except the last one, which must be set.
1	—	Reserved, should be cleared during initialization.
2	F/S	First/Second. 0 Indicates that the signaling information occupies the **first nibble** in the CAS block (LSB). 1 Indicates that the signaling information occupies the **second nibble** in the CAS block (MSB).
3–7	SOP	Signaling Offset Pointer. Offset of the signaling nibble from the internal CAS base address. Note that in ESF mode the maximum offset is 23 and in E1 framing format the maximum offset is 31.

35.4.7.2 TDM-to-ATM CAS Support

During the segmentation process, the AAL1 CES transmitter reads the CAS data from the internal CAS block and packs the data and the signaling information at the end of an AAL1 super frame (depicted in Figure 35-3). All AAL1 functions operate normally (generating AAL1 PDU-headers, structured pointers, etc.). Each common (MCC, ATM) BD table should point to buffers that can contain a whole number of super frames. The last buffer of the super frame is marked as the end of a super frame (BD[EOSF]=1). After closing a buffer with the EOSF indication, the ATM transmitter processes the CAS data—reads it from the internal CAS block and inserts it into the cell payload at the transmit side. The EOSF indication in the BD is statically set by the CPU when initializing the BD table.

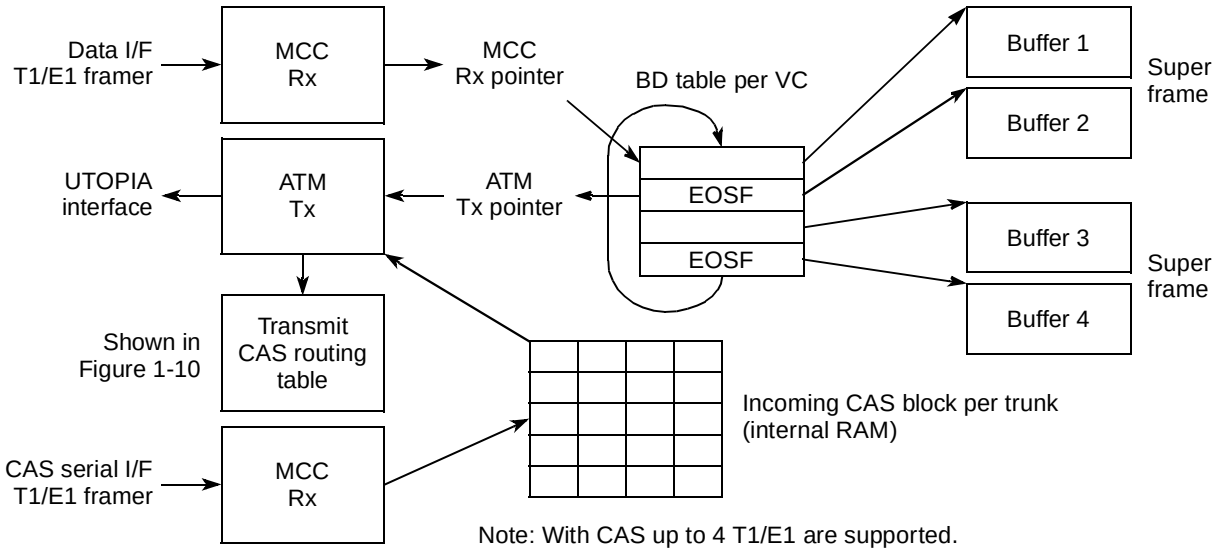

Figure 35-12. CAS Flow TDM-to-ATM

The CAS block is automatically written to internal RAM by the MCC receiver using a separate TDM. When a super frame is received the MCC should be triggered with a super-frame (multi-frame) SYNC from the external framer. The incoming CAS block should be captured by the MCC only once for each super frame (on the last frame).

The user may use external logic to convert the framer super-frame SYNC to trigger the MCC. The MCC captures the CAS block from the external framer and copies it transparently into one of four internal CAS blocks. Each byte in the CAS block contains a nibble of valid CAS information (depicted in Figure 35-8).

Note that the buffer data size should not include the CAS octets.

35.4.7.2.1 CAS Mapping Using the Core (Optional)

To avoid using another TDM dedicated to CAS information, the user can use a parallel interface (controlled by the core) to deliver the CAS information from the framer to the incoming CAS block. In this case, the core service routine reads the CAS information from the external framer and writes it to the incoming CAS block. To optimize the process, the framer can interrupt the core only when new information is received.

35.4.7.3 ATM-to-TDM CAS Support

During the reassembly process, the AAL1 CES receiver unpacks the signaling information from the end of an AAL1 super frame (depicted in Figure 35-3) and places it in the internal CAS block (using the receive CAS routing table). All AAL1 functions operate normally (AAL1 PDU-header verification, bit count integrity, 3-step-SN algorithm, etc.). Each common (MCC, ATM) BD table should point to buffers that can contain a whole number of super

frames. The last buffer of the super frame is marked with EOSF. After closing a buffer with an EOSF indication, the ATM receiver processes the CAS data (copies it to the internal CAS block from the AAL1 cell payload at the receive side). The EOSF indication in the BD is statically set by the CPU while initializing the BD table. See Figure 35-13.

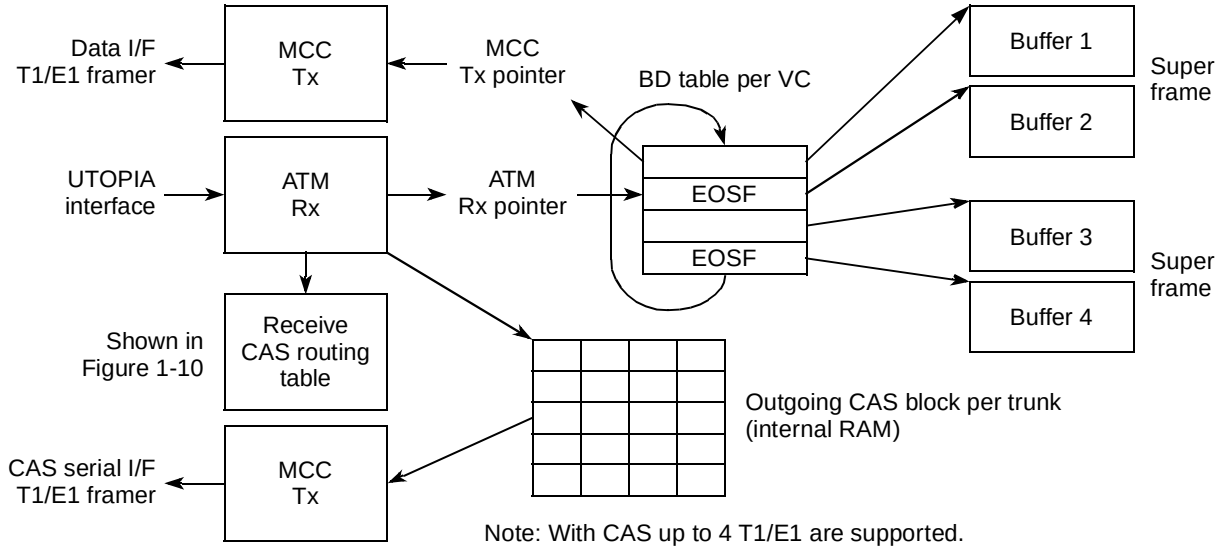

Figure 35-13. CAS Flow ATM-to-TDM

The CAS block is read from the internal RAM by the MCC. The MCC transmitter continuously reads the signaling information from one of the four outgoing internal CAS blocks and writes it transparently into

the external framer. Each byte in the CAS block contains one nibble of valid CAS information (depicted in Figure 35-8).

Note that the buffer data size should not include the CAS octets.

35.4.7.3.1 CAS Updates Using the Core (Optional)

To avoid using another TDM dedicated to CAS information, the user can use a parallel interface controlled by the core to deliver the outgoing CAS block to the framer. In this case, the ATM receiver should be programmed to operate in core CAS modify mode RCT[CCASM=1] (and RCT[CASM=1]). In this mode, the RISC adds an entry to the ATM interrupt queue and sets the appropriate sticky bit in OCASSR each time an AAL1 cell is received with new signaling information (one or more signaling nibble has changed). (See Section 35.10, "Outgoing CAS Status Register (OCASSR).") A core interrupt service routine can then write the updated outgoing CAS block to the framer.

Note to avoid additional latency, the interrupt queue assigned to this connection should have a global interrupt threshold of one. See the INT_ICNT parameter discussed in Section , ".

35.5 ATM-to-TDM Adaptive Slip Control

Two types of slip can occur in ATM-to-TDM operation: overrun and underrun. The two cases are handled by the MCC and ATM controller automatically without requiring CPU intervention.

Overrun occurs when the MCC transmitter fetches data from the common BD table at a slower rate than it is being filled by the ATM receiver. In this case, the ATM write pointer meets the MCC read pointer and a BSY state is declared (an entry is added to the ATM interrupt table) on the ATM side.

Underrun occurs when the MCC transmitter fetches data from the common BD table at a higher rate than it is being filled by the ATM receiver. In this case, the MCC read pointer reaches a BD that is not ready and a buffer-not-ready state is declared on the MCC side.

In both slip cases, the MCC and ATM controller automatically recover and restart the ATM-to-TDM interworking function.

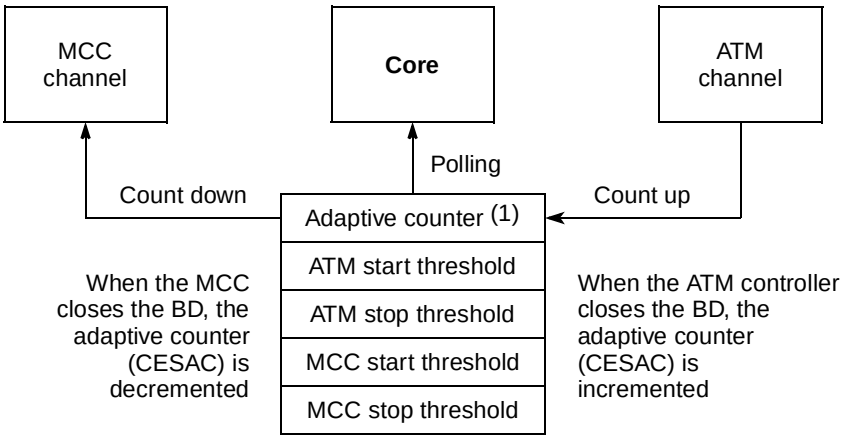
In order to prevent overrun and underrun conditions, the QUICC Engine block maintains an adaptive slip control using a set of 4 threshold pointers for each ATM-TDM (VC - super channel) connection.

The pre-underrun state (shown in Figure 35-14) occurs when the MCC read pointer goes faster than the ATM write pointer. When the adaptive counter reaches the MCC_Stop threshold, the MCC read pointer does not advance. At this point, the current BD (or the underrun template) is retransmitted a multiple of the frame size. In the meantime, the ATM receiver continues to receive valid data and advance the ATM write pointer. When the adaptive counter reaches the MCC_start threshold and the MCC has finished sending a multiple of the frame size, the MCC starts to transmit the valid received data and advance the MCC read pointer.

Note that when the pre-underrun state occurs, the MCC transmitter can transmit the last buffer continuously or the underrun template. This is determined by the MCC channel configuration; see the CHAMR[UTM] bit description in Section 34.2.2.2.3, "Channel Mode Register (CHAMR)—Transparent Mode." In the example shown in Figure 35-14, the MCC is programmed to send the current BD during the pre-underrun condition.

The pre-overrun state occurs when the ATM write pointer goes faster than the MCC read pointer. When the adaptive counter reaches the ATM_Stop threshold, the ATM write pointer does not advance. The ATM receiver waits until the adaptive counter reaches the ATM_start threshold. In the meantime, the MCC read pointer continues to process valid data from the common BD table. When CESAC reaches the ATM start threshold, the ATM write pointer advances to the first BD after the one that marked with EOSF (in CAS mode). When this BD is ready, the ATM receiver begins the resynchronization process: for unstructured AAL1 type the ATM receiver waits for the first valid cell, and for structured AAL1 type the receiver waits for the first valid cell that contains a valid pointer. The first received octet becomes the first byte of the new BD (new super frame).

Note that this implementation for slip control provides a good interface for an adaptive FIFO implemented in software. CESAC represents the difference between the ATM and MCC pointers; the software application need only convert this value into an SRTS format. Figure 35-14 shows the 8-byte data structure used to implement ATM-to-TDM slip control. (Three of the bytes are unused.)



CES adaptive threshold table address: CATB + MCC_Super_Channel*8

Notes:

1. The MCC start threshold, in effect, implements a CDV jitter buffer.
2. MCC stop threshold should be programmed to (BD Table size -b) to prevent buffer underrun.
3. ATM stop threshold should be programmed to (BD Table size - a) to prevent buffer overrun.
4. The MCC and ATM stop thresholds determine the CDVT.
5. The ATM start threshold determines the time the ATM receiver waits before restarting synchronization process.
6. (MCC start - MCC stop) >= frame size.
7. b and a are integers less the BD table size.

Figure 35-14. Data Structure for ATM-to-TDM Adaptive Slip Control

35.5.1 CES Adaptive Threshold Tables

The CES adaptive threshold tables (see Table 35-15) reside in the multi-user RAM and hold the CES thresholds on a per-VC basis. The CES adaptive threshold base (CATB), located in the AAL1 CES parameter RAM, points to the base address of these tables. Each AAL1-MCC channel has its own table with a starting address given by CATB + RCT[Super_Channel_Number]# × 8.

	0 — 7	8 — 15
Offset + 0x00	—	CES Adaptive Counter
Offset + 0x02	ATM Stop Threshold	ATM Start Threshold
Offset + 0x04	MCC Stop Threshold	MCC Start Threshold
Offset + 0x06	—	

Figure 35-15. CES Adaptive Threshold Table

Table 35-2 describes CES adaptive threshold table fields.

Table 35-2. CES Adaptive Threshold Table Field Descriptions

Offset[1]	Bits	Name	Description
0x00	0-7	—	Reserved, should be cleared during initialization.
	8-15	CESAC	CES adaptive counter.This field contains the difference between the ATM write pointer and the MCC read pointer on the common BD table.This field should be cleared by the user during the channel initialization.
0x02	0-7	ASTP	ATM stop threshold.This threshold determines the maximum amount of buffering (CDVT) that required in the common BD table (shown in Figure 35-16). When the CESAC reaches this value a pre-overrun condition occurs.This field should be defined by the user during the channel initialization.
	8-15	ASTRT	ATM start threshold.This threshold determines the Time interval that will take the ATM controller to restart the synchronize process (shown in Figure 35-16) after pre-overrun condition.This field should be defined by the user during the channel initialization.
0x04	0-7	MSTP	MCC stop threshold.This threshold determines the minimum amount of buffering in the common BD table (shown in Figure 35-16).When the CESAC reaches this value a pre-underrun condition occur and the MCC starts to transmit the underrun template or the last BD (see Section 35.5, “ATM-to-TDM Adaptive Slip Control”).This field should be defined by the user during the channel initialization.
	8-15	MSTRT	MCC start threshold.This threshold determines the effective depth of the jitter buffer, the amount of buffering required to cope with the ATM network’s CDV (shown in Figure 35-16).When the CESAC reaches this value the MCC transmitter starts sending the valid data from the common BD table.This field should be defined by the user during the channel initialization.
0x06	0-15	—	Reserved, should be cleared during initialization.

[1] The offset is CATB + RCT[Super_Channel_Number]# × 8

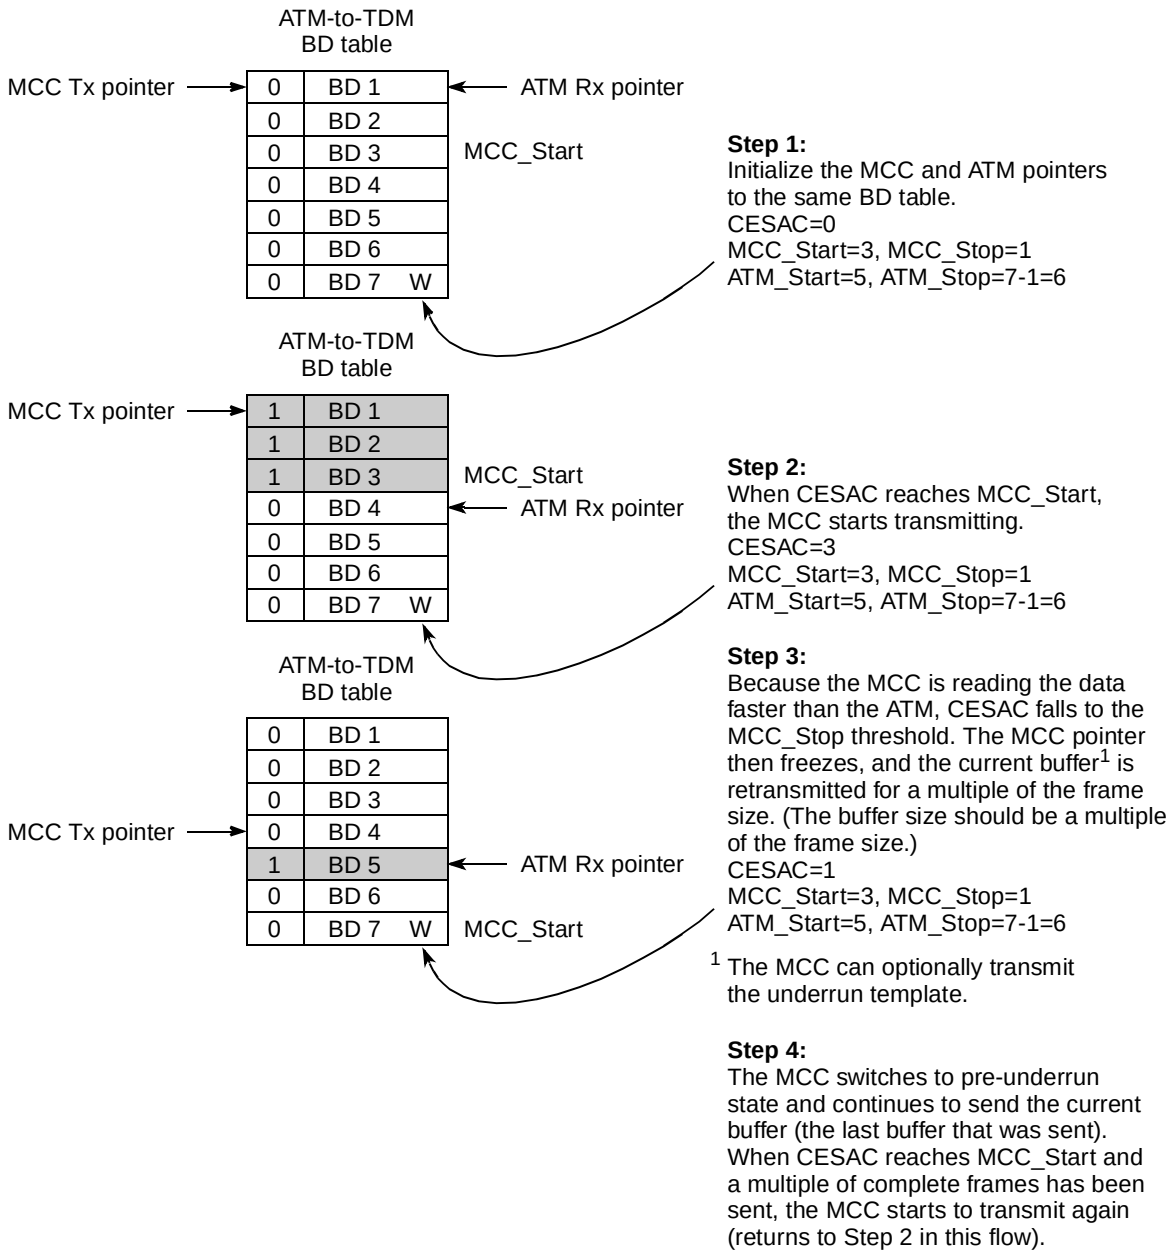


Figure 35-16. Pre-Underrun Sequence

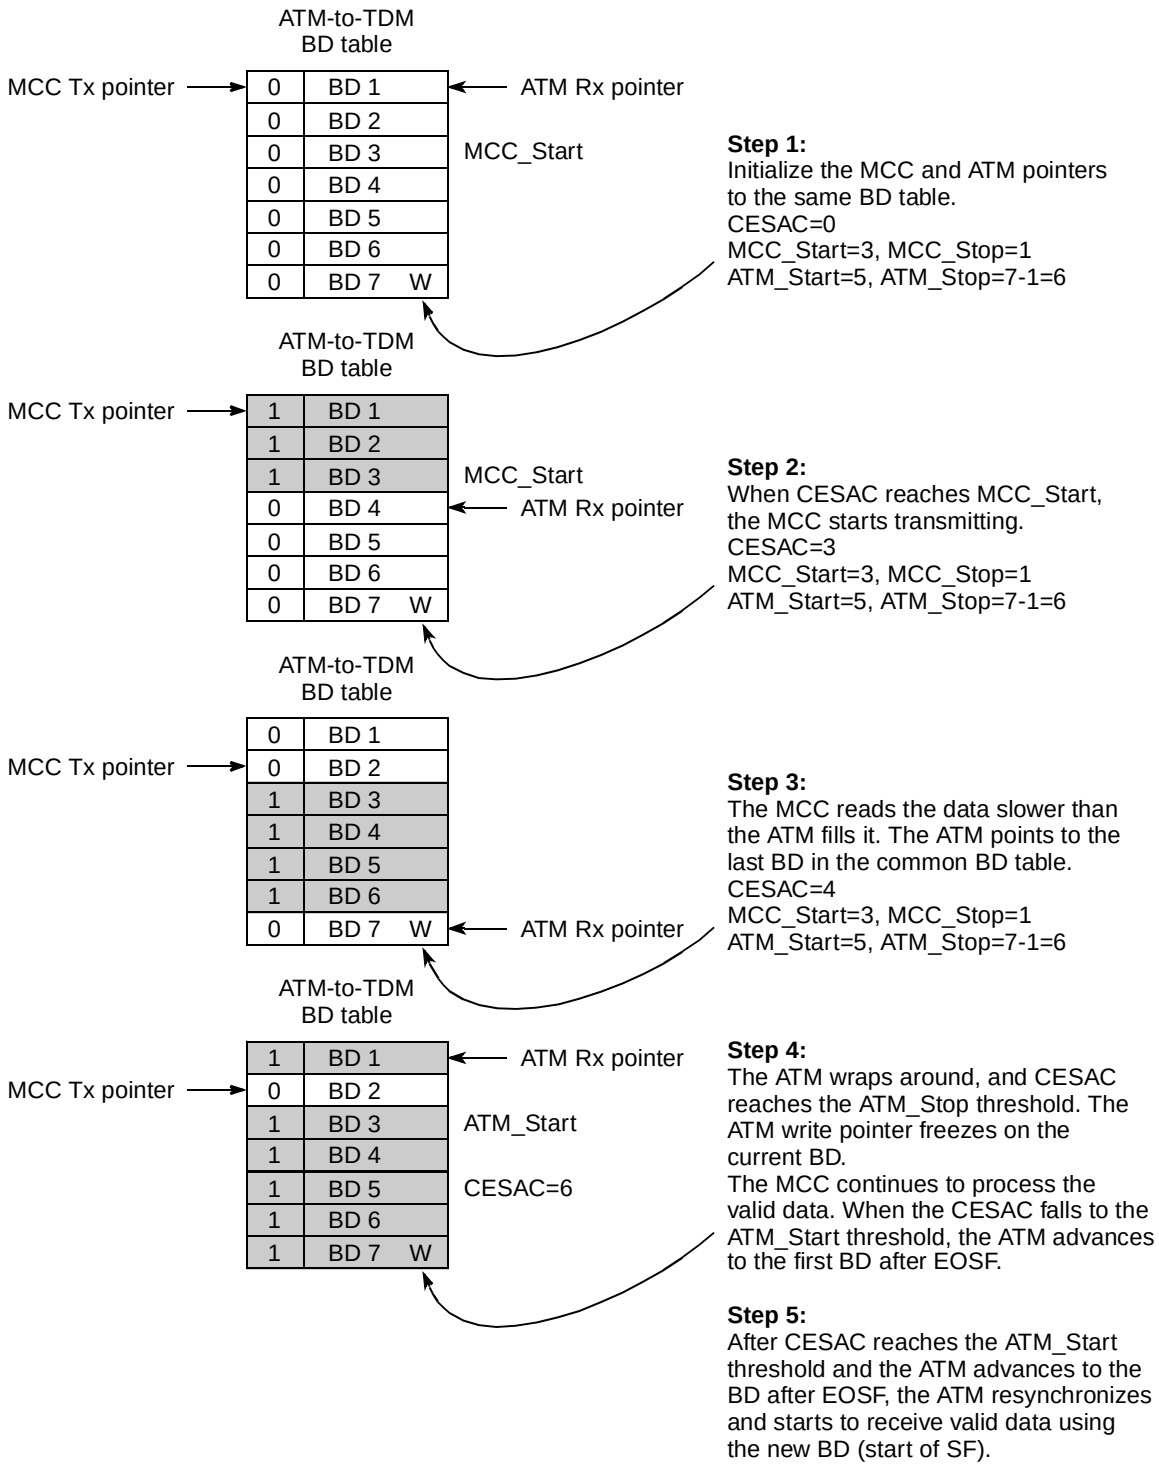

Figure 35-17. Pre-Overrun Sequence

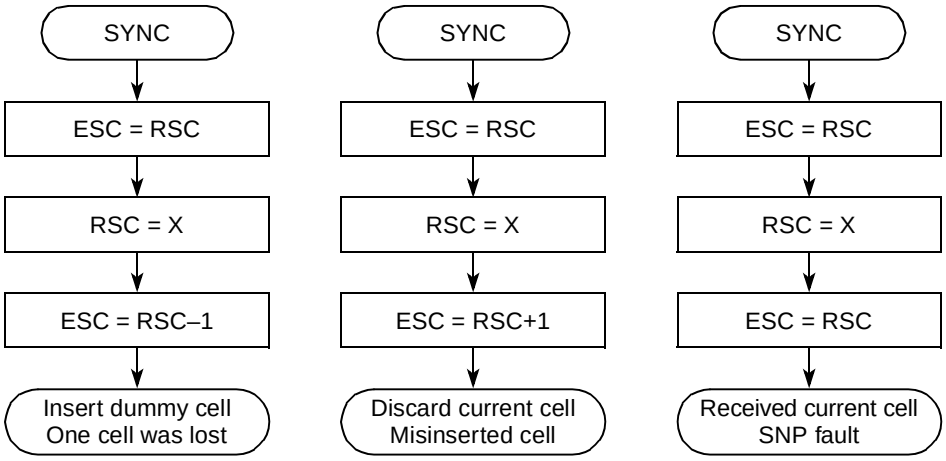
35.6 3-Step-SN Algorithm

The 3-step-SN algorithm is a fast and efficient state machine that has the ability to recover one lost or misinserted cell. The 3-step-SN algorithm does not add significant delay to the AAL1 CES reassembly process due to the fact that the decision to accept a cell is taken immediately after cell arrival. If a lost cell is detected, the receiver will insert a dummy cell. If a misinserted cell is detected, the receiver will discard the cell received after the misinserted cell. If more than one successive cell was lost or misinserted, the 3-step-SN algorithm will switch to hunt mode, where it stays until a cell with a valid SN field is received.

35.6.1 The Three States of the Algorithm

The 3-step-SN algorithm has three states:

1. Hunt—The Hunt state is the initial state of the algorithm or the first state after the receiver loses its synchronization. In this state no cell is delivered to the Rx buffer. When a valid cell is detected, the algorithm switches to the Sync state and delivers the current cell to the Rx buffer.
2. Sync—The Sync state is the steady state of the algorithm. In this state any received cell is automatically passed to the Rx buffer. The algorithm will switch from this state when an invalid cell is received (SNP error), or it receives a cell that does not sequence with the last valid cell (SC error).
3. Sync Fail—The Sync Fail state is a transient state. In this state the receiver checks the difference between the received sequence count (RSC) and the expected sequence count (ESC). If the difference between the two (ESC-RSC) is -1, 0, or 1, the receiver switches to sync mode and either discards the current cell, receives the current cell, or inserts a dummy cell, correspondingly. In any other cases the receiver will switch to hunt mode and discard the current cell.



ESC: Expected sequence count.
RSC: Received sequence count.
RSN=X: Invalid cell received or, a cell that does not match to the ESC.

Figure 35-18. Recoverable Sync Fail Sequence Options

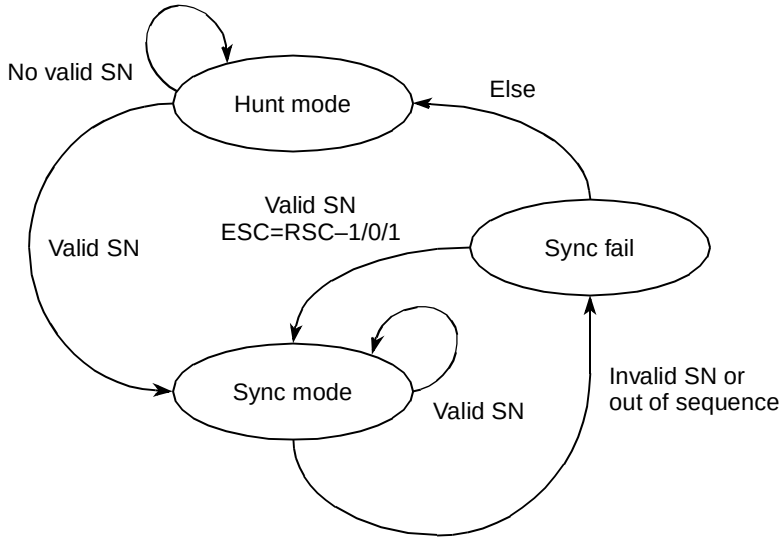


Figure 35-19. 3-Step-SN-Algorithm

35.7 Pointer Verification Mechanism

After the 3-step-SN algorithm processes the incoming cells, the cells status (Valid, Tag, Drop or Dummy) is delivered to the pointer verification mechanism. This state machine calculates the expected received pointer. If the current cell is valid and supposed to deliver a pointer, the received pointer is compared with the expected one. In the case of pointer mismatch or pointer error (i.e parity error), the pointer state machine switches to “Pre-Hunt-Mode”. If the cell status is not valid (i.e Tag, Drop or Dummy) and it supposed to carry a pointer, the pointer declared a mismatch and the pointer state machine switches to “Pre-Hunt-Mode”. The receiver stays in this transient state for only one AAL1 cell cycle (8 successive cells). When the pointer received in this state is different from the expected one or had a non-valid status, the receiver switches to hunt mode where it stays until a valid cell with a “start” structured pointer is received to regain synchronization.

Note that a “start” pointer is a valid pointer with a value not equal to 93or 127.

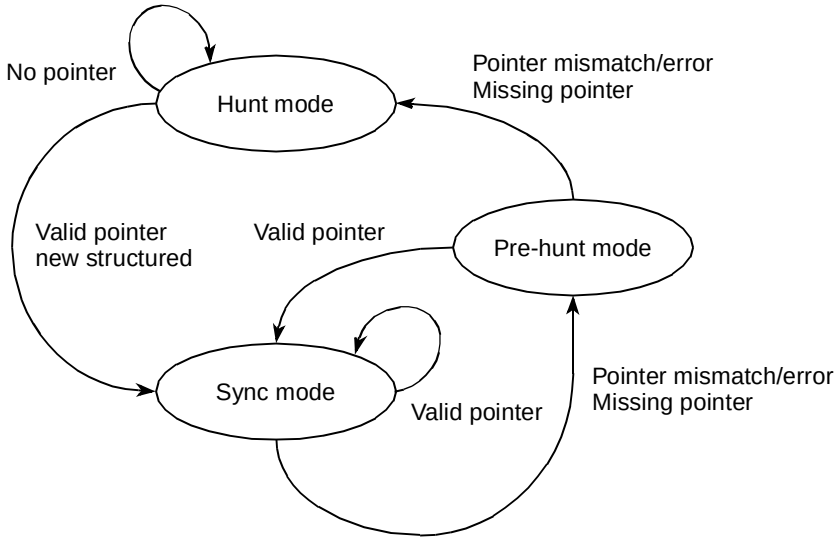

Figure 35-20. Pointer Verification Mechanism

35.8 AAL-1 Memory Structure

The QUICC Engine block manages ATM traffic by means of transmit and receive buffer descriptors (BD) and by transmit and receive connection tables (referred to as TCTs and RCTs, respectively). Buffer descriptors are circular lists of pointers into transmit and receive buffer space in external memory. The following sections describe the organization and configuration of the buffer descriptors, TCTs, and RCTs.

35.8.1 AAL1 CES Parameter RAM

The QUICC Engine parameter RAM is used to configure the three FCCs. The RISC also uses the parameter RAM to store operational and temporary values. When configured for ATM mode, the QUICC Engine block overlays the configuration structures shown in the next tables. The following table includes fields for AAL1 CES.

Note that some of the values must be initialized by the user; values set by the RISC should not be modified by the user.

Table 35-3. AAL1 CES Parameters

Location: Table 32-18	Name	Width	Description
Offset 0x36	INT_RTCRT_BASE	Hword	Internal receive/transmit CAS routing table extension base. User-defined. Should be 64-byte aligned. Each transmitter entry is accessed using: INT_RTCRT_BASE + CC * 64 and for a receiver INT_RTCRT_BASE + CC * 64 + 32.
Offset 0x38	EXT_RTCRT_BASE	Word	External receive/transmit CAS routing table extension base. User-defined. Should be 64-byte aligned. Each transmitter entry is accessed using: EXT_RTCRT_BASE + CC * 64 and for a receiver EXT_RTCRT_BASE + CC * 64 + 32.
Offset 0x4A	AAL1_INT_RX_CRT	Hword	(CES only) Points to a reserved scratchpad area of 32 bytes in the multi-user RAM used by the CES microcode. Should be 32 byte aligned. User-defined.

Table 35-3. AAL1 CES Parameters (continued)

Offset 0x48	OCASSR (AAL1_Out_CAS_Status_Reg)	Byte	Outgoing CAS Status Register. See Section 35.10, "Outgoing CAS Status Register (OCASSR)."
Offset 0x28	TCELL_TMP_BASE_EXT	Word	Transmit Cell Temporary base address (64-byte aligned). Points to an external memory block reserved for partially filled cells (64 octets for each CES channel). This area is allocated by the user but used by the RISC.
Offset 0x44	IN_CAS_BLOCK_BASE	Hword	Incoming CAS Block Base (depicted in Figure 35-12). Points to multi-user RAM. Should be 32-byte aligned. User-defined.
Offset 0x46	OUT_CAS_BLOCK_BASE	Hword	Outgoing CAS Block Base (depicted in Figure 35-10). Points to multi-user RAM. Should be 32-byte aligned. User-defined.
Offset 0x4C	AAL1_Int_STATT_BASE (AAL1_Int_STATS_BASE)	Hword	AAL1 Internal Statistics Table Base. Points to multi-user RAM. Should be 16-byte aligned. User-defined. See Section 35.15, "Internal AAL1 CES Statistics Tables."
Offset 0x34	AAL1_DUMMY_CELL_BASE	Hword	ALL1 Dummy cell base address. Points to multi-user RAM area contains the AAL1 dummy cell template (little-endian format). Should be 64-byte aligned. User-defined.
Offset 0x3E	CATB (ADAPTIVE_THRESHOLDS_BASE)	Hword	CES adaptive threshold tables base address. Points to the multi-user RAM area containing the CES slip control thresholds and the adaptive counter See Section 35.15, "Internal AAL1 CES Statistics Tables." Should be 8-byte aligned (8 octets for each AAL1-MCC channel). User-defined and should match the CATB value programmed in the MCC parameter RAM; see Section 34.2.2.3, "MCC Parameters for AAL1 CES Usage."
Offset 0x30	AAL1_Ext_STATT_BASE (AAL1_Ext_STATS_BASE)	Word	AAL1 External Statistics Table Base. Points to External memory. Should be 16-byte aligned (16 octets for each AAL1 channel).User-defined. See Section 35.16, "External AAL1 CES Statistics Tables."

35.9 Receive and Transmit Connection Tables (RCT, TCT)

The connection tables, RCT and TCT, hold channel configuration and temporary parameters for each receive and transmit channel (AAL type, connection traffic parameters, BDs' parameters and temporary parameters used during segmentation and reassembly).

The internal connection tables hold parameters for up to 128 channels (channels 0–127). In extended channel mode, parameters for channels 256 and above are kept in external memory. The only relationship between transmit and receive connection tables of the same channel is the CRT (CAS routing table); see Section 35.4.7.1, "CAS Routing Table."

Each connection table entry resides in 32 bytes. The pointers to these connection tables reside in the parameter RAM.

35.9.1 Receive Connection Table (RCT)

Figure 35-21 shows the format of an RCT entry.

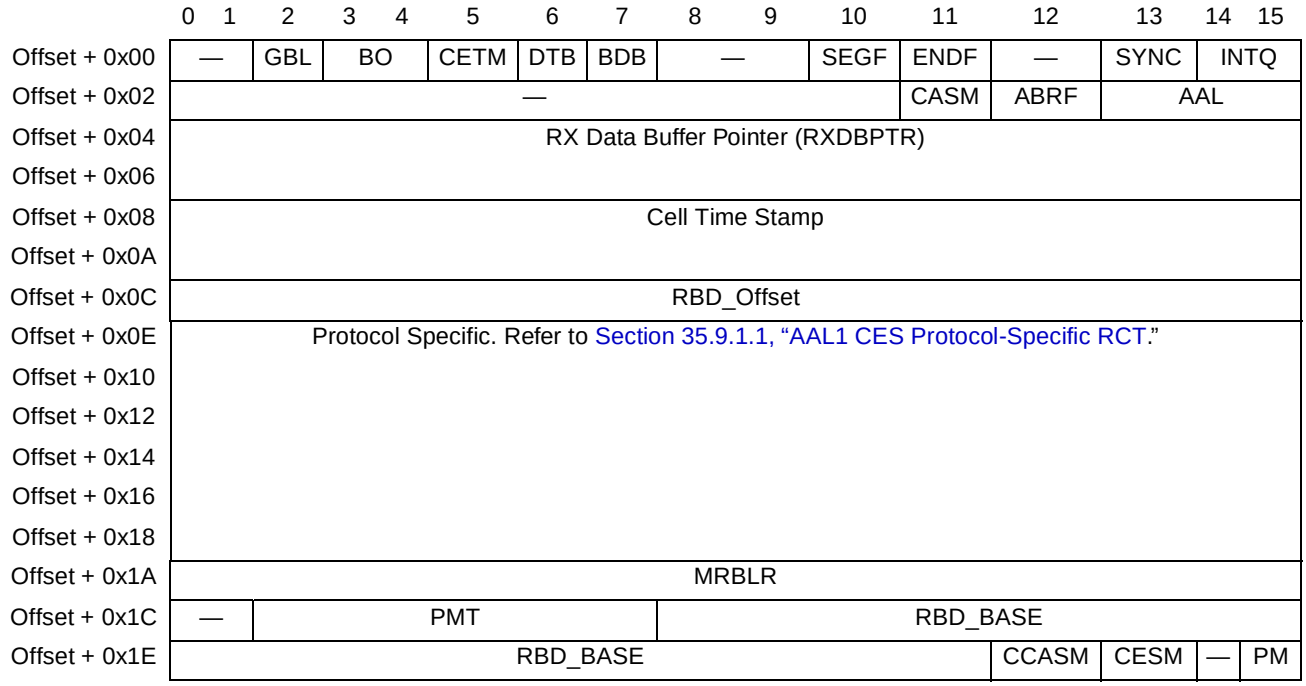

Figure 35-21. Receive Connection Table (RCT) Entry

NOTE

For an active channel, the RISC uses a burst cycle to fetch the 32-byte RCT and writes back only the first 24 bytes.

Table 35-4 describes RCT fields.

Table 35-4. RCT Field Descriptions

Offset	Bits	Name	Description
0x00	0–1	—	Reserved, should be cleared during initialization.
	2	GBL	Global. Asserting GBL enables snooping of data buffers, BD, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	BO	Byte ordering—used for data buffers. 00, 01, 11 Reserved 10 Big endian
	5	CETM	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1BDBSCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.See Figure 19-1 and Section 5.4.3.7, "Debug Configuration."
	6	DTB	Data buffers bus 0 Data buffers reside on the coherent system bus. 1 Data buffers reside on the QUICC Engine secondary bus.
	7	BDB	BD interrupt queues, free buffer pool, and CES external statistics tables bus placement 0 Reside on the coherent system bus. 1 Reside on the QUICC Engine secondary bus. Notes: 1. When in UDC mode (AAL5 or AAL1 or AAL1 CES), BDs and data should be placed on the same bus (RCT[DTB]=RCT[BDB]). 2. RCT[BDB] programming must be consistent across all CES receive channels because they share the same AAL1_Ext_STATT_BASE parameter.
	8–9	—	Reserved, should be cleared during initialization.
	10	SEGF	OAM F5 segment filtering 0 Do not send cells with PTI=100 to the raw cell queue. 1 Send cells with PTI=100 to the raw cell queue.
	11	ENDF	OAM F5 end-to-end filtering 0 Do not send cells with PTI=101 to the raw cell queue. 1 Send cells with PTI=101 to the raw cell queue.
	12	—	Reserved, should be cleared during initialization.
	13	SYNC	AAL1 SYNC. The user should set this bit for first AAL1 synchronization. Used internally by the RISC.
	14–15	INTQ	Points to one of four interrupt queues available.

Table 35-4. RCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0-3	—	Internal use only. Initialize to 0.
	4–10	—	Internal use only. Initialize to 0.
	11	CASM	Common associated signaling mode. 0 CAS operation mode is disable. 1 CAS operation mode is enable.
	12	—	Reserved, should be cleared during initialization.
	13–15	AAL	AAL type 000 AAL0 —Reassembly with no adaptation layer 001 AAL1 —ATM adaptation layer 1 010 AAL5 —ATM adaptation layer 5 100 AAL2 —ATM adaptation layer 2. Refer to Chapter 32, "ATM Controller AAL0, AAL1, and AAL5." 101 AAL1_CES —ATM adaptation layer 1 with circuit emulation service All others reserved.
0x04	—	RxDBPTR	Receive data buffer pointer. Holds real address of current position in the Rx buffer.
0x08	—	Cell Time Stamp	Used for reassembly time-out. Whenever a cell is received, the QUICC Engine time stamp timer is sampled and written to this field. See Section 20.3.9, "QUICC Engine Time-Stamp Control Register (CETSCR)."
0x0C	—	RBD_Offset	RxBD offset from RBD_BASE. Points to the channel's current BD. User-initialized to 0; updated by the RISC.
0x0E–0x18		—	Protocol-specific area.
0x1A	—	MRBLR	Maximum receive buffer length. Used in both static and dynamic buffer allocation. For better synchronization between ATM and TDM, while CES traffic is steady, or when re-sync is needed, this value must be a multiple of the number of slots used by the TDM super channel associated with this AAL1 channel. When working in CAS mode this value must be the size of the data block, meaning each buffer hold one data block. The value of the data block is computed as follows: Let N be the number of slots used by the TDM super channel associated with this AAL1 channel. Then for a Super Frame: Data block size = 16*N. For an Extended Super Frame: Data block size = 24*N

Table 35-4. RCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x1C	0–1	—	Reserved, should be cleared during initialization.
	2–7	PMT	Performance monitoring table. Points to one of the available 64 performance monitoring tables. The starting address of the table is PMT_BASE+PMT × 32. Can be changed on-the-fly.
	8–15	RBD_BASE	RxBD base. Points to the first BD in the channel's RxBD table. The 8 most-significant bits of the address are taken from BD_BASE_EXT in the parameter RAM. The four least-significant bits of the address are taken as zeros.
0x1E	0–11		
	12	CCASM	Core CAS modify. When this mode is enabled, the RISC sets OCASSR[MCASB*n*] sticky bit each time the outgoing (ATM to TDM) CAS block is changed. 0 Core CAS modify mode is disabled. 1 Core CAS modify mode is enabled. See Section 35.10, "Outgoing CAS Status Register (OCASSR)."
	13	CESM	Circuit Emulation Service Mode. 0 CES operation mode is disable. Adaptive Slip control mechanism is disabled. 1 CES operation mode is enable. Adaptive Slip control mechanism is enabled.
	14	—	Reserved, should be cleared during initialization.
	15	PM	Performance monitoring. Can be changed on-the-fly. 0 No performance monitoring for this VC. 1 Perform performance monitoring for this VC. Whenever a cell is received for this VC the performance monitoring table that its code is written in the PMT field is updated.

35.9.1.1 AAL1 CES Protocol-Specific RCT

Figure 35-22 shows the AAL1 CES protocol-specific area of an RCT entry.

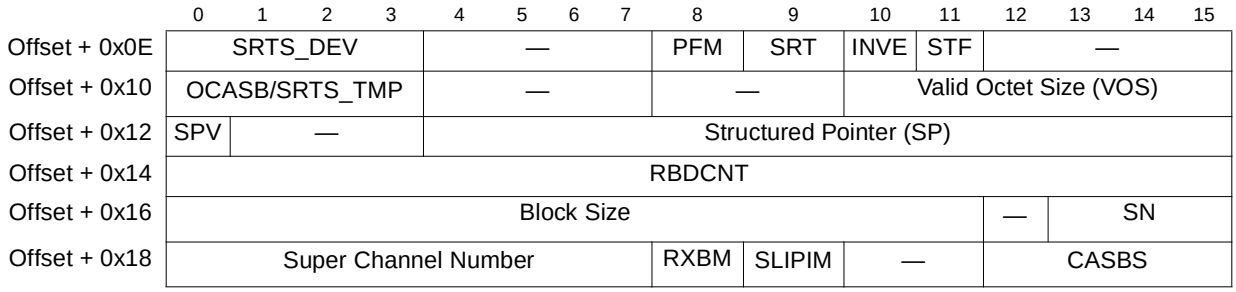

Figure 35-22. AAL1 CES Protocol-Specific RCT

Table 35-5 describes AAL1 CES protocol-specific RCT fields.

Table 35-5. AAL1 CES Protocol-Specific RCT Field Descriptions

Offset	Bits	Name	Description
0x0E	0–3	SRTS_DEV	Selects an SRTS device, whose address is SRTS_BASE[0–27] + SRTS_DEV[28–31]. The 16 byte-aligned SRTS_BASE is taken from the parameter RAM.
	4–7	—	Reserved, should be cleared during initialization.
	8	PFM	Partially filled mode. 0 Partially filled cells mode is not used. 1 Partially filled cells mode is used. The receiver copies only valid octets from the AAL1 cell to the Rx buffer. The number of the valid octets from the beginning of the AAL1 user data field is specified in the VOS (valid octet size) field.
	9	SRT	Synchronous residual time stamp. Unstructured format only. The QUICC Engine block supports clock recovery using an external SRTS PLL. The QUICC Engine block tracks the SRTS from the incoming four cells with SN = 1, 3, 5, and 7 and writes it to the external SRTS device. Every eight cells the RISC writes a valid SRTS to external logic. (See Section 32.2.22.4.1, “SRTS Generation and Clock Recovery Using External Logic.”) 0 SRTS mode is not used. 1 SRTS mode is used.
	10	INVE	Inverted empty. 0 RxBD[E] is interpreted normally (1 = empty, 0 = not empty). 1 RxBD[E] is handled in negative logic (0 = empty, 1 = not empty). Note that in CES mode (CESM=1) this bit must be set by the user; see Section 35.4.1, “Automatic Data Forwarding.”
	11	STF	Structured format. 0 Unstructured format is used. 1 Structured format is used. Note that although the structured format may be used, if the block size is one, the user should clear STF. Only non P-format AAL1 cells are received. The receiver does not check the AAL1 structured pointer because there is no need to when the block size is one.
	12-15	—	Reserved, should be cleared during initialization.
0x10	0–3	OCASB/SRTS_TMP	OCASB applies when in CAS mode. Outgoing CAS Block. Points to one of the eight available internal CAS blocks. The starting address of the table is OUT_CAS_BLOCK_BASE+OCASB¥32. See Section 35.4.7.1, “CAS Routing Table” for more details. Note that the RCT and TCT use the same CAS routing table (CRT). SRTS_TMP applies when not in CAS mode. Used by the RISC to store the received SRTS code. After a cell with SN = 7 is received, the RISC writes the SRTS code to the external SRTS device. Note that when the receiver is in hunt mode SRTS information is not updated.
	4–9	—	Reserved, should be cleared during initialization.
	10–15	VOS	Valid octet size. Specifies the number of valid octets from the beginning of the AAL1 user data field. For unstructured, service values 1–47 are valid; for structured service, values 1-46 are valid. Partially filled cell mode only.
0x12	0	SPV	Structured pointer valid. Should be user-initialized user to zero. Structured format only.
	1–3	—	Reserved, should be cleared during initialization.
	4–15	SP	Structured pointer. Used by the RISC to calculate the structured pointer. This field should be initialized by the user to zero. Used in structured format only.

Table 35-5. AAL1 CES Protocol-Specific RCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x14	—	RBDCNT	RxBD count. Indicates how many bytes remain in the current Rx buffer. Initialized with MRBLR whenever the RISC opens a new buffer.
0x16	0–11	Block Size	Used only in structured format. Specifies the structured block size (Block Size = 0xFFF = 4 Kbytes maximum). Note that when working in CAS mode (CESM=1 and CASM=1), the block size should be programmed to the superframe block size plus the size of the CAS block. However, when working in basic mode (CES without CAS: CESM=1 and CASM=0) the block size should be programmed to the number of MCC slots (Nx64) per frame assigned to this channel.
	12	—	Reserved, should be cleared during initialization.
	13–15	SN	Sequence number. Used by the RISC to check incoming cell's sequence number.
0x18	0-7	SCN	Super Channel Number. This field should contain the MCC Super Channel Number that mapped to this ATM channel. This field must be initialized by the user in CES mode only. See Section 35.4.7, "Mapping VC Signaling to CAS Blocks."
	8	RXBM	Receive buffer interrupt mask 0 The receive buffer event of this channel is disabled. (The event is not sent to the interrupt queue.) 1 The receive buffer event of this channel is enabled.
	9	SLIPIM	Slip interrupt mask 0 The slip interrupts SLIPS and SLIPE are both masked. 1 When the receiver switches to hunt mode due to a 3-step-SN algorithm fault, or due to two successive mismatched pointers, or due to a pre-overrun condition, the SLIPS interrupt is sent to the interrupt queue. See Section 35.6, "3-Step-SN Algorithm," and Section 35.13, "AAL1 CES Exceptions." When the receiver resynchronizes, SLIPE interrupt is sent to the interrupt queue. Note that this is the error reporting mechanism during automatic data forwarding (ATM-to-TDM bridging).
	10-11	—	Reserved, should be cleared during initialization.
	12-15	CASBS	CAS block size.This field contains the number divided by two (**N/2**) of signaling nibbles mapped to this ATM channel. See Section 35.4.7, "Mapping VC Signaling to CAS Blocks." **Note** that if the number of signaling nibbles is **odd**, this field should be programmed to (**N+1)/2**. See Section 35.2.2, "Signaling Path." **Example**: ESF with three T1 time slots connected to one ATM channel. The **Data_Size** = 3*24 = 72 octets and the **CAS Block= 2** octets (**N=3, (N+1)/2 = 2**), so in this case the **Block_Size** = 72+2 = 74

35.9.2 Transmit Connection Table (TCT)

Figure 35-23 shows the format of an TCT entry.

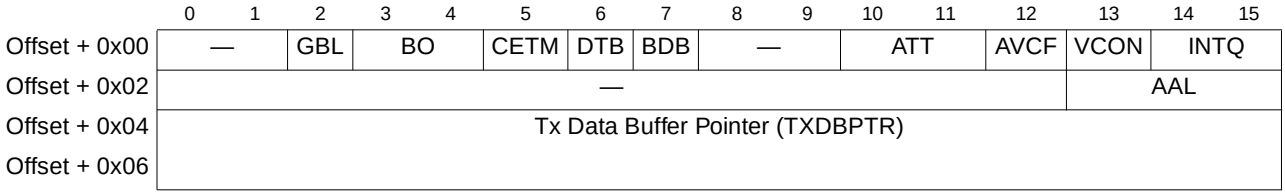

Figure 35-23. Transmit Connection Table (TCT) Entry

Offset + 0x08	TBDCNT						
Offset + 0x0A	TBD_OFFSET						
Offset + 0x0C	Rate Remainder		PCR Fraction				
Offset + 0x0E	PCR						
Offset + 0x10	Protocol Specific. Refer to Section 35.9.2.1, “AAL1 CES Protocol-Specific TCT.”						
Offset + 0x12							
Offset + 0x14							
Offset + 0x16	APC Linked Channel						
Offset + 0x18	ATM Cell Header (VPI,VCI,PTI,CLP)						
Offset + 0x1a							
Offset + 0x1C	—	PMT	TBD_BASE				
Offset + 0x1E	TBD_BASE			BNM	STPT	IMK	PM

Figure 35-23. Transmit Connection Table (TCT) Entry (continued)

Table 35-6 describes general TCT fields.

Table 35-6. TCT Field Descriptions

Offset	Bits	Name	Description
0x00	0–1	—	Reserved, should be cleared during initialization.
	2	GBL	Global. Asserting GBL enables snooping of data buffers, BDs, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	BO	Byte ordering. This field is used for data buffers. 00, 01, 11 Reserved. 10 Big endian.
	5	CETM	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1 and Section 5.4.3.7, "Debug Configuration."
	6	DTB	Data buffer and CES transmit cell scratchpad bus placement 0 Reside on the coherent system bus. 1 Reside on the QUICC Engine secondary bus. Note: TCT[DTB] programming must be consistent across all CES transmit channels because they share the same TCELL_TMP_BASE_EXT parameter.
	7	BDB	BD and interrupt queue bus 0 Reside on the coherent system bus. 1 Reside on the QUICC Engine secondary bus. Note: When using AAL5, AAL1 or AAL1 CES in UDC mode, BDs and data should be placed on the same bus (TCT[DTB]=TCT[BDB]).
	8-9	—	Reserved, should be cleared during initialization.
	10-11	ATT	ATM traffic type 00 Peak cell-rate pacing. The host must initialize PCR and the PCR fraction. Other traffic parameters are not used. 01 Peak and sustain cell rate pacing (VBR traffic). The APC performs a continuous-state leaky bucket algorithm (GCRA) to pace the channel-sustain cell rate. The host must initialize PCR, PCR fraction, SCR, SCR fraction, and BT (burst tolerance). 10 Peak and minimum cell rate pacing (UBR+ traffic). The host must initialize PCR, PCR fraction, MCR, MCR fraction, and MDA. 11 Reserved.
	12	AVCF	Auto VC off. Determines APC behavior when the last buffer associated with this VC has been sent and no more buffers are in the VC's TxBD table, 0 The APC does not remove this VC from the schedule table and continues to schedule it to transmit. 1 The APC removes this VC from the schedule table. To continue transmission after the host adds buffers for transmission, a new ATM TRANSMIT command is needed, which can be issued only after the RISC clears the VCON bit. (Bit 13)
	13	VCON	Virtual channel is on Should be set by the host before it issues an ATM TRANSMIT command. When the host sets TCT[STPS] (stop transmit), the RISC deactivates this channel and clears VCON when the channel is next encountered in the APC scheduling table. The host can issue another ATM TRANSMIT command only after the RISC clears VCON.
	14–15	INTQ	Points to one of four interrupt queues available.

Table 35-6. TCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0-12	—	Reserved, should be cleared during initialization.
	13–15	AAL	AAL type 000 AAL0 —Reassembly with no adaptation layer 001 AAL1 —ATM adaptation layer 1 010 AAL5 —ATM adaptation layer 5. 100 AAL2 —ATM adaptation layer 2. Refer to Chapter 32, "ATM Controller AAL0, AAL1, and AAL5." 101 AAL1_CES —ATM adaptation layer 1 with circuit emulation service All others reserved.
0x04	—	TxDBPTR	Tx data buffer pointer. Holds the real address of the current position in the Tx buffer.
0x08	—	TBDCNT	Transmit BD count. Counts the remaining data to transmit in the current transmit buffer. Its initial value is loaded from the data length field of the TxBD when a new buffer is open; its value is subtracted for any transmitted cell associated with this channel.
0x0A	—	TBD_Offset	Transmit BD offset. Holds offset from TBD_BASE of the current BD. Initialize to 0.
0x0C	0–7	Rate Reminder	Rate remainder. Used by the APC to hold the rate remainder after adding the pace fraction to the additive channel rate. Initialize to 0.
	8–15	PCR Fraction	Peak cell rate fraction. Holds the peak cell rate fraction of this channel in units of 1/256 slot. If this is an ABR channel, this field is automatically updated by the RISC.
0x0E	—	PCR	Peak cell rate. Holds the peak cell rate (in units of APC slots) permitted for this channel according to the traffic contract. Note that for an ABR channel, the RISC automatically updates PCR to the ACR value.
0x10	—	—	Protocol-specific
0x16	—	APCLC	APC linked channel. Used by the RISC. Initialize to 0 (null pointer).
0x18	—	ATMCH	ATM cell header. Holds the full (4-byte) ATM cell header of the current channel. The transmitter appends ATMCH to the cell payload during transmission.
0x1C	0–1	—	Reserved, should be cleared during initialization.
	2–7	PMT	Performance monitoring table. Points to one of the available 64 performance monitoring tables. The starting address of the table is PMT_BASE+PMT × 32. Can be changed on-the-fly.
	8–15	TBD_BASE	TxBD base. Points to the first BD in the channel's TxBD table. The 8 most-significant bits of the address are taken from BD_BASE_EXT in the parameter RAM. The four least-significant bits of the address are taken as zero.
0x1E	0–11		
	12	BNM	Buffer-not-ready interrupt mask. Can be changed on-the-fly. 0 The transmit buffer-not-ready event of this channel is masked. (TBNR event is not sent to the interrupt queue.) 1 The buffer-not-ready event of this channel is enabled.
	13	STPT	Stop transmit. Initialize to 0. When the host sets this bit, the RISC deactivates this channel and clears TCT[VCON] when the channel is next encountered in the APC scheduling table. Note that for AAL5 if STPT is set and frame transmission is already started (TCT[INF]=1), an abort indication will be sent (last cell with zero length field).
	14	IMK	Interrupt mask. Can be changed on-the-fly. 0 The transmit buffer event of this channel is masked. (TXB event is not sent to the interrupt queue.) 1 The transmit buffer event of this channel is enabled.
	15	PM	Performance monitoring. Can be changed on-the-fly. 0 No performance monitoring for this VC. 1 Performance is monitored for this VC. When a cell is sent for this VC, the performance monitoring table indicated in PMT field is updated.

35.9.2.1 AAL1 CES Protocol-Specific TCT

Figure 35-24 shows the AAL1 CES protocol-specific transmission connection tables (TCT).

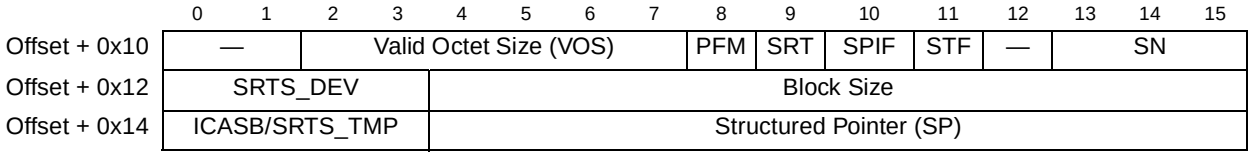

Figure 35-24. AAL1 CES Protocol-Specific TCT

Table 35-7 describes AAL1 CES protocol-specific TCT fields.

Table 35-7. AAL1 CES Protocol-Specific TCT Field Descriptions

Offset	Bits	Name	Description
0x10	0-1	—	Reserved, should be cleared during initialization.
	2–7	VOS	Valid octet size. Partially filled cell mode only. Specifies the number of valid octets from the beginning of the AAL1 user data field. For unstructured service, values 1-47 are valid; for structured service, values 1-46 are valid.
	8	PFM	Partially filled mode. 0 Partially filled cells mode is not used. 1 Partially filled cells mode is used. The transmitter copies only valid octets from the buffer to the AAL1 cell. The size of the valid octets from the beginning of the AAL1 user data field is specified in the VOS (valid octet size) field.
	9	SRT	Synchronous residual time stamp. Unstructured format only. The QUICC Engine block supports SRTS generation using external logic. If this mode is enabled, the QUICC Engine block reads the SRTS from external logic and inserts it into four cells for which SN = 1, 3, 5, or 7. The QUICC Engine block reads the new SRTS from external logic every eight cells. 0 SRTS mode is not used. 1 SRTS mode is used.
	10	SPIF	Structured pointer inserted flag. Indicates that a structured pointer has been inserted in the current cycle. The user should initialize this field to zero. **Used by the RISC only**.
	11	STF	Structured format. 0 Unstructured format is used. 1 Structured format is used. Note that although the structured format may be used, if the block size is one, the user should clear STF so that only non P-format AAL1 cells are generated.
	12	—	Reserved, should be cleared during initialization.
	13–15	SN	Sequence number field. Used by the CP to generate and maintain the SN of the cell. Should be cleared initially.
0x12	0–3	SRTS_DEV	Used to select a SRTS device. The SRTS device address is SRTS_BASE[0–27]+SRTS_DEV[28:31]. SRTS_BASE is taken from the parameter RAM and is 16-byte aligned.
	4–15	Block Size	Used only in structured format. Specifies the structured block size (Block Size = 0xFFF = 4 Kbytes maximum). Note that when working in CAS mode (CESM=1 and CASM=1), the block size should be programmed to the superframe block size plus the size of the CAS block. However, when working in basic mode (CES without CAS: CESM=1 and CASM=0) the block size should be programmed to the number of MCC slots (Nx64) per frame assigned to this channel.

Table 35-7. AAL1 CES Protocol-Specific TCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x14	0–3	ICASB/SRTS_TMP	ICASB applies when in CAS mode. Incoming CAS Block. Points to one of the eight available internal CAS block. The starting address of the table is IN_CAS_BLOCK_BASE+ICASB × 32. See Section 35.4.7.1, "CAS Routing Table" for more details. Note that the RCT and TCT use the same CAS routing table (CRT). SRTS_TMP applies when not in CAS mode. Before a cell with SN = 1 is sent, the RISC reads the SRTS code from external SRTS logic, writes it to SRTS_TMP, and then inserts SRTS_TMP into the next four cells with an odd SN.
	4–15	SP	Structured pointer. Used by the RISC to calculate the structured pointer. Initialize to 0. Structured format only.

35.10 Outgoing CAS Status Register (OCASSR)

Figure 35-25 shows the layout of the outgoing CAS block status register (OCASSR).

	0	7	8	9	10	11	12	13	14	15
Field	—		MCASB7	MCASB6	MCASB5	MCASB4	MCASB3	MCASB2	MCASB1	MCASB0

Figure 35-25. Outgoing CAS Status Register (OCASSR)

This status register contains sticky bits that give the software application an indication that the RISC has modified the associated CAS block. When the ATM receiver operates in core CAS modify mode RCT[CCASM=1], the RISC generates an interrupt and sets the appropriate sticky bit in OCASSR each time an AAL1 cell is received with new signaling information (one or more signaling nibble has changed).

Note that this flag bit stays set until it is cleared by software. If new signaling is received and the relevant sticky bit is already set, the RISC updates the CAS block without generating another interrupt.

Table 35-8 describes OCASSR fields.

Table 35-8. OCASSR Field Descriptions

Bits	Name	Description
0–7	—	Reserved, should be cleared during initialization.
8, 9, 10, 11, 12, 13, 14, 15	MCASB*n*	Modify CAS Block *n*. When the RISC updates this outgoing CAS block, it sets the MCASB*n* sticky bit and generates an interrupt to notify the core that the signaling information has changed in block *n*. Each channel selects the CAS block number in its RCT; see Section 35.9.1.1, "AAL1 CES Protocol-Specific RCT."

35.11 Buffer Descriptors

The AAL1 CES controller operates as a multi-channel protocol, performing simultaneous segmenting and reassembling of transmit and receive data, to and from different sets of memory buffers for all channels. This behavior makes it necessary to have a separate list of BDs for each channel. Each channel is configured with two BD lists: one for transmit and the other for receive operations. The amount of BDs' in the table is defined by the user.

The BD table is a circular list, the last BD in the table holds a wrap indication. When the QUICC Engine block reaches the last BD, it returns to the head of the list. Each BD in the TxBD table points to a buffer to send. At the receive side, the user allocates dedicated buffers to each channel (that is, one BD for each buffer). When the receiver or transmitter completes writing or reading the buffer, it moves to the next buffer in the list and optionally issues an interrupt.

35.11.1 Transmit Buffer Operation

The user prepares a table of BDs pointing to the buffers to be sent. The address of the first BD is put in the channel's TCT[TBD_BASE]. The transmit process starts when the core issues an ATM transmit command. The RISC reads the first TxBD in the table and sends its associated buffer. When the current buffer is finished, the RISC increments TBD_OFFSET, which holds the offset from TBD_BASE to the current BD. It then reads the next BD in the table. If the BD is ready (TxBD[R] = 1), the RISC continues sending. If the current BD is not ready, the RISC polls the ready bit at the channel rate unless TCT[AVCF] = 1, in which case the RISC removes the channel from the APC and clears TCT[VCON]. The core must issue a new atm transmit command to restart transmission.

Note that when the ATM transmitter is in CES mode, the buffer-not-ready state is ignored by the ATM controller; see Section 35.4.1.2, "TDM-to-ATM."

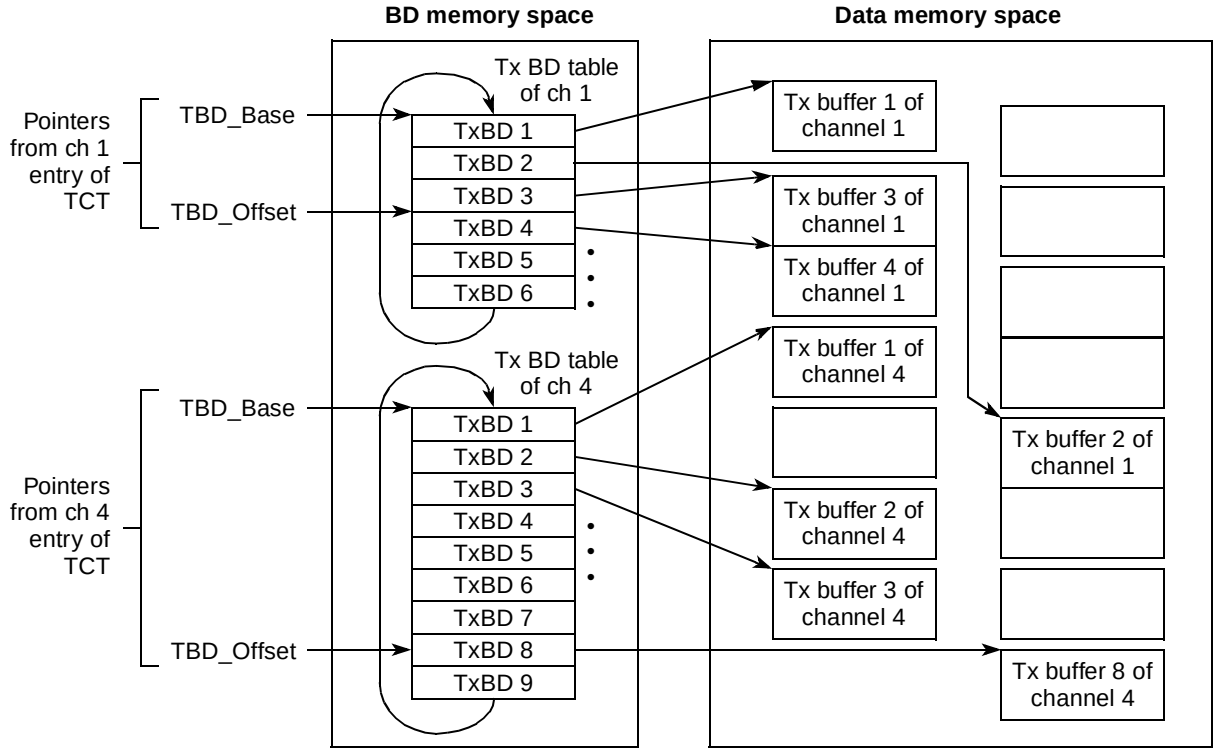

Figure 35-26. Transmit Buffers and BD Table Example

35.11.2 Receive Buffer Operation

The user prepares a table of BDs pointing to the receive buffers. The address of the first BD is put in the channel's RCT[RBD_BASE]. When an ATM cell arrives, the RISC opens the first BD in the table and

starts filling its associated buffer with received data. When the current buffer is full, the RISC increments RBD_OFFSET, which is the offset to the current BD from RBD_BASE, and reads the next BD in the table. If the BD is empty (RxBD[E] = 1), the RISC continues receiving. If the BD is not empty, a busy condition has occurred and the ATM receiver optionally issues an interrupt to the event queue.

Note that when the ATM receiver is in CES mode, the buffer-not-ready (busy) state is handled by an automatic slip control mechanism; see Section 35.5, "ATM-to-TDM Adaptive Slip Control."

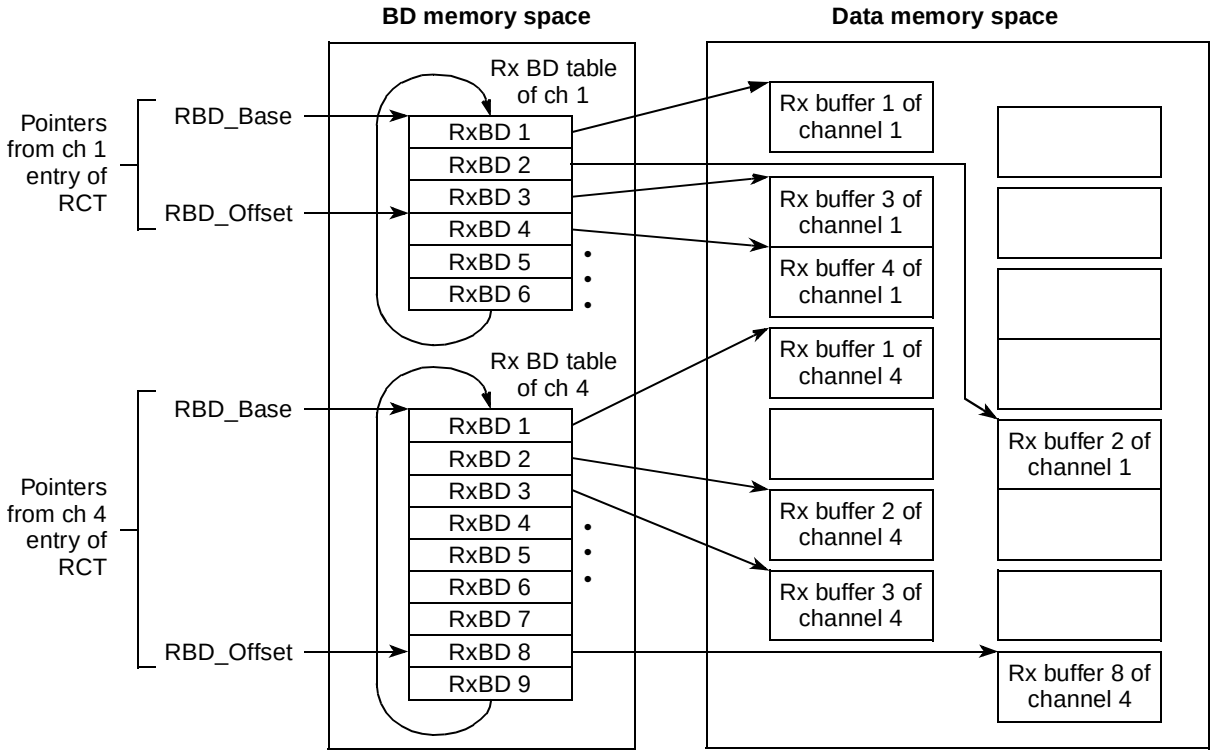

Figure 35-27. Receive Buffers and BD Table Example

35.12 ATM Controller Buffers

Table 35-9 describes properties of the ATM receive and transmit buffers.

Table 35-9. Receive and Transmit Buffers

AAL	Receive		Transmit	
	Size	Alignment	Size	Alignment
AAL5	Multiple of 48 octets (except last buffer in frame)	Double word aligned	Any	No requirement
AAL3/4	At least 44 octets (except last buffer in frame)	Double word aligned	At least 44 octets	No requirement
AAL1/ AAL1 CES	Multiple of 8 octets	No requirement	Multiple of 8 octets	No requirement
AAL0	52-64 octets.	Burst-aligned	52–64 octets.	No requirement

35.12.1 AAL1 CES RxBD

Figure 35-28 shows the AAL1 CES RxBD.

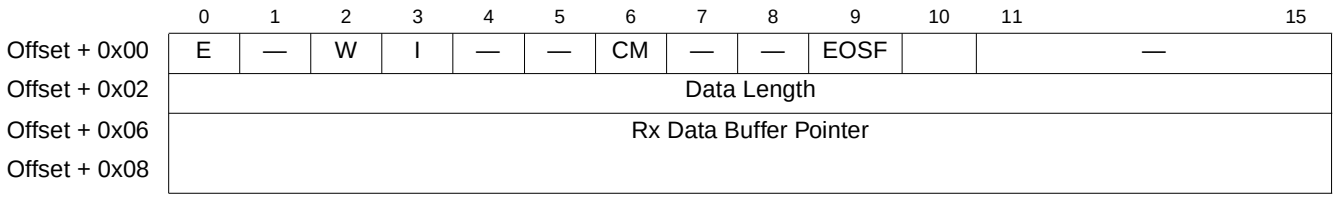

Figure 35-28. AAL1 CES RxBD

Table 35-10 describes AAL1 CES RxBD fields.

Table 35-10. AAL1 CES RxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	E	Empty. 0 The buffer associated with this RxBD is filled with received data or data reception was aborted due to an error. The core can read or write any fields of this RxBD. The RISC cannot use this BD again while E = 0. 1 The buffer is not full. This RxBD and its associated receive buffer are owned by the RISC. Once E is set, the core should not write any fields of this RxBD.
	1	—	—
	2	W	Wrap (final BD in table) 0 This is not the last BD in the RxBD table of the current channel. 1 This is the last BD in the RxBD table of this current channel. After this buffer is used, the RISC receives incoming data into the first BD in the table. The number of RxBDs in this table is programmable and is determined only by the W bit. The current table overall space is constrained to 64 Kbytes.
	3	I	Interrupt 0 No interrupt is generated after this buffer has been used. 1 An Rx buffer event is sent to the interrupt queue after the ATM controller uses this buffer. FCCE[GINT*x*] is set when the INT_CNT reaches the global interrupt threshold.
	4-5	—	—
	6	CM	Continuous mode 0 Normal operation. 1 The empty bit (RxBD[E]) is not cleared by the RISC after this BD is closed, allowing the associated buffer to be overwritten automatically when the RISC next accesses this BD.
	7-8	—	—
	9	EOSF	End of super frame. CES mode (RCT[CESM=1]) only. 0 No signaling information should be inserted after closing this buffer. 1 When closing this buffer, the ATM receiver unpacks the CAS information from the incoming AAL1 cells and stores it in the internal CAS block. Note that this bit should be set by the user at the end of each super-frame in the common (MCC, ATM) BD table. See Section 35.4.6, “Channel Associated Signaling (CAS) Support.”
	10-15	—	—

Table 35-10. AAL1 CES RxBD Field Descriptions

Offset	Bits	Name	Description
0x02	—	DL	Data length. The number of octets the RISC writes into the buffer once its BD is closed.
0x04	—	RXDBPTR	Rx data buffer pointer. Points to the first location of the associated buffer; may reside in either internal or external memory. This pointer must be burst-aligned.

35.12.2 AAL1 CES TxBDs

Figure 35-29 shows the AAL1 CES TxBD.

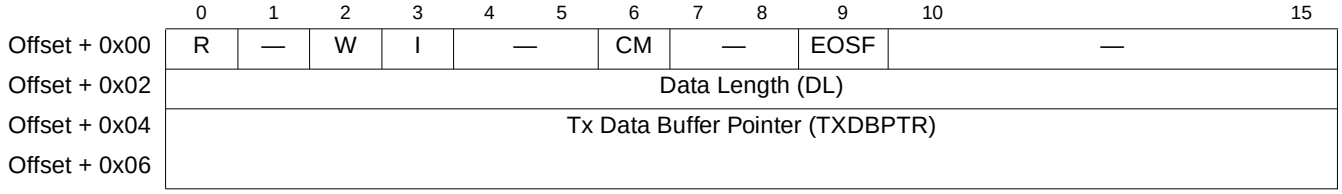

Figure 35-29. AAL1 CES TxBD

Table 35-11 describes AAL1 CES TxBD fields.

Table 35-11. AAL1 CES TxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	R	Ready 0 The buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated buffer. The RISC clears this bit after the buffer has been sent or after an error condition is encountered. 1 The buffer prepared for transmission by the user has not been sent or is being sent. No fields of this BD may be written by the user once R is set.
	1	—	—
	2	W	Wrap (final BD in table) 0 Not the last BD in the TxBD table. 1 Last BD in the TxBD table. After this buffer is used, the RISC sends outgoing data from the first BD in the table (the BD pointed to by the channel's TCT[TBD_BASE]). The number of TxBDs in this table is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	I	Interrupt 0 No interrupt is generated after this buffer has been serviced. 1 A Tx buffer event is sent to the interrupt queue after this buffer is serviced. FCCE[GINT*x*] is set when the INT_CNT counter reaches the global interrupt threshold.
	4–5	—	—
	6	CM	Continuous mode 0 Normal operation. 1 The RISC does not clear the ready bit after this BD is closed, allowing the associated buffer to be retransmitted automatically when the RISC next accesses this BD.
	7–8	—	—

Table 35-11. AAL1 CES TxBD Field Descriptions (continued)

Offset	Bits	Name	Description
	9	EOSF	End of super frame. CES mode (TCT[CESM=1]) only. 0 No signaling information should be inserted after closing this buffer. 1 When closing this buffer the ATM transmitter fetches the CAS information from the internal CAS block and packs it to the outgoing AAL1 cells. Note that this bit should be set by the user at the end of each super-frame in the common (MCC, ATM) BD table. See Section 35.4.6, "Channel Associated Signaling (CAS) Support.". This implies each buffer contains no more then a single super-frame size data.
	10–15	—	—
0x02	—	DL	The number of octets the ATM controller should transmit from this BD's buffer. It is not modified by the RISC. The value of DL should be greater than zero.
0x04	—	TXDBPTR	Tx data buffer pointer. Points to the address of the associated buffer. The buffer may reside in either internal or external memory. This value is not modified by the RISC.

35.13 AAL1 CES Exceptions

There are four circular interrupt queues available for each channel. The interrupt queue number is programmed in RCT[INTQ] and TCT[INTQ]. Events can be masked by clearing interrupt mask bits in the RCT and TCT.

When one of the AAL1 channels generates an interrupt request, the RISC writes a new entry to the table consisting of the channel's number and a description of the exception. The valid (V) bit is then set and INTQ_PTR is incremented. When INTQ_PTR reaches the entry in which W is set, it returns to the first entry of the queue. Each one-word entry provides detailed interrupt information to the host. More details can be found in Section 29.11, "ATM Exceptions."

35.13.1 AAL1 CES Interrupt Queue Entry

The figure below shows an interrupt queue entry.

	0	1	2	3–7	8	9	10	11	12	13	14	15
Offset + 0x00	**V**	—	**W**	—	**SLIPE**	**SLIPS**	**CASUP**	TBNR	RXF	BSY	TXB	RXB
Offset + 0x02	Channel Code (CC)											

Figure 35-30. AAL1 CES Interrupt Queue Entry

The table below describes interrupt queue entry fields.

Table 35-12. AAL1 CES Interrupt Queue Entry Field Descriptions

Offset	Bits	Name	Description
0x00	0	V	Valid interrupt entry 0 This interrupt queue entry is free and can be use by the RISC. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	—	—
	2	W	Wrap bit. When set, this is the last interrupt circular table entry. During initialization, the host must clear all W bits in the table except the last one, which must be set.

Table 35-12. AAL1 CES Interrupt Queue Entry Field Descriptions (continued)

Offset	Bits	Name	Description
	3–7	—	—
	8	**SLIPE**	**Slip End**.Set when an AAL1 channel exits a slip state (the channel's adaptive counter reaches the ATM_Start threshold and the ATM channel regains its SYNC). At this point the receiver starts to receive the incoming cells. See Section 35.6, "3-Step-SN Algorithm." Note that this interrupt can be masked with RCT[SLIPIM=0]. See Section 35.9.1, "Receive Connection Table (RCT)." This interrupt has an associated channel code.
	9	**SLIPS**	**Slip Start**.Set when an AAL1 channel enters a slip state (the channel's adaptive counter reaches the ATM_Stop threshold or the ATM channel loses its SYNC). At this point the receiver drops incoming cells until the adaptive counter reaches the ATM_Start threshold and the channel is resynchronized. See Section 35.6, "3-Step-SN Algorithm." Note that this interrupt can be masked with RCT[SLIPIM=0]. See Section 35.9.1, "Receive Connection Table (RCT)." This interrupt has an associated channel code.
	10	**CASUP**	**CAS Update Interrupt**. Set when one of the eight outgoing CAS blocks is updated by the RISC. New signaling information has been received within the received AAL1 cells. Note that this interrupt available in CES mode and when RCT[CCASM=1] mode. This interrupt has an associated channel code.
	11	TBNR	Tx buffer-not-ready. Set when a transmit buffer-not-ready interrupt is issued. This interrupt is issued when the RISC tries to open a TxBD that is not ready (R = 0). This interrupt is sent only if TCT[BNM] = 1. This interrupt has an associated channel code. Note that for AAL5, this interrupt is sent only if frame transmission is started. In this case, an abort frame transmission is sent (last cell with length=0), the channel is taken out of the APC, and the TCT[VCON] flag is cleared.
	12	RXF	Rx frame. RXF is set when an Rx frame interrupt is issued. This interrupt is issued at the end of AAL5 PDU reception. This interrupt is issued only if RCT[RXFM] = 1. This interrupt has an associated channel code.
	13	BSY	Busy condition. The BD table or the free buffer pool associated with this channel is busy. Cells were discarded due to this condition. This interrupt has an associated channel code.
	14	TXB	Tx buffer. TXB is set when a transmit buffer interrupt is issued. This interrupt is enabled when both TxBD[I] and TCT[IMK] = 1. This interrupt has an associated channel code.
	15	RXB	Rx buffer. RXB is set when an Rx buffer interrupt is issued. This interrupt is enabled when both RxBD[I] and RCT[RXBM] = 1. This interrupt has an associated channel code.
0x02	—	CC	Channel code specifies the channel associated with this interrupt.

35.14 AAL1 Sequence Number (SN) Protection Table

The 32-byte sequence number protection table, pointed to by AAL1_SNPT_BASE in the ATM parameter RAM, resides in multi-user RAM and is used for AAL1 only. The table should be initialized according to Figure 35-31.

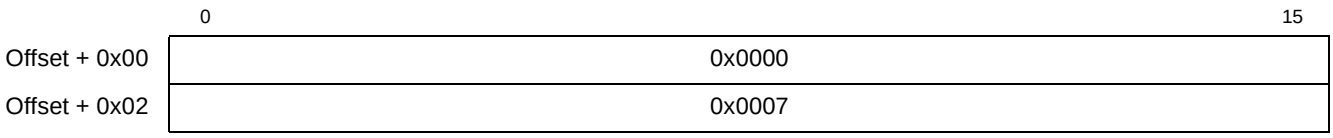

Figure 35-31. AAL1 Sequence Number (SN) Protection Table

Figure 35-31. AAL1 Sequence Number (SN) Protection Table (continued)

35.15 Internal AAL1 CES Statistics Tables

An AAL1 CES statistics table, shown in Table 35-13, resides in the multi-user RAM and holds AAL1 CES statistics on a per-VC basis. AAL1_Int_STATT_BASE points to the base address of these tables. Each AAL1 channel has its own table with a starting address given by AAL1_Int_STATT_BASE + ATM_CHANNEL# × 8.

Table 35-13. AAL1 CES Multi-user RAM Statistics Table

Offset	Name	Width	Description
0x00	Rx_AAL1_VALID	Hword	16-bit cyclic counter. Counts the total received AAL1 cells delivered to the receive buffers. This counter includes the tag cells (with SCE, SNE).
0x02	Rx_AAL1_BOV	Hword	16-bit cyclic counter. Counts the number of ATM buffer-pre overrun events i.e the ATM write pointer reaches the ATM_STOP threshold.See Section 35.5, “ATM-to-TDM Adaptive Slip Control.”
0x04	Tx_AAL1_VALID	Hword	16-bit cyclic counter. Counts the transmitted AAL1 cells.
0x06	Tx_AAL1_BUN	Hword	16-bit cyclic counter. Counts the number of ATM buffer underrun events. See Section 35.4.1.2, “TDM-to-ATM.”

35.16 External AAL1 CES Statistics Tables

An AAL1 CES statistics table, shown in Table 35-14, resides in the external memory and holds AAL1 CES statistics on a per-VC basis. AAL1_Ext_STATT_BASE points to the base address of these tables. Each AAL1 channel has its own table with a starting address given by AAL1_Ext_STATT_BASE + ATM_CHANNEL# × 16.

Table 35-14. AAL1 CES External Statistics Table

Offset	Name	Width	Description
0x00	Rx_AAL1_LOST	Hword	16-bit cyclic counter. Counts the number of AAL1 lost cells events. See Section 35.6, "3-Step-SN Algorithm."
0x02	Rx_AAL1_MISS	Hword	16-bit cyclic counter. Counts the number of AAL1 misinserted events. See Section 35.6, "3-Step-SN Algorithm."
0x04	Rx_AAL1_SCE	Hword	16-bit cyclic counter. Counts the number of AAL1 sequence errors i.e the expected SC is not match with the received one (ESC!= RSC). See Section 35.6, "3-Step-SN Algorithm."
0x06	Rx_SNP_Error	Hword	16-bit cyclic counter. Counts the number of ATM cell that received with SNP error. (AAL1 PDU Header Error)
0x08	Rx_AAL1_SPE	Hword	16-bit cyclic counter. Counts the number of structured pointer error events (i.e parity error, Tag cell or pointer mismatch). See Section 35.7, "Pointer Verification Mechanism."
0x0A	Rx_ReSYNC	Hword	16-bit cyclic counter. Counts the number of AAL1 resynchronized events: pointer reframes, slip events, two consecutive cells with errors (SNE, SCE, Tag…), and two consecutive pointers with errors (parity error or pointer mismatch).
0x0C–0x0E	—	Word	Reserved, should be cleared during initialization.

Note that both the internal and the external statistics tables should be cleared by the user.

35.17 CES-Specific Additions to the MCC

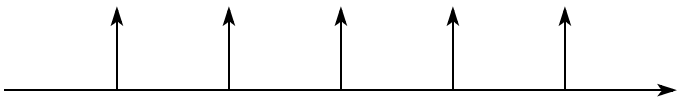
Additions to the MCC global parameter RAM and modifications to the channel-specific CHAMR and INTMASK registers have been implemented to support CES operation. Refer to Section 34.2.2.3, "MCC Parameters for AAL1 CES Usage," Section 34.2.2.3.3, "Interrupt Circular Table Entry and Interrupt Mask (INTMSK)—AAL1 CES," and Table 34-8 for more information.

35.18 Application Considerations

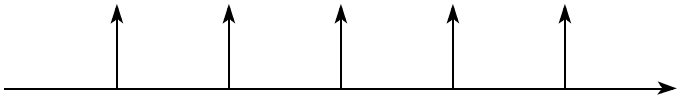
- The buffer size (MCC [MRBLR]) must be a multiple of 8 octets.
- The CAS buffer operates in continuous mode with newer signaling information continuously overwriting older signaling.
- The CES application does not use super-frame synchronization for the data flow in ATM-to-TDM and TDM-to-ATM interworking. However, for the signaling flow, the QUICC Engine block uses the super-frame sync signal to know when to supply the signaling information to the external framer. The external framer then places the signaling information at the appropriate position in the super frame. See Section 35.4.6, "Channel Associated Signaling (CAS) Support."
- Simple external logic is needed to synchronize the MCC-to-framer serial connection. When going from TDM-to-ATM, the CAS information should be read by the MCC on the 24th frame of a super frame.
- The adaptive rate FIFO method can be implemented by the core by calculating the difference between the ATM and MCC pointers.

- When going from TDM-to-ATM, the ATM channel should be programmed to work at a higher rate than the MCC super-channel rate. We expect that the jitter caused by the APC traffic reshaping will depend on the ATM channel rate (PCR, PCR_FRACTION). Figure 35-32 illustrates this timing issue. See also Section 35.4.1.2, "TDM-to-ATM."

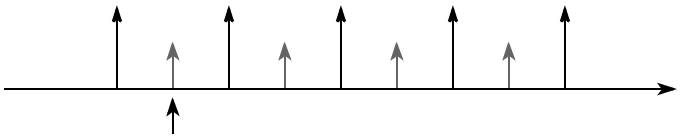
MCC timing:
BDs are ready to be transmitted at the rate shown below.



ATM timing:
The optimal ATM channel rate would match the MCC super channel rate exactly.



ATM timing (adjusted to higher rate):
If PCR and PCR_FACTION cannot provide the exact MCC super channel rate, the ATM channel should be programmed to a higher rate to avoid the MCC buffer-not-ready state. It is recommended that the ATM rate be double that of the MCC.



Extra request at the higher rate to compensate for jitter.

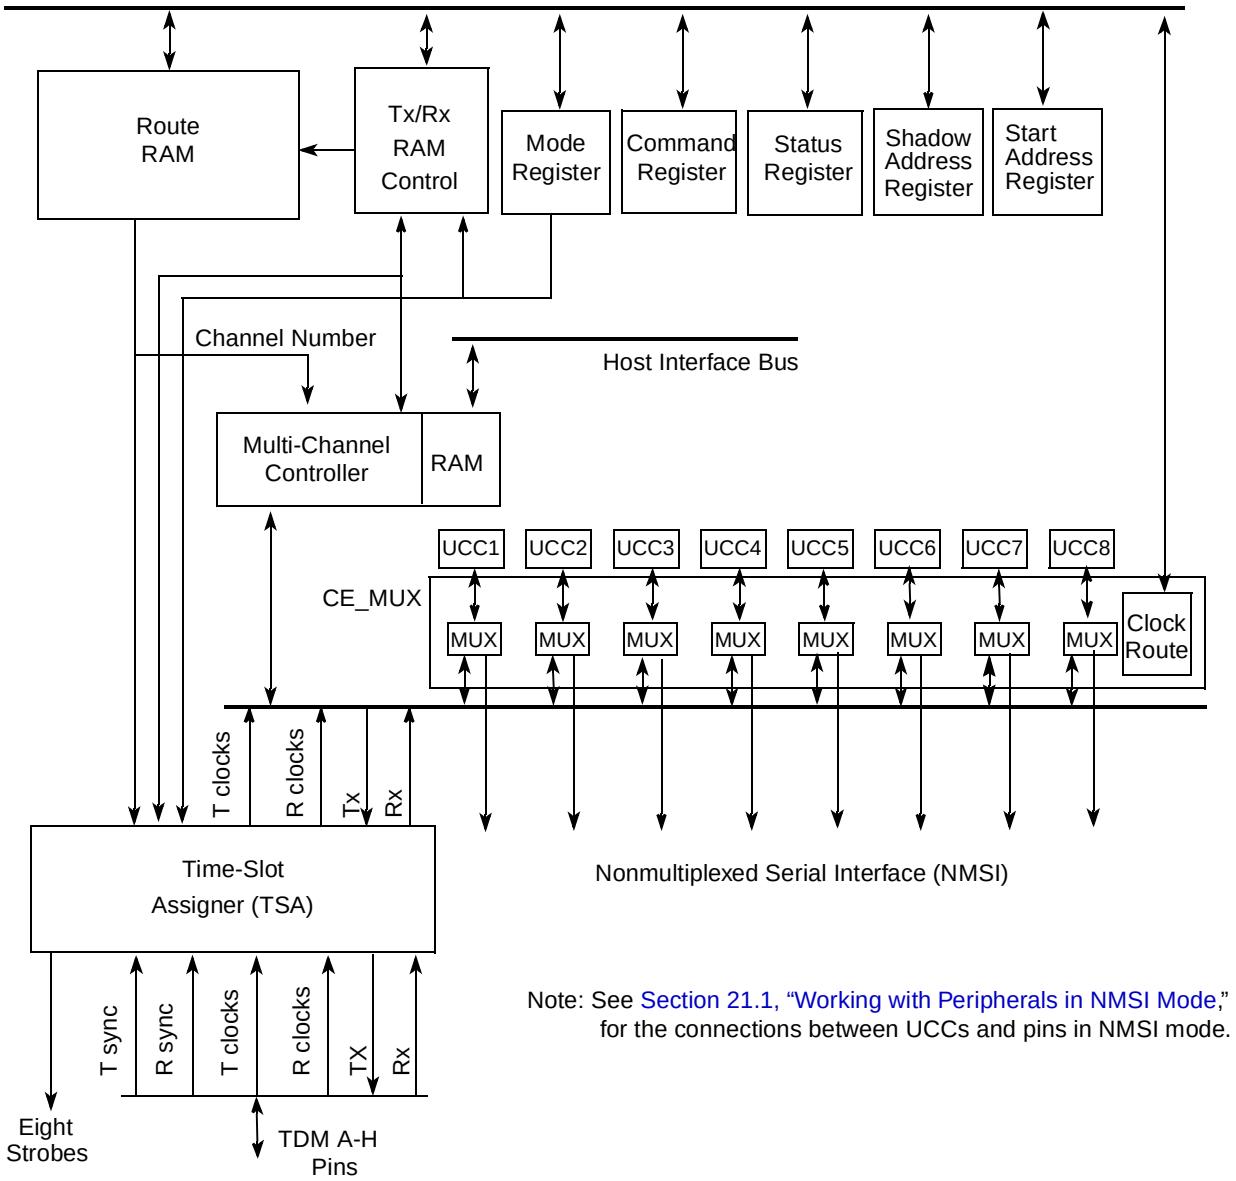
Note that some of the extra requests will not be needed (buffer-not-ready) and will be ignored by the ATM controller.

Figure 35-32. TDM-to-ATM Timing Issue

Chapter 36
Serial Interface with Time-Slot Assigner

36.1 Serial Interface Block Diagram

The serial interface (SI) block diagram is shown in Figure 36-1.



Note: See Section 21.1, "Working with Peripherals in NMSI Mode," for the connections between UCCs and pins in NMSI mode.

Figure 36-1. SI Block Diagram

NOTE

The QUICC Engine MUX and the multi-channel controller are not part of the SI but they are shown because SI is tightly coupled with them.

36.2 Overview

The serial interface (SI) manages the routing of eight time-division multiplexing (TDM) lines to the QUICC Engine block serial drivers, the MCC and the UCCs, for receive and transmit. TDM is technique used in data communications for combining several lower-speed channels into one transmission path at a higher speed in which each low-speed channel is assigned a specific position based upon time in the signal stream.

The SI has eight time-slot assigner (TSA) modules, each handling one TDM line and is connected to a dedicated MCC router. Each TSA can also route time slots to any UCC. The SI stores the routing entries in a RAM. In its simplest mode, the TSA identifies the frame using one sync pulse and one clock signal provided externally by the user. This can be enhanced to allow independent routing of the receive and transmit data on the TDM. Additionally, the definition of a time-slot need not be limited to 8 bits or even to a single contiguous position within the frame. Finally, the user can provide separate receive and transmit syncs as well as clocks. Various TDM configurations are shown in Figure 36-2 through Figure 36-5. TSA programming is independent of the protocol used by the MCC or UCC. For instance, the fact that UCC2 can be programmed for the HDLC protocol does not affect TSA programming.

The TSA implements both internal route selection and time-division multiplexing for multiplexed serial channels. The TSA supports the serial bus rate for most standard TDM buses, including T1 and CEPT highways, pulse-code modulation (PCM) highway, and the ISDN buses in both basic and primary rates.

Each TDM can support E3 or DS-3 rates as a clear channel in either a parallel-nibble or serial interface.

NOTE: On Backward-Compatibility

GCI mode is not supported in the QUICC Engine block.

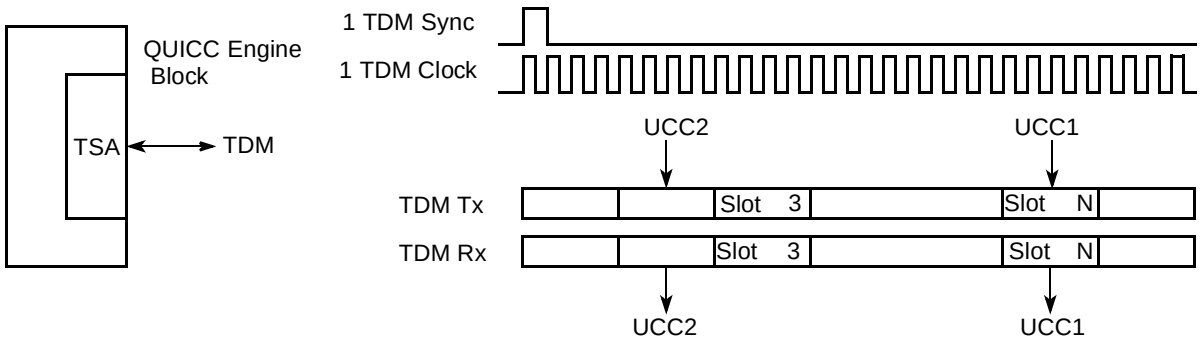


Figure 36-2. Simple TDM Example

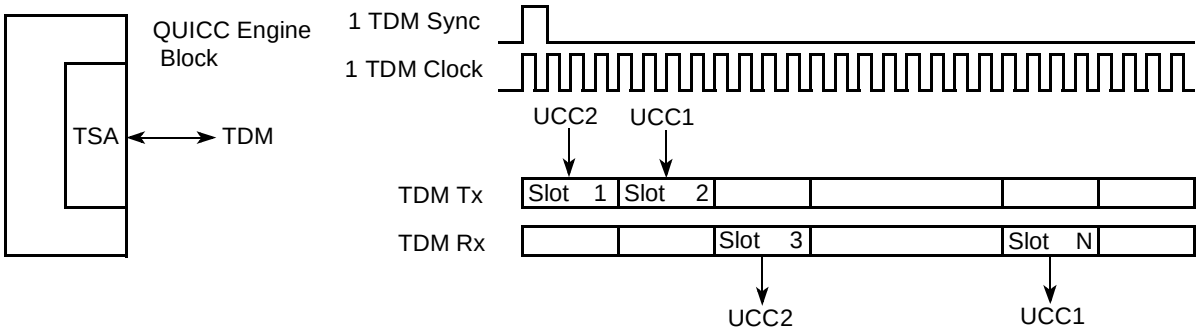

Figure 36-3. TDM Example—Different Tx and Rx Routing

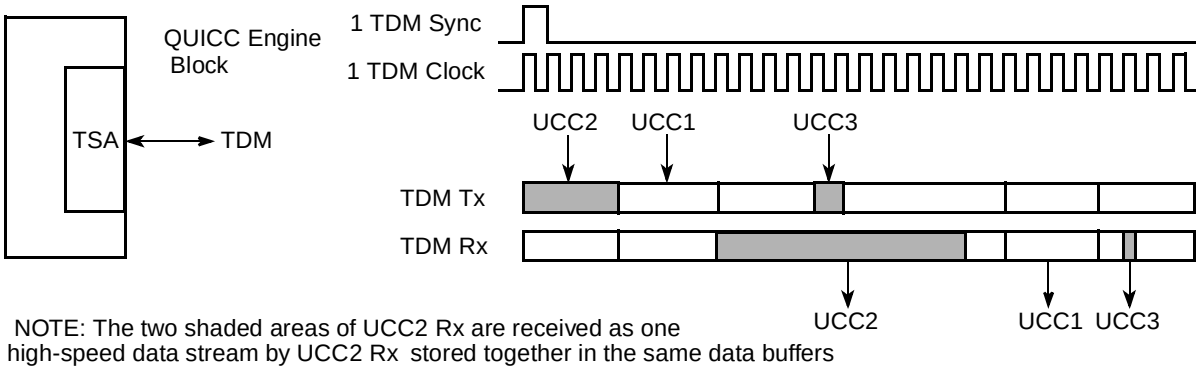

Figure 36-4. TDM Example—Multiple Time Slot Per Channel With Varying Sizes of Time Slot

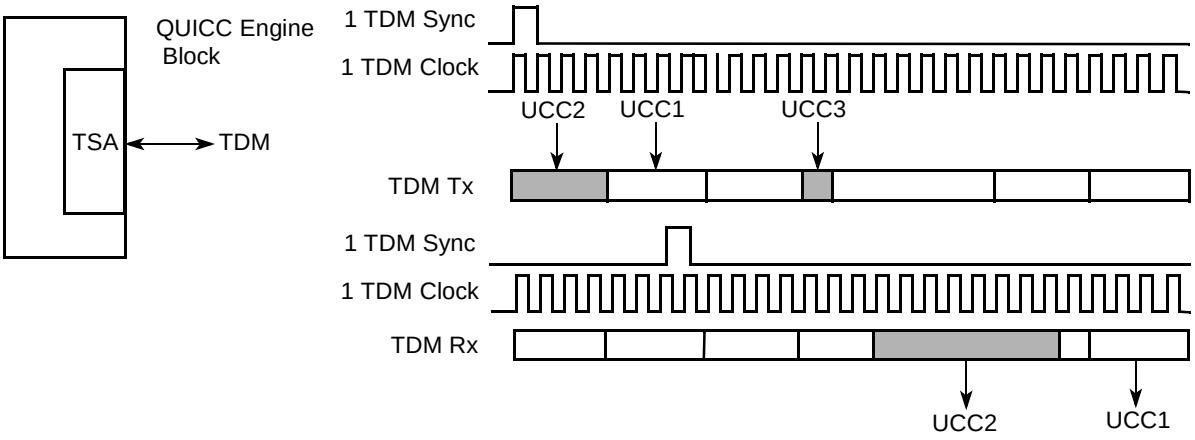

Figure 36-5. TDM Example—Totally Independent Rx and Tx

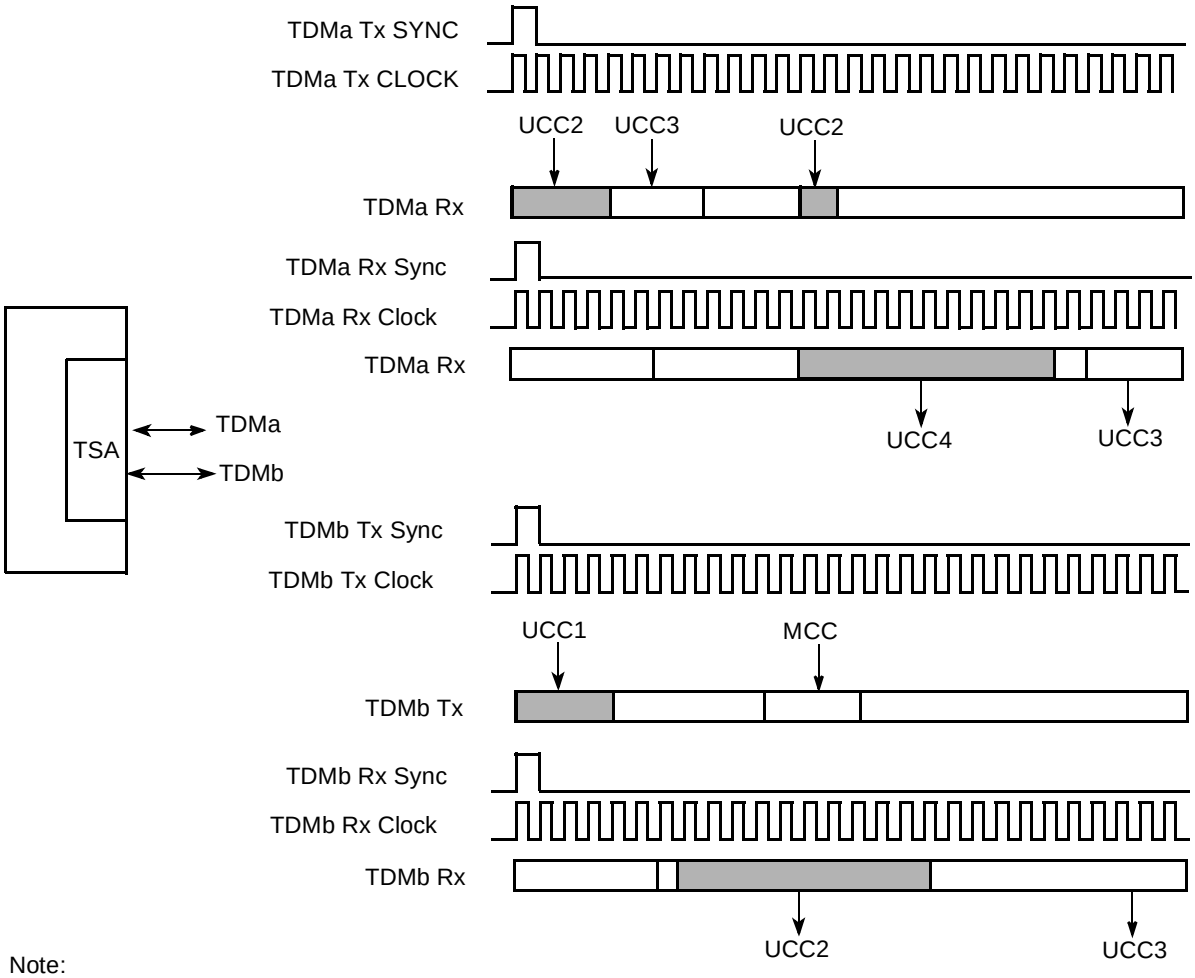
At its most flexible, the TSA can provide eight separate TDM channels, each with independent receive and transmit routing assignments and independent sync pulse and clock inputs. Thus, the TSA can support sixteen, independent, half-duplex TDM sources, eight in reception and eight in transmission, using eight sync inputs and eight clocks each. A dual-channel example is shown in Figure 36-6.



Note:
UCCs can receive on one TDM and transmit on another (UCC2 and UCC3).

Figure 36-6. Dual TDM Channel Example

In addition to channel programming, the TSA supports up to eight strobe outputs that may be asserted on a bit or byte basis (per routing entry). These strobes are completely independent from the channel routing used by the UCCs and MCC. The strobe outputs are useful for interfacing to other devices that do not support the multiplexed interface or for enabling/disabling three-state I/O buffers in a multiple-transmitter architecture. Notice that open-drain programming on the TXDx pins that supports a multiple-transmitter architecture occurs in the parallel I/O block. These strobes can also be used for generating output wave forms to support such applications as stepper-motor control. Note that several strobes may be driven for the same frame. Each strobes can be used by each channel, but care must be taken if using the same strobe by two different TDMs.

Most TSA programming is done in two of 512 entries × 16-bit SI RAMs (receive and transmit). These SI RAMs are directly accessible by the host processor in the chip. One SI RAM is always used to program the transmit routing; the other is always used to program the receive routing. SI RAMs can be used to define the number of bits/bytes to be routed to the MCC or UCC and determine when external strobes are to be asserted and negated.

The number of SI RAM entries available for time-slot programming depends on the user's configuration. For each TDM the user defines how many of the 512 entries are used by that TDM. If on-the-fly changes are allowed, the SI RAM entries are reduced according to the user's programming.

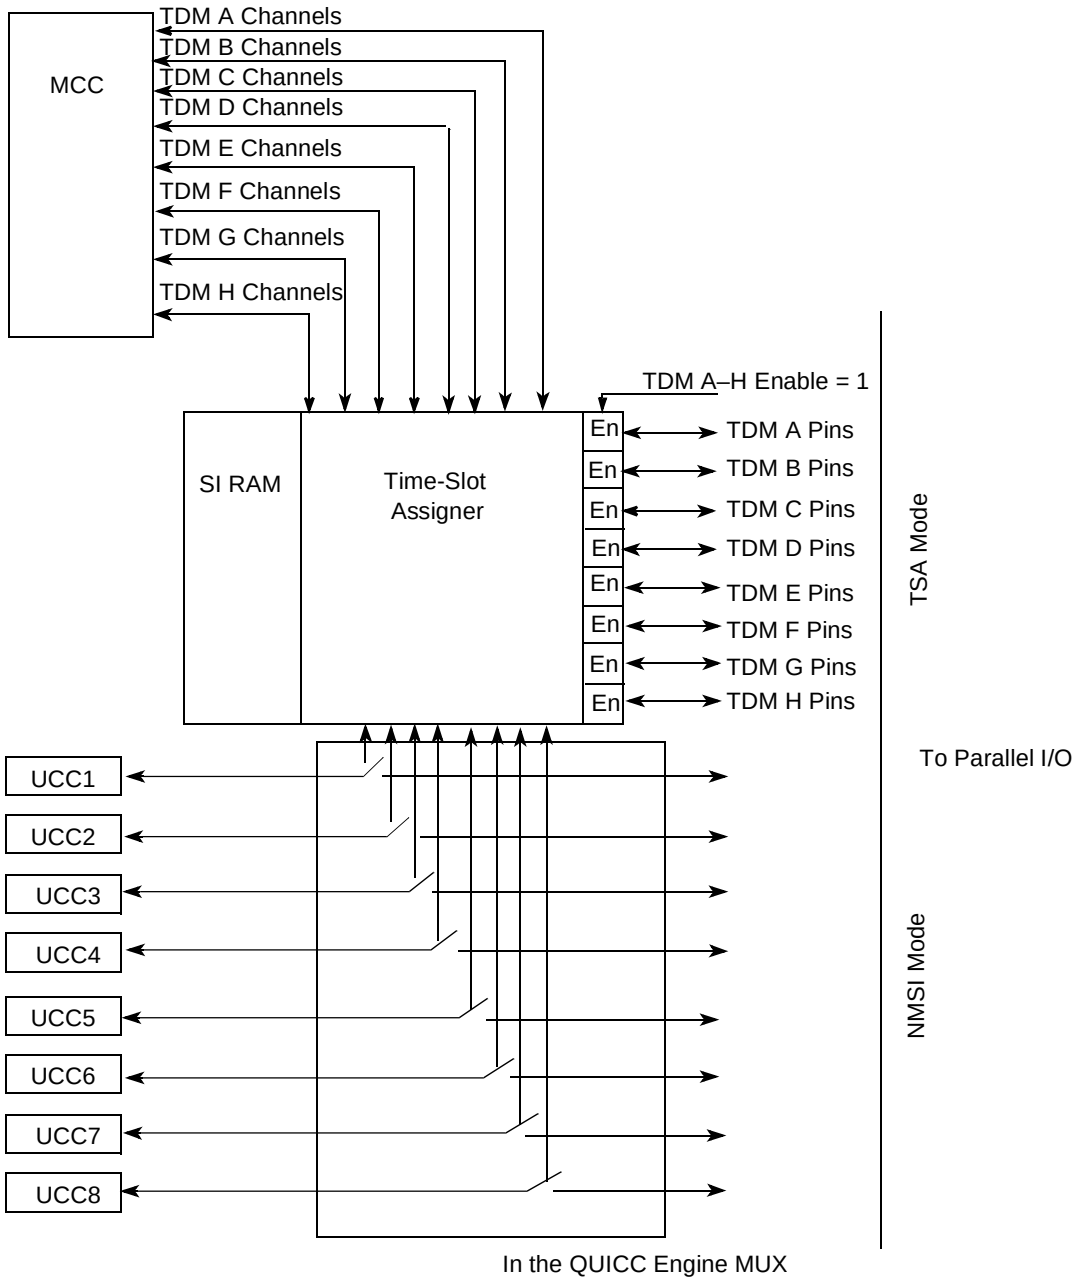
The SI supports two testing modes—echo and loopback.

- The echo mode provides a return signal from the physical interface by retransmitting the signal it has received.The physical interface echo mode differs from the individual UCC echo mode in that it can operate on the entire TDM signal rather than just on a particular serial channel.
- Loopback mode causes the physical interface to receive the same signal it is sending. The SI loopback mode checks more than the individual serial loopback; it checks the SI and the internal channel routes. When applying external/internal loopback with SIxMR[CRT]= 0, rx/tx synchronization is kept by one of the following conditions:
  - First RSYNC/TSYNC is asserted 10 serial clocks after TDM is enabled.
  - Only one RSYNC/TSYNC is asserted per frame.

Note that the flexibility described in the preceding section can be applied to each of the eight TDM channels and to all MCC and UCC's interfaces independently.

36.2.1 Enabling Connections to TSA

Each UCC can be independently enabled to connect to TSA or dedicated external pins (NMSI). The MCC can be connected to any of the eight TDMs with different numbers of channels. The eight TDMs are connected to eight independent TDM interfaces. The connection between the TSA and the serial interfaces is shown in Figure 36-7. The connection is made by programming the CE_MUX and the parallel I/O. After the connections are made, the exact routing decisions are made following the SI RAM entries.



Note: The connections between UCC's and pins in NMSI mode are not shown in this figure.

Figure 36-7. Enabling Connections to the TSA

36.3 Features

The SI includes the following features:

- Can connect to eight independent TDM channels. Each can be one of the following:
  — T1 or CEPT line

  - Integrated services digital network primary rate (PRI)
  - ISDN basic rate–interchip digital link in 4 channels (IDL)
  - E3 or DS3 clear channel.
  - User-defined interfaces.
- Independent, programmable transmit and receive routing paths.
- Total of 512 routing entries for receive and transmit each.
- Total of 256 routing entries + 256 shadow routing entries for receive and transmit each.
- Common or independent transmit and receive frame syncs allowed.
- Common or independent transmit and receive clocks allowed.
- Selection of rising/falling clock edges for the frame sync and data bits.
- Selectable delay (0–3 bits) between frame sync and frame start.
- Eight programmable strobe outputs and eight clock output pins.
- 1- or 8-bit resolution in routing, masking, and strobe selection.
- Internal routing and strobe selection can be dynamically programmed.
- Loopback or echo per bit.
- Switch RxD and TxD lines per bit.
- Supports automatic echo and loopback mode for each TDM.
- Supports parallel-nibble interface for E3 or DS3 on each TDM.
- Can route any of 0–255 time slots to MCC or to any of 8 UCCs.

For the MCC route, the SI performs the following features:

- Up to 256 independent communication channels (on 256 time slots).
- Arbitrary mapping of any of the 256 channels to any TDM time slots.
- Can connect up to eight independent TDM channels. Each TDM channel can support up to 256 channels (all 8 channels can support up to 256 channels together).
- Independent mapping for receive/transmit.
- Individual channel echo or loop mode.
- Switch RxD and TxD lines per bit.
- Global echo or loopback mode through the SI.
- Periodic Multiframe support.[1] An efficient way of interleaving two independent frames and reduce the usage of the shadow RAM.

NOTE: On Backward-Compatibility

Backward-compatibility for the programming model is kept in the SI except for the following cases:

1. Feature available for TDM E only.

- TDMs E-H different memory map.
- GCI normal mode is not supported in the QUICC Engine block.

NOTE: Enhancements

- Base address for current or shadow ram in 16 entries granularity.
- Enhanced debug mode: Switch transmit and receive, loopback/echo per entry for each MCC and UCC.
- Multiframe for all TDMs.
- 256 channels for MCC
- Eight programmable strobe outputs (was only four strobe outputs)
- High-speed operation for UCC entries (the minimal clock ratio between serial and CE clock is 1:8, the maximal clock ratio is 1:16). See Section 36.6.14, "SI Speed Register (SISPD)."

36.4 Modes of Operation

The SI has three main operating modes for the TDMs:

- Static routing. The TDMs routing definitions in RAM can be changed only when the TDM is disabled. After enabling the TDM the new definitions will take place. (The entire RAM may be used but not for shadow RAM).
- Dynamic routing. The TDMs routing definitions can be modified while the TDM is enabled, by programming a different routing RAM and using a host command to switch the routing RAM. (Part of the RAM is used for shadow configuration).
- Multi-frame: The frame structure looks like a two repeating loops. The first loop executes from the TDM's current SI RAM and the second loop from the shadow RAM. The number of iterations per loop is programmable. This mode is used to compress the RAM size required for long frames.

In addition each mode has two testing modes—echo and loopback.

- Echo mode provides a return signal from the physical interface by retransmitting the signal it has received. The physical interface echo mode differs from the serials echo mode in that it can operate on the entire TDM signal rather than just on a particular serial channel.
- Loopback mode cause the physical interface to receive the same signal it is sending. The SI loopback mode checks more than the individual serial loopback. It checks both the SI and the internal channel route.

36.5 SI External Signal Descriptions

This section defines the SI to TDM I/O pins. SI external signal list is shown in Table 36-1.

Table 36-1. SI External Signal Table

Name	Function	I/O
SI:STRB[1:8]	SI strobe signal	O
TDM[A:H]:CLKO	clock out for TDM[A:H]	O

Table 36-1. SI External Signal Table

Name	Function	I/O
TDM[A:H]:RSYNC	Receive data sync TDM[A:H]	I
TDM[A:H]:RXD[0:3]	Receive data TDM[A:H]	I
TDM[A:H]:TSYNC	Transmit data sync TDM[A:H] or IDL grant.	I
TDM[A:H]:TXD[0:3]	Transmit data TDM[A:H]	O
TDM[A:H]:RQ	IDL request permission to transmit on D channel	O

36.5.1 SI Detailed Signal Descriptions

Detailed information about SI external signal list is shown in Table 36-2.

Table 36-2. Interface A—Detailed Signal Descriptions

Signal	I/O	Description	
SI:STRB[1:8]	O	SI strobe signal. The strobe signals may be needed for interfacing other devices.	
		State Meaning	Asserted—Strobe signal is set. Negated—strobe signal is reset.
		Timing	Assertion—in 0-bit delay frame - May occur at any time, otherwise synchronous to clock edge according to SIMR FE & CE fields. Negation—in 0-bit delay frame - May occur at any time, otherwise synchronous to clock edge according to SIMR FE & CE fields.
TDM[A:H]:CLKO	O	clock out for TDM[A:H].This clock is in a rate of 1:1 regarding TDM's receive clock.	
		State Meaning	Asserted / Negated— TDM's receive clock: Data is sampled on clock's rising edge.
		Timing	Assertion / Negation—according to TDM's receive clock.
TDM[A:H]:RSYNC	I	Receive frame sync from TDM [A:H].	
		State Meaning	SIxMR[SL] is cleared: Rising edge of RSYNC will trigger start of frame according to delay in SIxMR[RFSD]. In-frame rising edge is ignored. SIxMR[SL] is set: Falling edge of RSYNC will trigger start of frame according to delay in SIxMR[RFSD]. In-frame falling edge is ignored.
		Timing	Assertion / Negation— Sampled or latched on TDM Rclk edge depending on SIxMR[FE] mode.
TDM[A:H]:RxD[0:3]	I	Receive data from TDM[A:H]**.**Four bits are for nibble mode, RxD[0] used for serial-bit interface.	
		State Meaning	Asserted / Negated— according to received data.
		Timing	Assertion / Negation—Data is sampled on TDM receive clock edge, depending on SIxMR[CE] mode.

Table 36-2. Interface A—Detailed Signal Descriptions (continued)

Signal	I/O	Description	
TDM[A:H]:TSYNC	I	Transmit frame sync to TDM [A:H]. For IDL circuit thus is a grant permission to transmit on the D channel.	
		State Meaning	Sync mode: SIxMR[SL] is cleared: Rising edge of TSYNC will trigger start of frame according to delay in SIxMR[TFSD]. In-frame rising edge is ignored. SIxMR[SL] is set: Falling edge of TSYNC will trigger start of frame according to delay in SIxMR[TFSD]. In-frame falling edge is ignored. Grant mode: assertion is qualified only when RSYNC (sync pulse) is set, negation is qualified regardless of RSYNC: Negated: The TDM has no grant or has lost the grant access to the ISDN D-channel. Asserted: The TDM has granted access on the ISDN D-channel
		Timing	Assertion / Negation— Sync mode: Sampled or latched on TDM Tclk edge depending on SIxMR[FE] mode. Grant mode: Assertion is qualified only when RSYNC (sync pulse) is set, negation is qualified regardless of RSYNC.
TDM[A:H]:TxD[0:3]	O	transmit data to TDM [A:H].Four bits are for nibble mode, TxD[0] used for serial-bit interface.	
		State Meaning	Asserted / Negated— according to transmitted data.
		Timing	Assertion / Negation—Data is driven on TDM transmit clock edge, depending on SIxMR[CE] mode.
TDM[A:H]:RQ	O	IDL request permission to transmit on D channel	
		State Meaning	Asserted - request to transmit data on D channel. Negated - IDLE
		Timing	Assertion / Negation—according to TDM transmit clock.

36.6 SI Register Definition

The list of all internal SI registers is shown in Table 36-3.

Table 36-3. SI Register Summary

Offset from SI1_base	Registers Name	Size	Access	Section/Page
General Registers				
0x00	SI TDM A mode register (SIAMR)	16 bits	R/W	36.6.4/36-18
0x02	SI TDM B mode register (SIBMR)	16 bits	R/W	36.6.4/36-18
0x04	SI TDM C mode register (SICMR)	16 bits	R/W	36.6.4/36-18
0x06	SI TDM D mode register (SIDMR)	16 bits	R/W	36.6.4/36-18
0x08	SI global mode register high (SIGLMRH)	8 bits	R/W	36.6.2/36-16

Table 36-3. SI Register Summary (continued)

Offset from SI1_base	Registers Name	Size	Access	Section/Page

36.6.1 SI RAM Entry

SI RAM is shown in Figure 36-8.

Access: Read/Write

	0	1	2	3	4	5	6	7	10	11	13	14	15
R W	MCC	SWTR	SSEL 1	SSEL 2	SSEL 3	SSEL 4	SGS	CSEL		CNT		BYT	LST
Reset	All zeros												

Figure 36-8. SI RAM Entry for UCC

Table 36-4 describes the SI RAM fields.

Table 36-4. SI RAM Entry Field Description, MCC = 0

Bits	Name	Description
0	MCC	The entry controls the functionality of the other bits in the SI RAM entry. 0 The entry refers to UCC. 1 The entry refers to the MCC.
1	SWTR	Switch Tx and Rx. SWTR should be asserted in both Receive and Transmit route RAM. SWTR affects the operation of both L1RXD and L1TXD. SWTR is set only in special situations where the user prefers to receive data from a transmit pin and transmit data on a receive pin. For instance, where devices A and B are connected to the same TDM, each with different time-slots. Normally, there is no opportunity for stations A and B to communicate with each other directly over the TDM, because they both receive the same TDM receive data and transmit on the same TDM transmit signal. 0 Normal operation of L1TXD and L1RXD. 1 Data for this entry is sent on L1RXD and received from L1TXD.

Table 36-4. SI RAM Entry Field Description, MCC = 0 (continued)

Bits	Name	Description
2–5	SSELx	Strobe select. There are eight strobes available that can be assigned to the receive RAM and asserted/negated with the received clock of this TDM channel (L1RCLKx). They can also be assigned to the transmit RAM and asserted/negated with the transmit clock of this TDM channel (L1TCLKx). Each bit corresponds to the value the strobe should have during this bit/byte group. There are eight strobe pins for all sixteen strobe bits in the SI RAM entries, so the value on a strobe pin is the logical OR of the Rx and Tx RAM entry strobe bit.s Multiple strobes can be asserted simultaneously. A strobe configured to be asserted in consecutive SI RAM entries remains continuously asserted for both entries. A strobe asserted on the last entry in a table is negated after the last entry is processed. **Note:** Each strobe is changed with the corresponding RAM entry and is output only if the corresponding parallel I/O is configured as a dedicated pin. If a strobe is programmed to be asserted in more than one set of entries (the SI route entries for more then one TDM channel select the same strobe), the assertion of the strobe corresponds to the logical OR of all possible sources. This use of strobes is not useful for most applications. A given strobe should be selected in only one set of SI RAM entries. **Note:** Strobes combination can be only of the same SGS group, e.g. there can not be a combination of strobe1 and strobe6. If SGS is 0: 1xxx Strobe 1. x1xx Strobe 2. xx1x Strobe 3. xxx1 Strobe 4. If SGS is 1: 1xxx Strobe 5. x1xx Strobe 6. xx1x Strobe 7. xxx1 Strobe 7.
6	SGS	Strobe group select. Select between four first strobes and four last strobes. 0 Four first strobes are selected. 1 Four last strobes are selected
7–10	CSEL	Channel select 0000 The bit/byte group is not supported by the QUICC Engine block. The transmit data pin is three-stated and the receive data pin is ignored. 0001 The bit/byte group is routed to ucc5. 0010 The bit/byte group is routed to ucc6. 0011 The bit/byte group is routed to ucc7. 0100 The bit/byte group is routed to ucc8. 0101 Reserved. 0110 Reserved. 0111 The bit/byte group is not supported by the QUICC Engine block. 1000 Reserved. 1001 The bit/byte group is routed to ucc1. 1010 The bit/byte group is routed to ucc2. 1011 The bit/byte group is routed to ucc3. 1100 The bit/byte group is routed to ucc4. 11xx Reserved.
11–13	CNT[0-2]	Count. Indicates the number of bits/bytes (according to the BYT bit) that the routing and strobe select of this entry controls. 000 = 1 bit/byte; 111= 8 bits/bytes. **Note:** In nibble mode CNT is in four bits multiplication, i.e. CNT=1 equals 4 bits in parallel.

Table 36-4. SI RAM Entry Field Description, MCC = 0 (continued)

Bits	Name	Description
14	BYT	Byte resolution. 0 Bit resolution–The CNT value indicates the number of bits in this group. 1 Byte resolution–The CNT value indicates the number of bytes in this group.
15	LST	Last entry in the RAM. Whenever SI RAM is used, LST must be set in one of the Tx or Rx entries of each group. Even if all entries of a group are used, this bit must still be set in the last entry. 0 Not the last entry in this section of the route RAM. 1 Last entry in this RAM. After this entry, the SI waits for the sync signal to start the next frame.

NOTE: On Backward-Compatibility

As in PowerQUICC II Pro, there is a minimal restriction of two entries per frame. There is also a minimal restriction of two bits per UCC entry if CDP or CTSP modes are set.

SWTR example is shown in Figure 36-9. The SWTR option lets station B listen to transmissions from station A and send data to station A. To do this, station B would set SWTR in its receive route RAM. For this entry, receive data is taken from the L1TXD pin and data is sent on the L1RXD pin. If the user wants to listen only to station A transmissions and not send data on L1RXD, the CSEL bits in the corresponding transmit route RAM entry should be cleared to prevent transmission on the L1RXD pin.

Station B can transmit data to station A by setting the SWTR bit of the entry in its receive route RAM. Data is sent on L1RXD rather than L1TXD, according to the transmit route RAM. Note that this configuration could cause collisions with other data on L1RXD unless an available (quiet) time slot is used. To transmit on L1RXD and not receive data on L1TXD, clear the CSEL bits in the receive route RAM.

Note that if the transmit and receive sections of the TDM do not use a single clock source, this feature can cause erratic behavior.

This feature does not work with nibble operation.

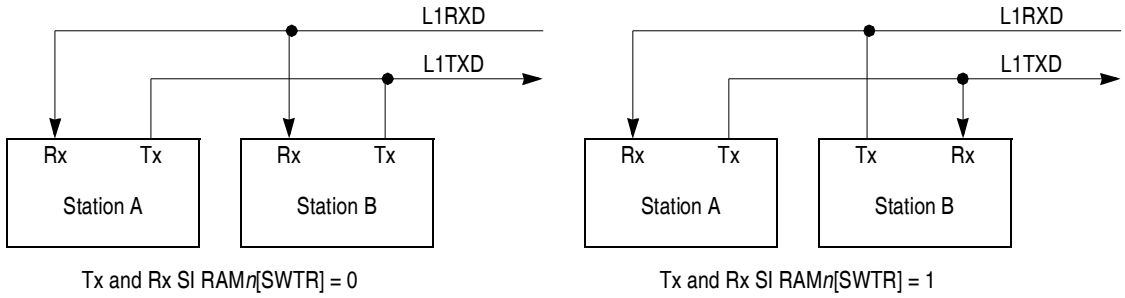

Figure 36-9. Using the SWTR Feature

SI RAM entry register with MCC = 1, is shown in Figure 36-10.

Access: Read/Write

	0	1	2	3	10	11	13	14	15
R W	MCC	LOOP/ ECHO	SUPER	MCSEL		CNT		BYT	LST
Reset	All zeros								

Figure 36-10. SI RAM Entry for MCC

Table 36-5 describes SI RAM entry with MCC = 1 fields.

Table 36-5. SI RAM Entry with MCC = 1

Bits	Name	Description
0	MCC	The entry controls the functionality of the other bits in the SI RAM entry. 0 The entry refers to UCC. 1 The entry refers to the MCC.
1	LOOP/ECHO	Channel loopback or echo. In the receive SI RAM, this bit selects loopback mode for this MCC channel. The channel's transmit data is sent to both the receiver's input and to the data output line. In the transmit SI RAM, this bit selects echo mode for this MCC channel. The channel's receive data is sent both to the transmitter's line and to the receiver input. **Note:** For loopback operation, set LOOP/ECHO=1 in the Rx and LOOP/ECHO=0 in the Tx. For echo operation, set LOOP/ECHO=0 in the Rx and LOOP/ECHO=1 in the Tx. **Note:** To use the loop/echo modes program the receive and transmit SIx RAMs identically, except that the LOOP/ECHO field. **Note:** To switch between Rx and Tx pin functionality set LOOP/ECHO=1 in both the Rx and Tx entries, see Section 36.6.1, "SI RAM Entry," SWTR. 0 Normal mode of operation. 1 Operation depends on the above configurations:
2	SUPER	MCC super channel enable 0 The current entry refers to a super channel.
3–10	MCSEL	MCC channel select. Indicates the MCC channel the bit/byte group is routed to 0000_0000 selects channel 0; 1111_1111, selects channel 255.
11–13	CNT	If SUPER = 0 (normal mode), CNT indicates the number of bits/bytes (according to the BYT bit) that the routing select of this entry controls. 000 = 1 bit/byte; 111 = 8 bits/bytes. If SUPER = 1 (MCC super channel), CNT and BYT together indicate whether the current entry is the first byte of the MCC super channel. BYT = 1—The current entry is the first byte of this MCC super channel. BYT = 0—The current entry is not the first byte of this MCC super channel. CNT: The length may be one of the following: 5,6,7,8 or 16 bits. Refer to Table 36-6 for more information. **Note:** when SUPER = 1, all SI RAM entries relating to MCC must be of the same length.
14	BYT	Byte resolution. 0 Bit resolution–The CNT value indicates the number of bits in this group. 1 Byte resolution–The CNT value indicates the number of bytes in this group.
15	LST	Last entry in the RAM. Whenever SI RAM is used, LST must be set in one of the Tx or Rx entries of each group. Even if all entries of a group are used, this bit must still be set in the last entry. 0 Not the last entry in this section of the route RAM. 1 Last entry in this RAM. After this entry, the SI waits for the sync signal to start the next frame.

36.6.1.1 MCC Superchannel Coding

Table 36-6 shows coding of MCC command entry for different cases.

Table 36-6. Super Channel Coding

SuperChannel Bit Entry bit[2]	CNT Entry Bits[11:13]	Bit/Byte Entry Bit[14]	Description
1	000	1	First byte in super channel
1	111	0	Not first byte in super channel
1	001	1	First 2 bytes in super channel
1	001	0	Not first 2 bytes in super channel (SuperChannel does not use a single bit)
1	100	1	First 5 bits in super channel
1	100	0	Not First 5 bits in super channel (SuperChannel does not use 5 bytes)
1	101	1	First 6 bits in Super channel
1	101	0	Not first 6 bits in super channel (SuperChannel does not use 6 bytes)
1	110	1	First 7 bits in super channel
1	110	0	Not First 7 bits in super channel (SuperChannel does not use 7 bytes)

Superchannel is not a protocol dependant mode, rather a performance enhancing mode.

Superchannelling is used for sending multiple back-to-back timeslots from the same MCC channel. A single MCC channel is the combination of one MCC channel and one set of related channel parameters and buffer descriptors. A superchannel is the combination of multiple MCC TX channels and one set of MCC channel's parameters and buffer descriptors to manage this group of channels. This provides the ability to construct a larger overall channel than that of a single normal MCC TX channel. Superchannel makes use of HW resources of unused channels to enhance its performance, the user may not use the channels in the superchannel for any other purpose nor use the same channel twice in the construction of a superchannel.

The length of superchannelled timeslot may be one of the following sizes 5, 6, 7, 8 or 16 bits.

36.6.2 SI Global Mode Register High (SIGLMRH)

SI Global Mode Register High is shown in Figure 36-11.

Offset 0x08 Access: Read/Write

Reset	All zeros									

Figure 36-13. SI Mode Register (SI*x*MR)

NOTE

Adjacent sync signals should have minimum delay between them of at least one clock cycle.

Table 36-9 describes SI Mode Register fields.

Table 36-9. SI Mode Register Description

Bits	Name	Description
0–3	SADx	Starting address for the RAM of TDM*x*. These four bits define the starting address of the SI RAM section that belongs to TDM*x* channel. The last entry of a certain TDM is determined by the LST bit in the SI RAM entry. The user must set LST within the entries of SI RAM blocks for every TDM used i.e. before the starting address of the next TDM. 0000 Entries 0-31, bank0 0001 Entries 32-63, bank0 0010 Entries 64-95, bank1 0011 Entries 96-127, bank1 0100 Entries 128-159, bank2 0101 Entries 160-191, bank2 0110 Entries 192-223, bank3 0111 Entries 224-255, bank3 1000 Entries 256-287, bank4 1001 Entries 288-319, bank4 1010 Entries 320-351, bank5 1011 Entries 352-383, bank5 1100 Entries 384-415, bank6 1101 Entries 416-447, bank6 1110 Entries 448-479, bank7 1111 Entries 480-511, bank7 **Note:** Each bank should be addressed by a single TDM only

Table 36-9. SI Mode Register Description (continued)

Bits	Name	Description
4–5	SDM*x*	SI Diagnostic Mode for all eight TDMs 00 normal operation. 01 Automatic echo. In this mode, the channel_x transmitter automatically retransmits the TDM received data on a bit-by-bit basis. The receive section operates normally, but the transmit section can only retransmit received data. In this mode, the L1GR*x* line is ignored. 10 Internal loopback. In this mode, the TDM transmitter output is internally connected to the TDM receiver input (L1TXD*x* is connected to L1RXD*x*). The receiver and transmitter operate normally. The data appears on the L1TXD*x* pin and in this mode, the L1RQ*x* line is asserted normally. The L1GR*x* line is ignored. 11 Loopback control. In this mode, the TDM transmitter output is internally connected to the TDM receiver input (L1TXD*x* is connected to L1RXD*x*). The transmitter output (L1TXD*x*) and the L1RQ*x* pin is inactive. This mode is used to accomplish loopback testing of the entire TDM without affecting the external serial lines.
6–7	RFSD*x*.	Receive frame sync delay for all eight TDM. Determines the number of clock delays between the receive sync and the first bit of the receive frame. Even if CRT*x* is set, these bits do not control the delay for the transmit frame. 00 No bit delay. The first bit of the frame is transmitted/received on the same clock as the sync. 01 1-bit delay. Use for IDL. 10 2-bit delay 01 3-bit delay
8	—	Reserved. Should be cleared.
9	CRT*x*	Common receive and transmit pins for all TDM. Useful when the transmit and receive sections of a given TDM use the same clock and sync signals. In this mode, L1TCLK*x* and L1TSYNC*x* pins can be used as general-purpose I/O pins. 0 Separate pins. The receive section of this TDM uses L1RCLK*x* and L1RSYNC*x* pins for framing and the transmit section uses L1TCLK*x* and L1TSYNC*x* for framing. 1 Common pins. The receive and transmit sections of this TDM use L1RCLK*x* as clock pin of channel x and L1RSYNC*x* as the receive and transmit sync pin. Use for IDL. RFSD and TFSD are independent of one another in this mode.
10	SL*x*	Sync level for all TDM's. 0 The L1RSYNC*x* and L1TSYNC*x* signals are active on logic "1". 1 The L1RSYNC*x* and L1TSYNC*x* signals are active on logic "0".
11	CE*x*	Clock edge for all TDM's. 0 The data is transmitted on the rising edge of the clock and received on the falling edge (use for IDL). 1 The data is transmitted on the falling edge of the clock and received on the rising edge
12	FE*x*	Frame sync edge for all TDM's. Determines whether L1RSYNC*x* and L1TSYNC*x* pulses are sampled with the falling/rising edge of the channel clock. 0 Falling edge. Use for IDL. 1 Rising edge.
13	GM*x*	Grant mode for all TDM's. 0 No grant mode is supported. 1 IDL mode. A GRANT mechanism is supported if the corresponding CMXSCR[GR*x*] is set. The grant is a sample of L1GR*x* while L1TSYNC*x* is asserted. This grant mechanism implies the IDL access controls for transmission on the D channel.

Table 36-9. SI Mode Register Description (continued)

Bits	Name	Description
14–15	TFSD*x*	Transmit frame sync delay for all TDM's. Determines the number of clock delays between the transmit sync and the first bit of the transmit frame. 00 No bit delay. The first bit of the frame is transmitted/received on the same clock as the sync. 01 1-bit delay 10 2-bit delay 11 3-bit delay

One-clock delay from sync to data when SI*x*MR[*n*FSD] = 01 is shown in Figure 36-14.

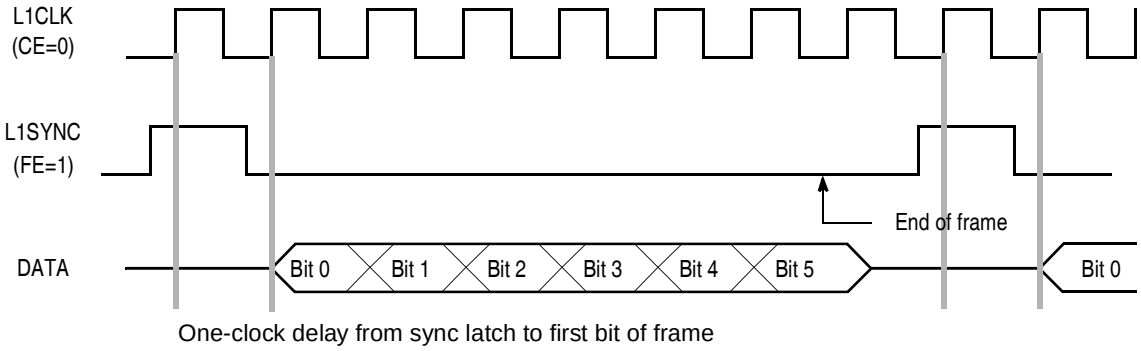

Figure 36-14. One-Clock Delay from Sync to Data (SI*x*MR[*n*FSD] = 01)

The elimination of the single-clock delay shown in Figure 36-15. Because SI*x*MR[*n*FSD] = 00 there is no delay between L1SYNC and the first bit of the frame.

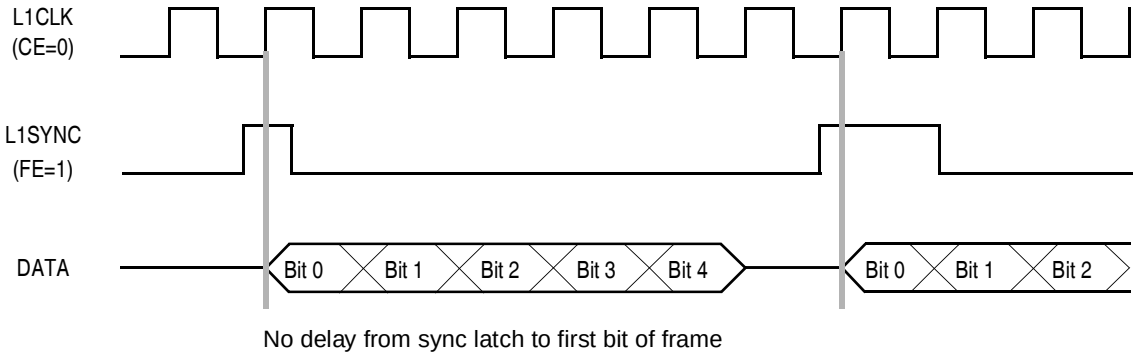

Figure 36-15. No Delay from Sync to Data (SI*x*MR[*n*FSD] = 00)

The difference between SI*x*MR[FE] = 0 and SI*x*MR[FE] = 1 is shown in Figure 36-16. In this example, SI*x*MR[CE] = 1 and there is 1-bit frame delay (SI*x*MR[*n*FSD] = 01).

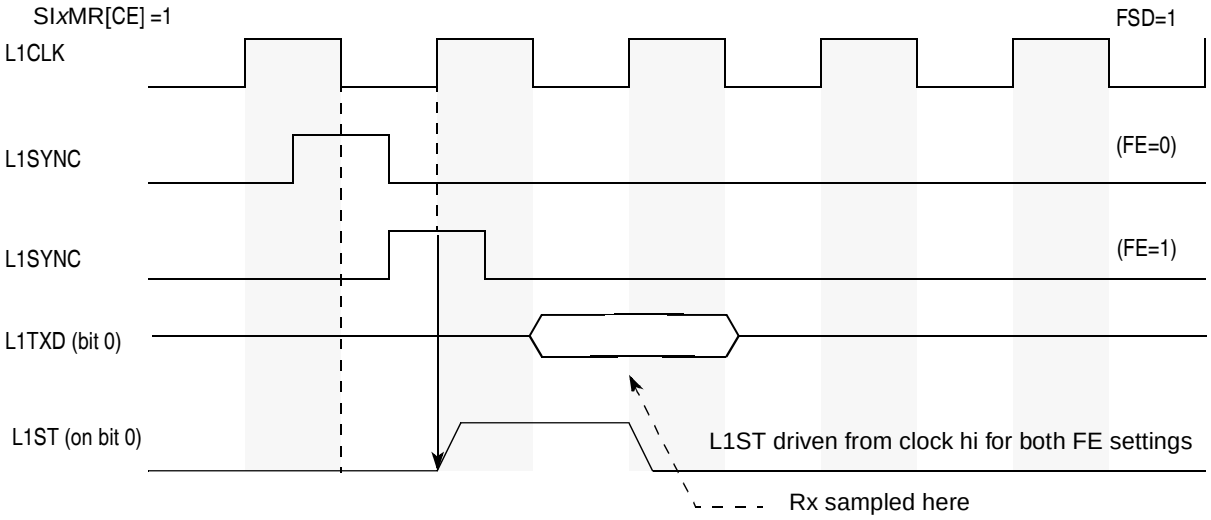

Figure 36-16. Falling Edge Effect when SI*x*MR[CE] = 1 and SI*x*MR[*n*FSD] = 01

The effect of SI*x*MR[CE] = 0 and different SI*x*MR[FE] values, with 1-bit frame sync delay is shown in Figure 36-17.

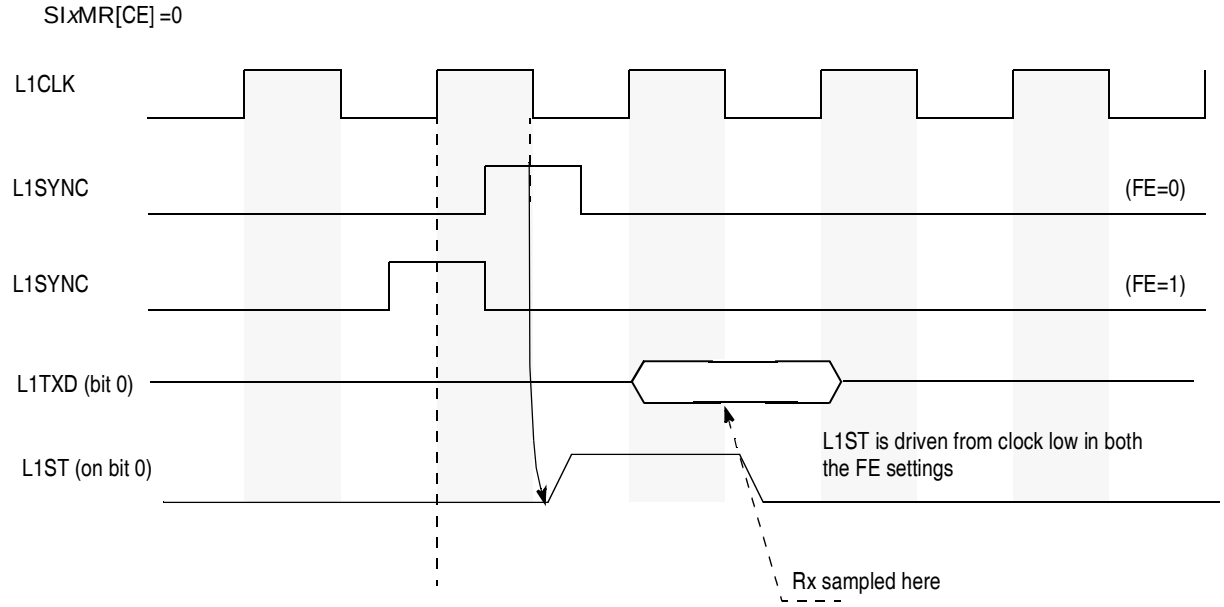

Figure 36-17. Falling Edge Effect when SI*x*MR[CE] = 0 and SI*x*MR[*n*FSD] = 01

The effect of different SI*x*MR[FE] settings when SI*x*MR[CE]=1 and no frame sync delay is shown in the following figures.

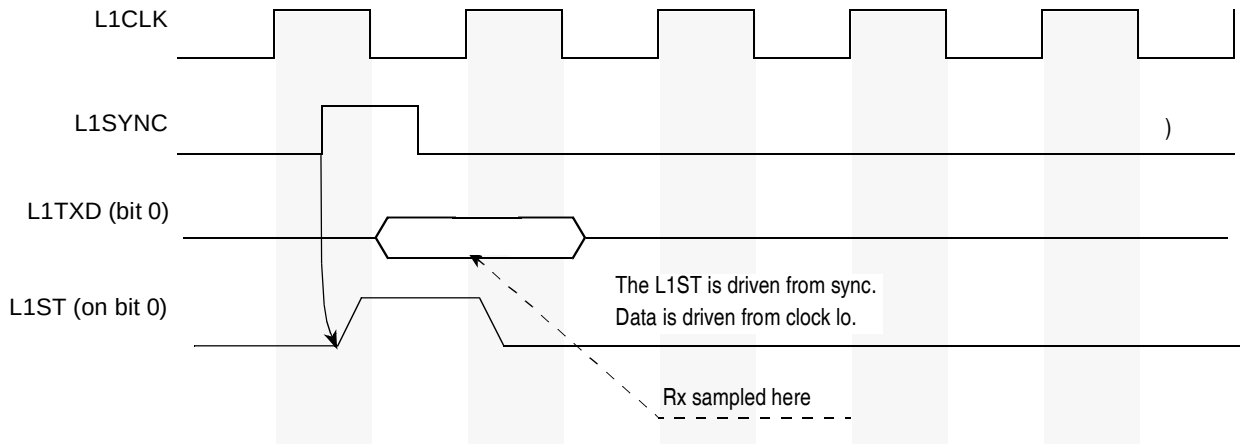

Figure 36-18. Falling Edge Effect When SI*x*MR[CE] = 1, SI*x*MR[FE] = 0 and SI*x*MR[*n*FSD] = 00 (SYNC Starts Before Falling Edge)

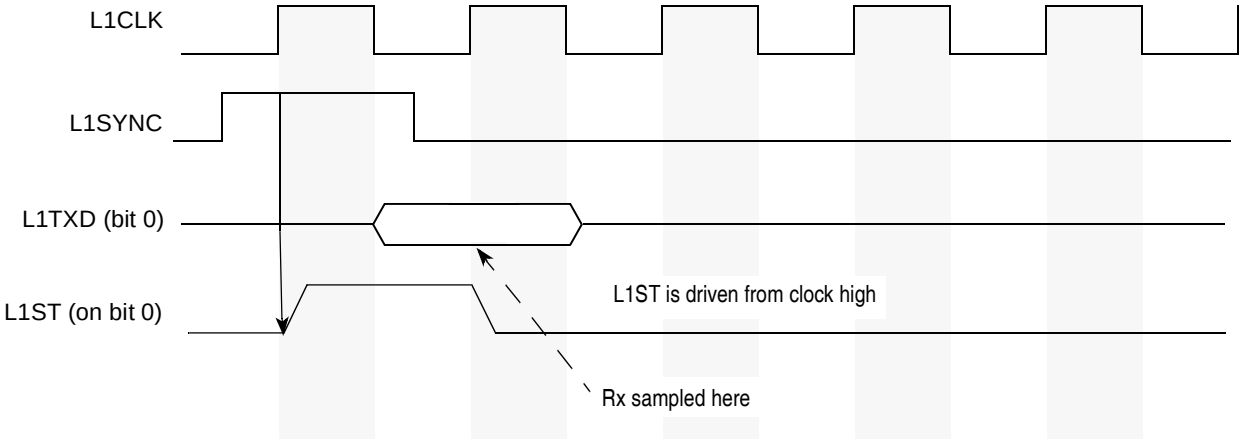

Figure 36-19. Falling Edge Effect When SI*x*MR[CE] = 1, SI*x*MR[FE] = 0 and SI*x*MR[*n*FSD] = 00 (SYNC Starts Before Rising Edge)

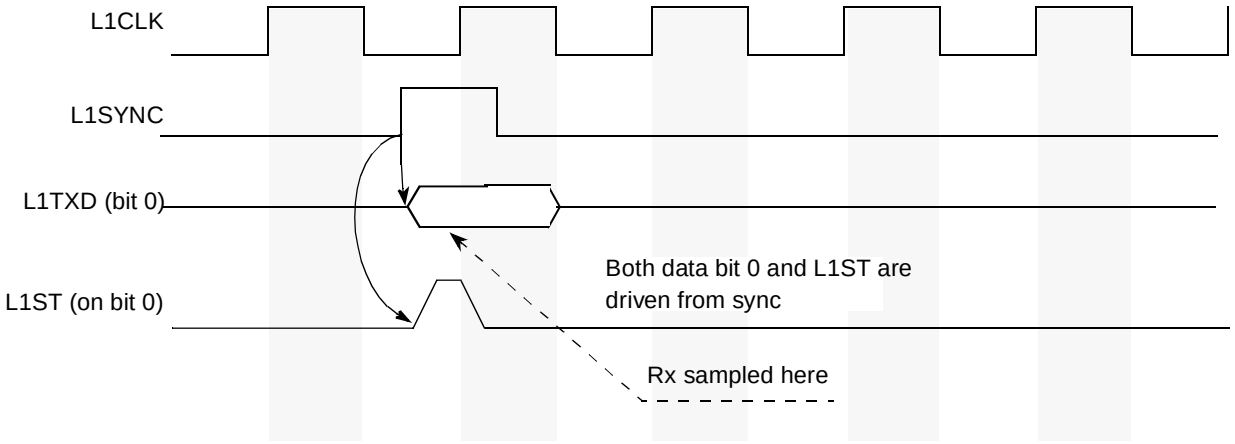

Figure 36-20. Falling Edge Effect when SI*x*MR[CE] =1, SI*x*MR[FE] =1 and SI*x*MR[*n*FSD] = 00 (Sync Starts Before Rising Edge)

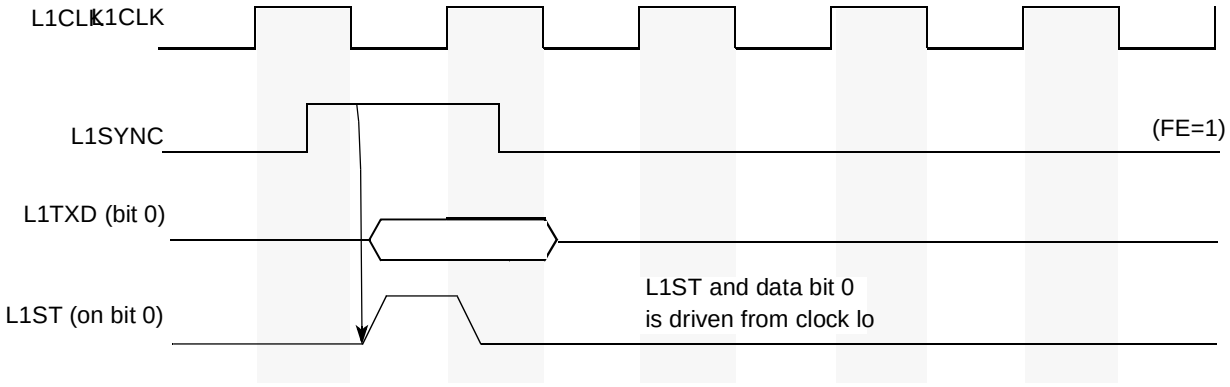

Figure 36-21. Falling Edge Effect when SI*x*MR[CE] =1, SI*x*MR[FE] =1 and SI*x*MR[*n*FSD] = 00 (Sync Starts Before Falling Edge)

The effects of different FE when SI*x*MR[CE] = 0 with no frame sync delay are shown in Figure 36-22 through Figure 36-25.

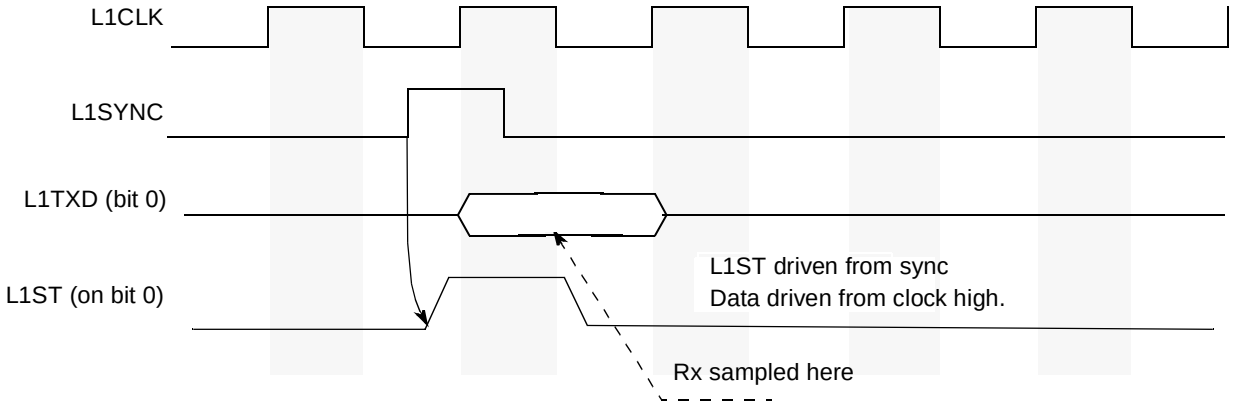

Figure 36-22. Falling Edge Effect when SI*x*MR[CE] = 0, SI*x*MR[FE] = 1 and SI*x*MR[*n*FSD] = 00 (SYNC Starts Before Rising Edge)

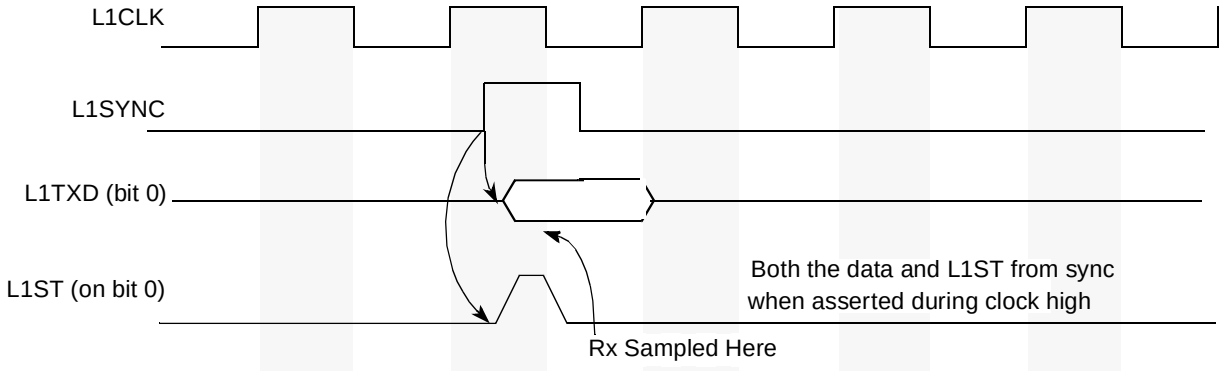

Figure 36-24. Falling Edge Effect when SI*x*MR[CE] = 0, SI*x*MR[FE] = 0 and SI*x*MR[*n*FSD] = 00 (SYNC Starts Before Falling Edge)

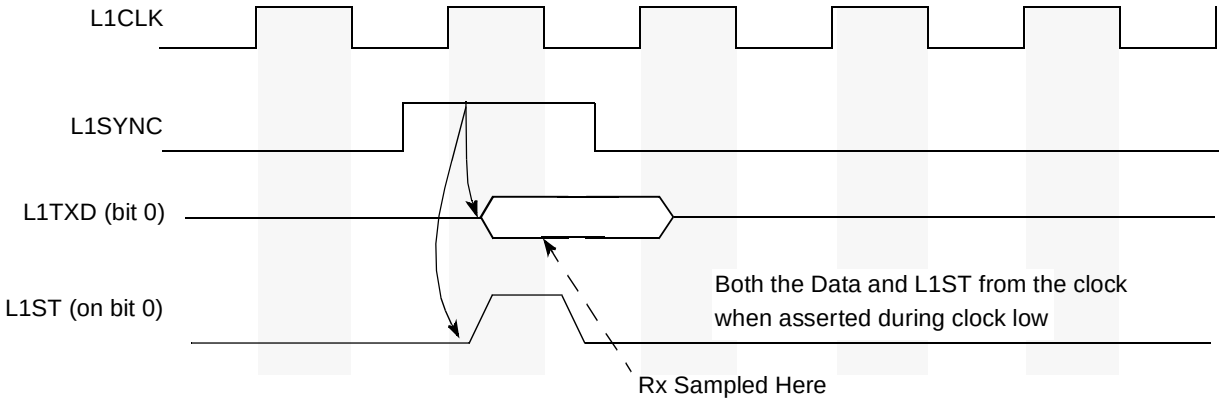

Figure 36-25. Falling Edge Effect when SI*x*MR[CE] = 0, SI*x*MR[FE] = 0 and SI*x*MR[*n*FSD] = 00 (SYNC Starts Before Rising Edge)

36.6.5 SI RAM Shadow Address Register High (SIRSRH)

SIRSRH, shown in Figure 36-26, defines the starting addresses of the shadow section in the SI RAM for each of the high four TDM channels (TDM A–TDM D).

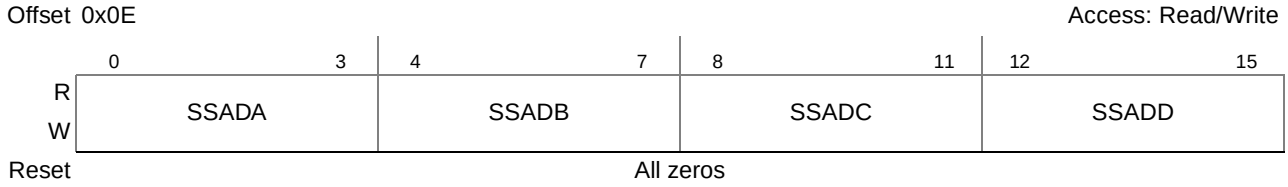

Figure 36-26. SI RAM Shadow Address Register High (SIRSRH)

SI RAM shadow address register field description is shown in Table 36-10.

Table 36-10. SI RAM Shadow Address Register High Field Descriptions

Bits	Name	Description
0–3, 4–7, 8–11, 12–15	SSAD*x*	Starting address for the RAM of TDM*x*. Defines the starting address of the SI RAM section that belongs to the TDM*x* channel. The last entry of a certain TDM is determined by the LST bit in the SI RAM entry. The user must set LST within the entries of SI RAM blocks for every TDM used— that is, before the starting address of the next TDM. 0000 Entries 0–31, bank0 0001 Entries 32–63, bank0 0010 Entries 64–95, bank1 0011 Entries 96–127, bank1 0100 Entries 128–159, bank2 0101 Entries 160–191, bank2 0110 Entries 192–223, bank3 0111 Entries 224–255, bank3 1000 Entries 256–287, bank4 1001 Entries 288–319, bank4 1010 Entries 320–351, bank5 1011 Entries 352–383, bank5 1100 Entries 384–415, bank6 1101 Entries 416–447, bank6 1110 Entries 448–479, bank7 1111 Entries 480–511, bank7 **Note:** Each bank should be addressed by a single TDM only

36.6.6 SI RAM Shadow Address Register Low (SIRSRL)

The SI RAM shadow address register low (SIRSRL), shown in Figure 36-27. It defines the starting addresses of the shadow section in the SI RAM for each of the low four TDM channels. When the TEG bit in SIMR is set the register has different structure, shown in Figure 36-27.

Offset 0x2E Access: Read/Write

	0–3	4–7	8–11	12–15
R W	SSADE	SSADF	SSADG	SSADH
Reset	All zeros			

Figure 36-27. SI RAM shadow address register low (SIRSRL)

SI RAM shadow address register field description is shown in Table 36-11.

Table 36-11. SI RAM Shadow Address Register Description

Bits	Name	Description
0–3, 4–7, 8–11, 12–15	SSAD*x*	Starting address for the RAM of TDM*x*. These four bits define the starting address of the SI RAM section that belongs to TDM*x* channel. The last entry of a certain TDM is determined by the LST bit in the SI RAM entry. The user must set LST within the entries of SI RAM blocks for every TDM used. that is. before the starting address of the next TDM. 0000 Entries 0-31, bank0 0001 Entries 32-63, bank0 0010 Entries 64-95, bank1 0011 Entries 96-127, bank1 0100 Entries 128-159, bank2 0101 Entries 160-191, bank2 0110 Entries 192-223, bank3 0111 Entries 224-255, bank3 1000 Entries 256-287, bank4 1001 Entries 288-319, bank4 1010 Entries 320-351, bank5 1011 Entries 352-383, bank5 1100 Entries 384-415, bank6 1101 Entries 416-447, bank6 1110 Entries 448-479, bank7 1111 Entries 480-511, bank7 **Note:** Each bank should be addressed by a single TDM only

36.6.7 SI Command Register High (SICMDRH)

SICMDRH, shown in Figure 36-28, allows the user to program the SI RAM dynamically. When the user can set the corresponding SICMDR bit, the SI switches to the shadow RAM at the end of the current-route RAM frame.

Offset 0x0A Access: Read/Write

	0	1	2	3	4	5	6	7
R W	CSRRA	CSRTA	CSRRB	CSRTB	CSRRC	CSRTC	CSRRD	CSRTD
Reset	All zeros							

Figure 36-28. SI Command Register High

SI Command register field descriptions are shown in Table 36-12.

Table 36-12. SI Command Register High Field Descriptions

Bits	Name	Description
0,2,4,6	CSRR*x*	Change shadow RAM for all TDM's receivers. Set CSRR*x* causes the SI receiver to replace the current route RAM with the shadow RAM. Set by the user and cleared by the SI. 0 The receiver shadow RAM is not valid. The user can write into the shadow RAM to program a new routing 1 The receiver shadow RAM is valid. The SI exchanges between the RAMs and take the new receive routing from the receiver shadow RAM. Cleared as soon as the switch has completed **Note:** There is a gap between setting the CSRR*x* bit by the user, and clearing it by the SI. This is because the switch can take place only after frame end.
1,3,5,7	CSRT*x*	Change shadow RAM for all TDM's transmitter. Set CRST*x* causes the SI transmitter to replace the current route RAM with the shadow RAM. Set by the user and cleared by the SI. 0 The transmitter shadow RAM is not valid. The user can write into the shadow RAM to program a new routing. 1 The transmitter shadow RAM is valid. The SI exchanges between the RAMs and take the new transmitter routing from the transmitter shadow RAM. Cleared as soon as the switch has completed. **Note:** There is a delay between setting the CSRT*x* bit by the user, and clearing it by the SI. This is because the switch can take place only after frame end.

36.6.8 SI Command Register Low (SICMDRL)

SICMDRL, shown in Figure 36-29, allows the user to program the SI RAM dynamically. When the user can set the corresponding SICMDR bit, the SI switches to the shadow RAM at the end of the current-route RAM frame.

Table 36-16 describes the SIML*x* fields.

Table 36-16. SIML*x* Field Descriptions

Bits	Name	Description
0–5	RRC	Regular address count. Holds tbe number of repetitions of the frame in current frame. Default value of zero stands for one occurrence of pattern in the current frame.
6–11	SRC	Shadow address count. Holds the number of repetitions of the frame in current frame.Default value of zero stands for one occurrence of pattern in the current frame.

Table 36-16. SIML*x* Field Descriptions

Bits	Name	Description
12	ME	Multiframe enable flag. 0 Multiframe is not enabled. 1 Multiframe mode enabled.
13–15	—	Reserved. should be cleared.

NOTE

In multiframe mode, the last two entries in a frame, should be at least two clocks wide.

36.6.11.1 Multiframe Description

In Multiframe mode, the frame is based on two patterns that repeat several times. The first pattern occurs several times repeatedly, followed by a second pattern that occurs several times repeatedly. The programmer can define two basic patterns in SIRAM. The first pattern is defined in the current RAM, and the second pattern in the shadow RAM. The number of repetitions is defined in the SI Multiframe counter register. The first pattern is configured in the SIML[RRC] field and the second pattern is configured in the SIML[SRC] field. Note that the default value of zero in the SIML[RRC] and SIML[SRC] fields stand for one occurrence of the pattern in Current frame.

Figure 36-33 provides an example of configuring Multiframe mode. The current RAM shows the first pattern, and the shadow RAM shows the second pattern. For this example, the SI Multiframe counter register SIML*x*, is configured to repeat the first pattern three times and repeat the second pattern four times.

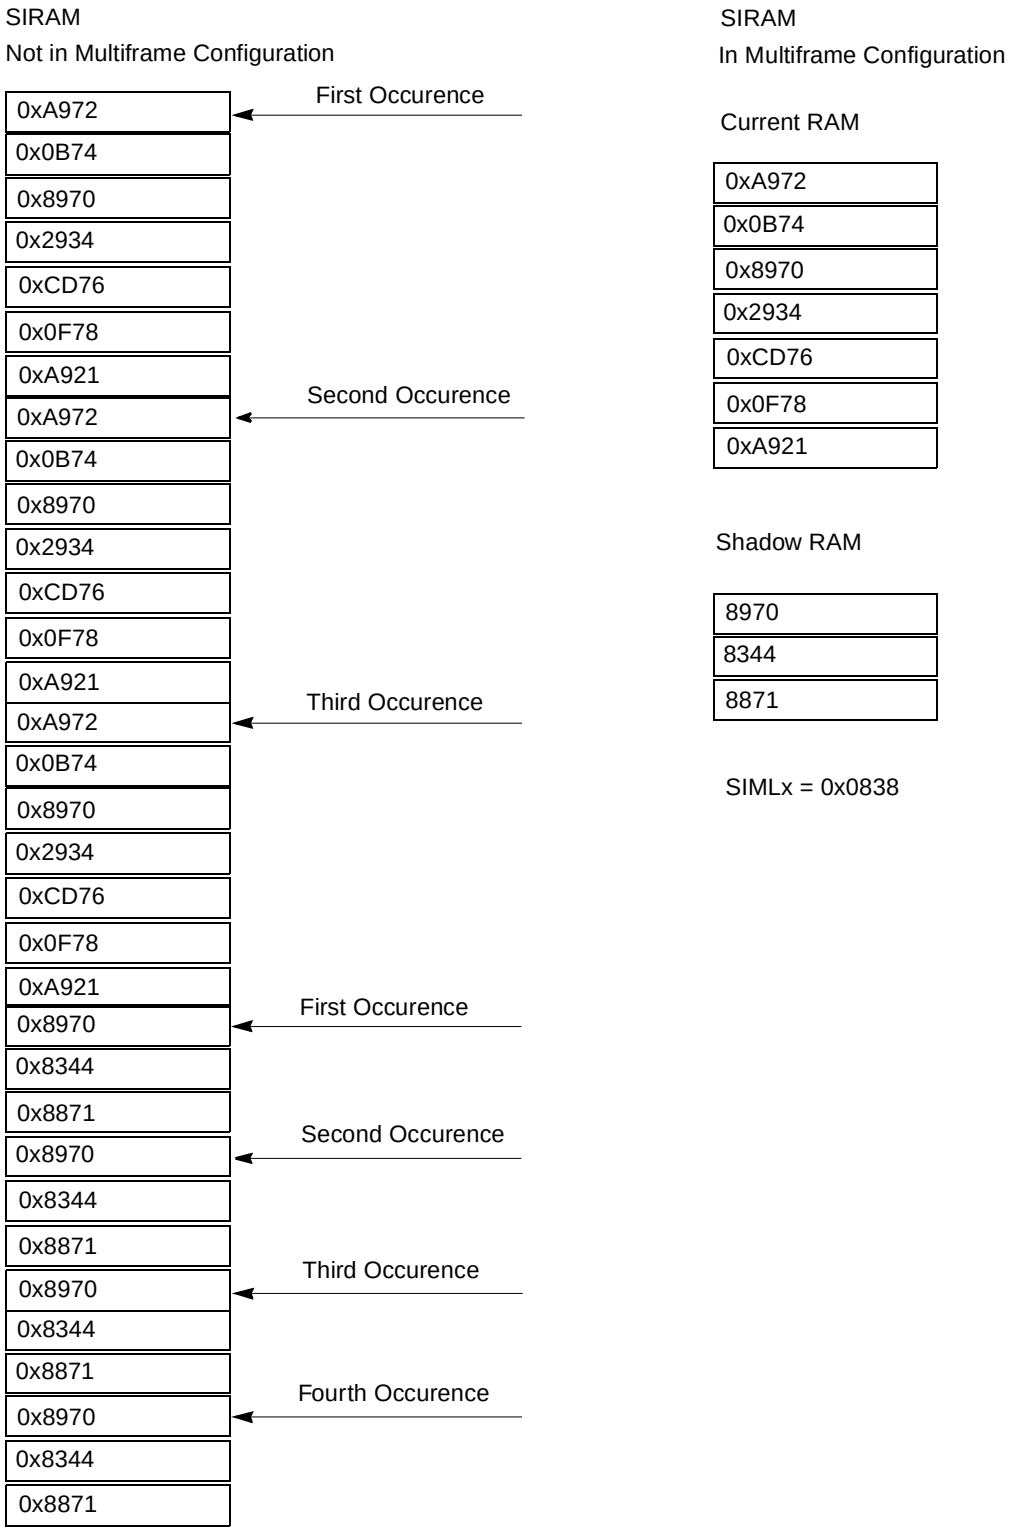

Figure 36-33. Multiframe Example

36.6.12 SI RAM Counter (SIR*x*RC and SIT*x*RC)

There are sixteen TDM*x* RAM counters, one for each TDM, receive and transmit. They show the current RAM line number to be fetched. The register is shown in Figure 36-34.

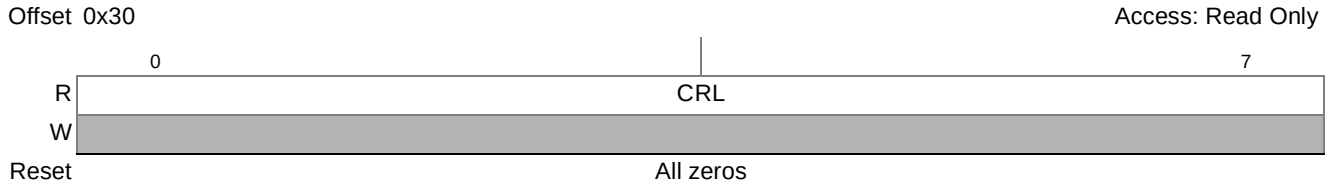

Figure 36-34. SI TDM*x* RAM Counter

Table 36-17 describes the bit fields of SIR*x*RC and SIT*x*RC.

Table 36-17. SIR*x*RC and SIT*x*RC Bit Field Descriptions

Bits	Name	Description
0–7	CRL	Current RAM line number.

36.6.13 SI Enhanced SDM Register (SIENS)

SIENS enhances diagnostic mode for both MCC and UCC entries.When a TSA-related bit is set, loop/echo mode is enabled in the UCC command entry, if command entry bit1 is set. When a TSA-related bit is set, SWTR mode is enabled in the MCC command entry, if command entry bit1 is set. The register is shown in Figure 36-35.

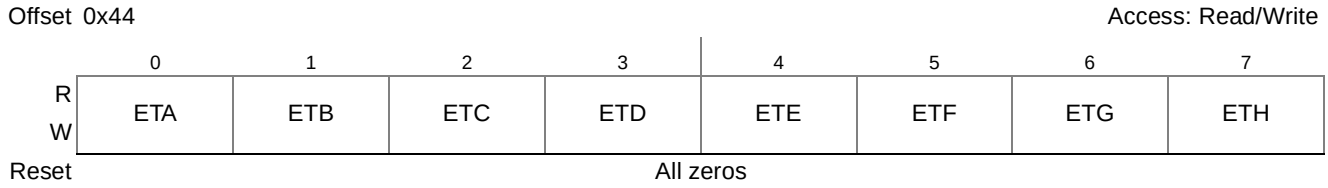

Figure 36-35. SI Enhanced SDM Register

Table 36-18 describes the SIENs bit fields.

Table 36-18. SIENS Bit Field Descriptions

Bits	Name	Description
0–7	ET*x*	0 Normal operation. 1 If bit 1 in MCC entry is set, switch Tx Rx is enabled in this TSA[A–H]. If bit 1 in UCC entry is set, loopback or echo mode is enabled.

36.6.14 SI Speed Register (SISPD)

SISPD, shown in Figure 36-36, holds the speed mode of TDM[A–H].

NOTE

High-speed mode is used under the following conditions:

- Only UCC entries are allowed (bit 0 in each entry must be cleared).

- Each frame must have an even number of entries.

Offset 0x46 Access: Read/Write

	0	1	2	3	4	5	6	7
R W	SPDA	SPDB	SPDC	SPDD	SPDE	SPDF	SPDG	SPDH
Reset	All zeros							

Figure 36-36. SI Speed Register

Table 36-19 describes the SISPD bit fields.

Table 36-19. SISPD Field Descriptions

Bits	Name	Description
0–7	SPD*x*	0 normal operation. The min frequency ratio between the serial clock and the Quick Engine clock is 1:16. 1 High-speed mode.The min frequency ratio between the serial clock and the Quick Engine clock is 1:8 and the max frequency ratio is 1:16. Only UCC entries are allowed.

36.6.15 SI TX Clock Edge Invert (SITXCEI)

SITXCEI, shown in Figure 36-37, inverts the TX clock edge. It is used for high serial clock frequencies.

Offset 0x47 Access: Read/Write

	0	1	2	3	4	5	6	7
R W	TXCEIA	TXCEIB	TXCEIC	TXCEID	TXCEIE	TXCEIF	TXCEIG	TXCEIH
Reset	All zeros							

Figure 36-37. SI TX Clock Edge Invert Register

Table 36-20 describes the SITXCE*x* bit fields.

Table 36-20. SITXCEI Bit Field Descriptions

Bits	Name	Description
0–7	TXCEI*x*	0 Normal operation. 1 TX Clock Edge Inverted. The Tx data is transmitted a serial clock phase earlier then it should be according to SI*x*MR[CE]. For example, If CE = 0, Txd should be driven on the positive edge of the clock, but if this bit is set, it is driven on the negative edge of the serial clock (a serial clock phase before).

NOTE

- TXCEI must be cleared if FSD is cleared.
- The STZ function should not be used when TXCEI = 1.

A case of SI*x*MR[FE] = 1, SI*x*MR[CE] = 0, SI*x*MR[*x*FSD] =01, and TXCEI = 1 is shown in Figure 36-38. L1SYNC is sampled on the rising edge, L1TXD should be driven on the rising edge, and L1RXD should be sampled on the falling edge of the clock. Since TXCEI = 1, L1TXD is driven on the falling edge (a serial clock phase earlier) and L1RXD is still sampled on the next falling edge.

This bit does not affect the strobe timing.

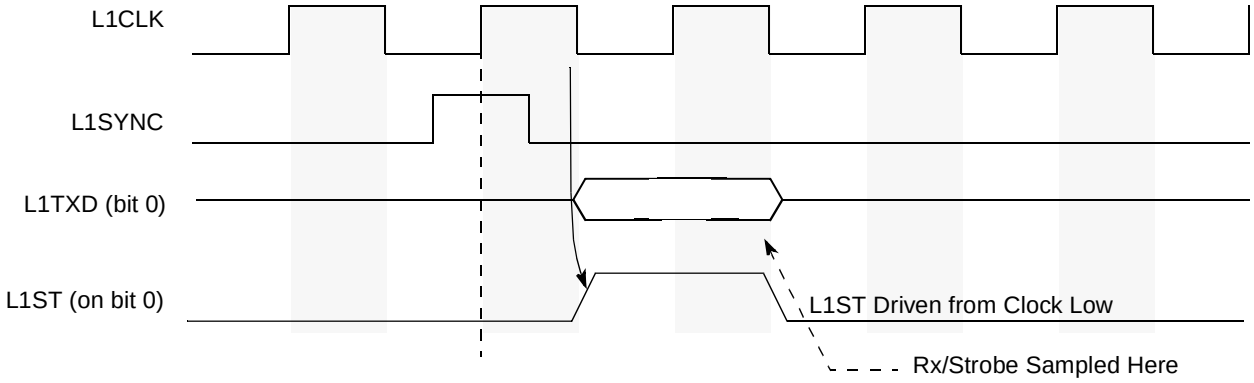

Figure 36-38. TXCEI Effect when SI*x*MR[CE] = 0, SI*x*MR[FE] = 1, and SI*x*MR[*x*FSD] = 01

A case of SI*x*MR[FE] = 1, SI*x*MR[CE] = 1, SI*x*MR[*x*FSD] = 01, and TXCEI = 1 is shown in Figure 36-39. L1SYNC is sampled on the rising edge, L1TXD should be driven on the falling edge, and L1RXD should be sampled on the rising edge of the clock. Because TXCEI = 1, L1TXD is driven on the rising edge (a serial clock phase earlier) and L1RXD is still sampled on the next rising edge. This bit does not effect the strobe timing.

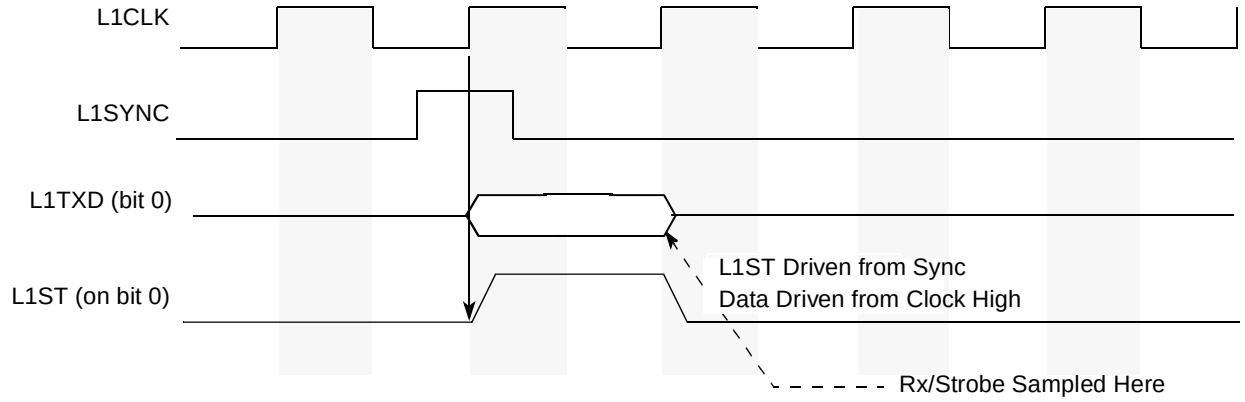

Figure 36-39. TXCEI Effect when SI*x*MR[CE] = 1, SI*x*MR[FE] = 1, and SI*x*MR[*x*FSD] = 01

36.7 SI Functional Description

36.7.1 SI RAM

The SI has a transmit RAM and a receive RAM, each with 512 entries to control TDM channel routing to all UCCs or the MCC. The SI RAM entries are uninitialized after power-on reset. Unwanted results can occur if the user does not program the SI RAM before enabling the multiplexed channels.

Each line of RAM consists of two 16-bit entries that define the routing control. Each entry can control 1–8 bits or 1–32 bytes at a time as determined in the entry. In addition to the routing, up to eight strobe pins (logic OR of four strobes in the transmit RAM and four in receive RAM) can be asserted according to the

programming of the RAMs. The SI RAM can be configured in many different ways to support various TDM channels. The user can define the size of each SI RAM related to a certain TDM channel by programming the starting address of that TDM. Programming the starting shadow bank address determines whether this RAM has a shadow for changing SI RAM entries while the TDM channel is active. This reduces the number RAM entries for that TDM. Following are two examples of static and dynamic SI RAM routing.

NOTE

The switch between current SI RAM and shadow SI RAM occurs on the frame boundary.

36.7.1.1 One Multiplexed Channel with Static Frames

With this configuration, the SI RAM has 512 entries for transmit data and strobe routing and 512 entries for receive data and strobe routing. This configuration should be chosen only when one TDM is required and the routing on that TDM does not need to be dynamically changed. The number of entries available in the SI RAM is determined by the user. A diagram of this configuration is shown in Figure 36-43.

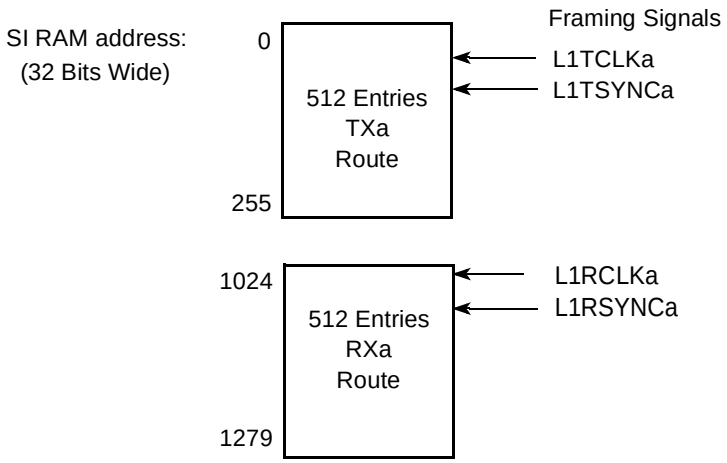

Figure 36-40. One TDM Channel with Static Frames and Independent Rx and Tx Routes

36.7.1.2 One Multiplexed Channel with Dynamic Frames

A configuration of one multiplexed channel with 256 entries for transmit and 256 entries for receive data and strobe routing is shown in Figure 36-41. Each RAM has two sections, the current-route RAM and a shadow RAM for changing serial routing dynamically. After programming the shadow RAM, the user sets SICMDR[CSR*xx*] for the associated channel. When the next frame sync arrives, the SI automatically exchanges the current-route RAM for the shadow RAM.

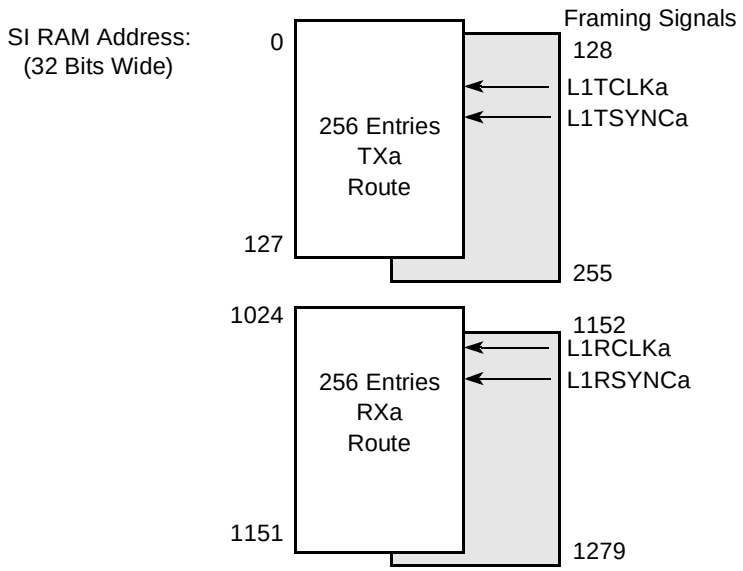

Figure 36-41. One TDM Channel with Shadow RAM for Dynamic Route Change

This configuration should be chosen when only one TDM is needed, but dynamic rerouting may be needed on that TDM. Similarly, for two TDM channels, the number of SI RAM entries are reduced for every TDM channel programmed for shadow mode.

36.7.1.3 Static and Dynamic Routing

The SI RAM has two operating modes for all TDMs:

- Static routing. The number of SI RAM entries is determined by the starting addresses the user relates to the corresponding TDM and is divided into two parts (Rx and Tx). Three requirements must be met before the new routing takes effect.
  - All serial devices connected to the TSA must be disabled.
  - SI routing can be modified.
  - All appropriate serial devices connected to the TSA must be reenabled.
- Dynamic routing. A TDM routing definition can be modified while UCCs are connected to the TDM. A TDM channel cannot be changed dynamically if an UCC is connected to that TDM. The number of SI RAM entries is determined by the starting address the user relates to the corresponding TDM channel and is divided into four parts (Rx, Rx shadow, Tx, and Tx shadow).

Dynamic changes divide portions of the SI RAM into current-route and shadow RAM. Once the current-route RAM is programmed, the TSA and SI channels are enabled, and TSA operation begins. When a change in routing is required, the shadow RAM must be programmed with the new route and SICMDR[CSR*xx*] must be set. As a result, the SI exchanges the shadow RAM and the current-route RAM as soon as the corresponding sync arrives and resets SICMDR[CSR*xx*] to signify that the operation is complete. At this time, the user may change the routing again. Notice that the original current-route RAM is now the shadow RAM and vice versa. An example of the shadow RAM exchange process for two TDM channels both with half the RAM as a shadow, is shown in Figure 36-42

For example, if one TDM with dynamic changes is programmed to own all four banks and the shadow is programed to the last tow banks, the initial current-route RAM addresses in the SI RAM are as follows.

- 0–255: TXa route
- 1024–1279: RXa route

The shadow RAMs are at addresses:

- 256–511: TXa route
- 1280–1535: RXa route

The user can read any RAM at any time, but for proper SI operation do not attempt to write the current-route RAM. The SI status register (SISTR) can be read to find out which part of the RAM is the current-route RAM. The user can also externally connect one of the strobes to an interrupt pin to generate an interrupt on a particular SI RAM entry starting or ending execution by the TSA.

An example is shown in Figure 36-42.

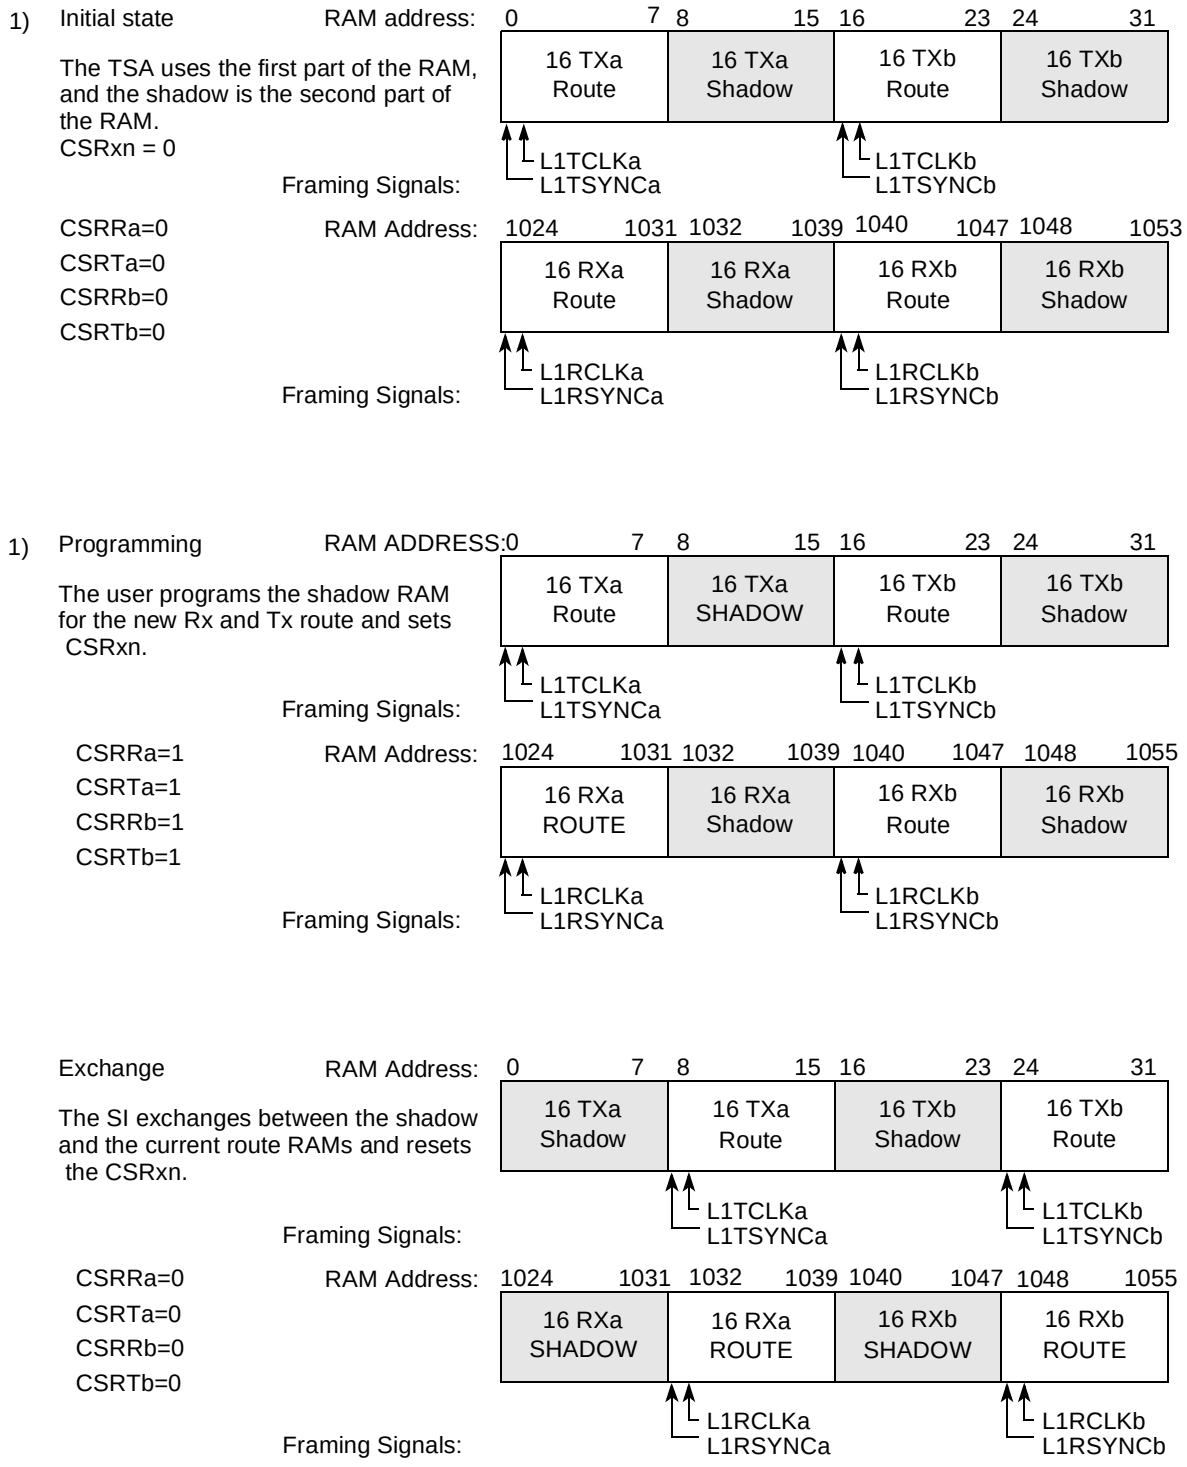

Figure 36-42. Example: SI RAM Dynamic Changes, TDM A and TDM B, Same SI RAM Size

36.7.2 Time-Slot Assigner

The TSA has two separate TSA inside: Rx TSA and Tx TSA.

36.7.2.1 Tx TSA

The Tx TSA implements route selection of data transmitted from the UCCs or MCC according to the relevant TDM SI RAM entries. All its internal registers are uninitialized after power-on reset.

After the TSA receives the SYNC signal from a TDM, data is transferred from the MCC or UCC to the TDM This procedure occurs for all TDMs.

36.7.2.2 Rx TSA

The Tx TSA implements route selection of data received from the TDMs to UCCs or MCC according to the relevant TDM SI RAM entries.All internal registers are uninitialized after power-on reset.

After the TSA receives the SYNC signal from the TDM, data is transferred from the TDM to the MCC or UCC. This procedure occurs for all TDMs.

36.8 SI Initialization Information

Following are steps to initialize the SI for proper operation:

1. Initialize the relevant SIxRAM entries.
2. Initialize the SI mode register (SI*x*MR).
3. Connect the UCCs to SI using CE_MUX.
4. Connect the clocks to the SI using CE_MUX.
5. Configure the TDMs, UCCs and MCC.
6. Enable the TDMs in the SI global mode register, SI*x*GMR.

NOTE

Changing the SI register in a different order; that is, changing SIxMR in the middle of a frame, can cause erratic behavior.

36.9 SI Application Information

36.9.1 SI RAM Programming Example

The example in this section shows how to program the RAM to support the 10-bit IDL bus shown in Figure 36-45. The TSA supports the B1 channel with UCC2, the D channel with UCC1, the first 4 bits of the B2 channel with an external device (using a strobe to enable the external device), and the last 4 bits of B2 with UCC3. Additionally, the TSA marks the D channel with another strobe signal.

First, divide the frame from the start (the sync) to the end of the frame according to the support that is required:

- 8 bits (B1)—UCC2

- 1 bit (D)—UCC1 + strobe1
- 1 bit—no support
- 4 bits (B2)—strobe2
- 4 bits (B2)—UCC3
- 1 bit (D)—UCC1 + strobe1

Each of these six divisions can be supported by a single SI RAM entry. Thus, six SI RAM entries are needed. See Table 36-21.

.

Table 36-21. RAM Word Descriptions

Entry Number	RAM Word							
	MCC	SWTR	SSEL	CSEL	CNT	BYT	LST	Description
1	0	0	0000	1010	000	1	0	8-bit UCC2
2	0	0	1000	1001	000	0	0	1-bit UCC1 strobe1
3	0	0	0000	0000	000	0	0	1-bit no support
4	0	0	0100	0000	011	0	0	4-bit strobe2
5	0	0	0000	1011	011	0	0	4-bit UCC3
6	0	0	1000	0001	000	0	1	1-bit UCC1 strobe1

Note that because IDL requires the same routing for both receive and transmit, an exact duplicate of these entries should be written to both the receive and transmit sections of the SI RAM. Then SIxMR[CRTx] can be used to instruct the SI RAM to use the same clock and sync to control both sets of SI RAM entries simultaneously.

36.9.2 One Multiplexed Channel with Static Frames

In the example configuration shown in Figure 36-43, the SI RAM has 512 entries for transmit and 512 entries for data and strobe routing. This configuration should be chosen when only one TDM is required and its routing does not need to be changed dynamically. The number of entries available in the SI RAM is determined by the user.

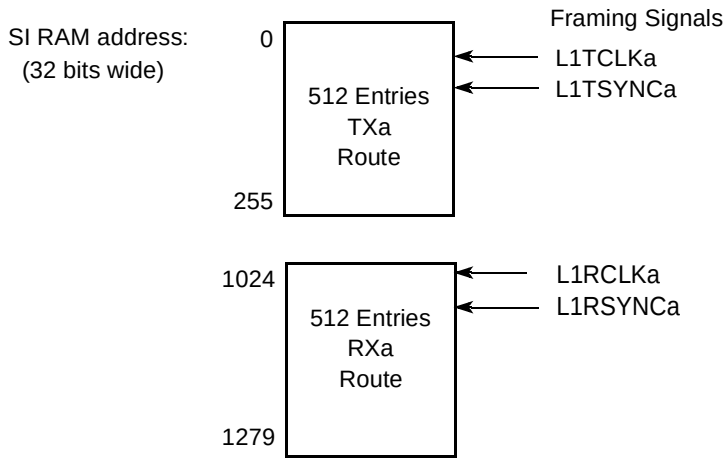

Figure 36-43. One TDM Channel with Static Frames and Independent Rx and Tx Routes

36.9.3 One Multiplexed Channel with Dynamic Frames

A configuration of one multiplexed channel, shown in Figure 36-41, has 256 entries for transmit and 256 entries for receive data and strobe routing. The IDL interface is a full-duplex ISDN interface to connect a physical layer device to the QUICC Engine block, which supports both the basic and primary rate of the IDL bus. In the basic rate of IDL, data on three channels (B1, B2, and D) is transferred in a 20-bit frame, providing 160-kbps full-duplex bandwidth. The QUICC Engine block is an IDL slave device that is clocked by the IDL bus master (physical layer device) and has separate receive and transmit sections. Because the QUICC Engine block can support all TDMs, it can actually support four independent IDL buses (the limitation is due to the number of serials that support IDL) using separate clocks and sync pulses (for two IDL buses) as illustrated in Figure 36-44.

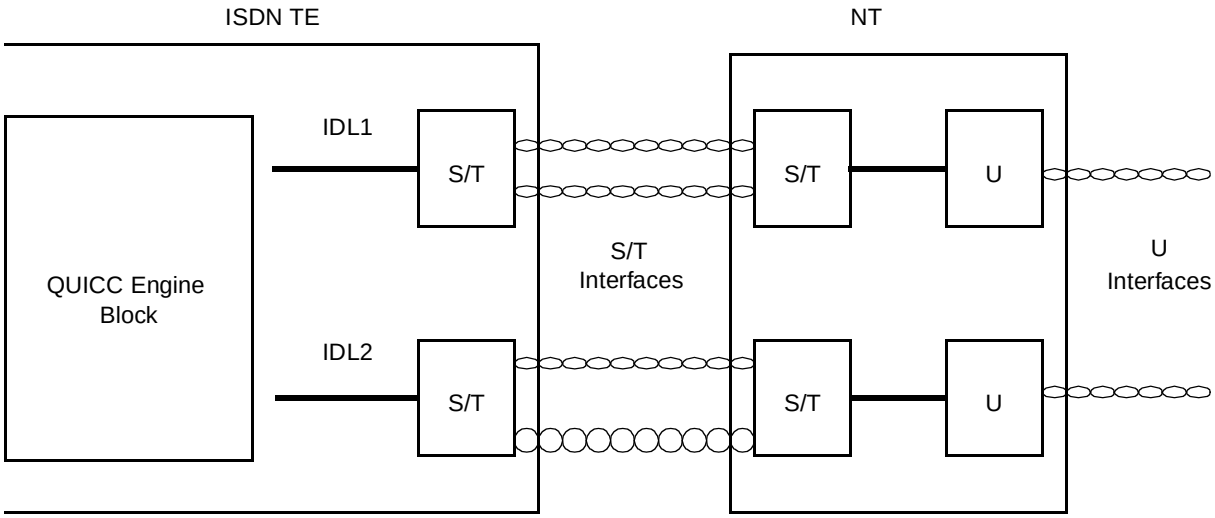

Figure 36-44. Dual IDL Bus Application Example

36.9.4 IDL Interface Example

An example of the IDL application is the ISDN terminal adaptor illustrated in Figure 36-45. The IDL interface connects the 2B+D channels between the QUICC Engine block, CODEC, and S/T transceiver. One of the QUICC Engine UCCs is configured to HDLC mode to handle the D channel; another QUICC Engine block UCC rate adapts the terminal data stream over the first B channel. That UCC is configured for HDLC mode if V.120 rate adoption is required. The second B channel is then routed to the CODEC as a digital voice channel, if preferred. The SPI sends initialization commands and periodically checks status from the S/T transceiver. Another UCC connected to the terminal is configured for UART. The QUICC Engine block can identify and support each IDL channel or output strobe lines for interfacing devices that do not support the IDL bus. The IDL signals for each transmit and receive channel are described in Table 36-22.

Table 36-22. IDL Signal Descriptions

Signal	Description
L1RCLKx	IDL clock; input to the device.
L1RSYNCx	IDL sync signal; input to the devce. This signal indicates that the clock periods following the pulse designate the IDL frame.
L1RXDx	IDL receive data; input to the device. Valid only for the bits supported by the IDL; ignored for any other signals present.
L1TXDx	IDL transmit data; output from the device. Valid only for the bits that are supported by the IDL; otherwise, three-stated.
L1RQx	IDL request permission to transmit on the D channel; output from the device on the L1RQx pin.
L1GRx	IDL grant permission to transmit on the D Channel; input to the device on the L1TSYNCx pin.

NOTE

x = A:H for all TDMs.

The basic rate IDL bus has the three following channels:

- B1 is a 64-Kbps bearer channel.
- B2 is a 64-Kbps bearer channel.
- D is a 16-Kbps signaling channel.

There are two definitions of the IDL bus frame structure—8 and 10 bits. The only difference between them is the channel order within the frame. See Figure 36-45.

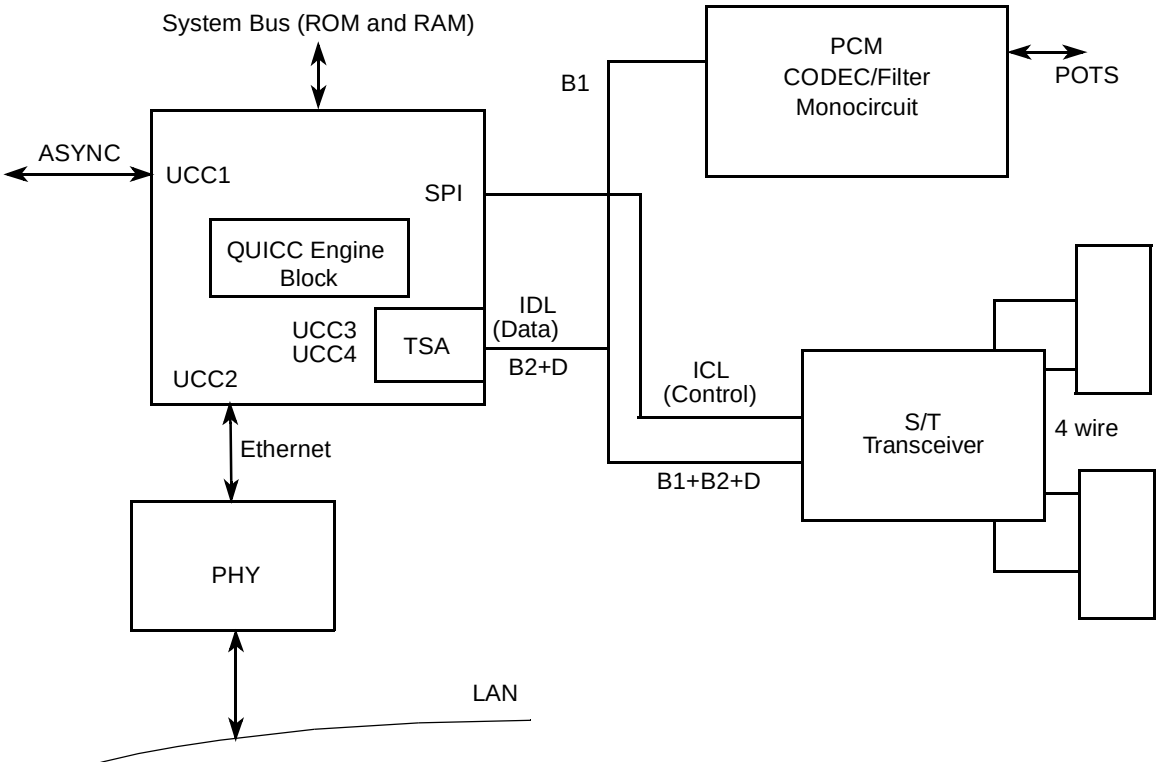

Figure 36-45. IDL Terminal Adaptor

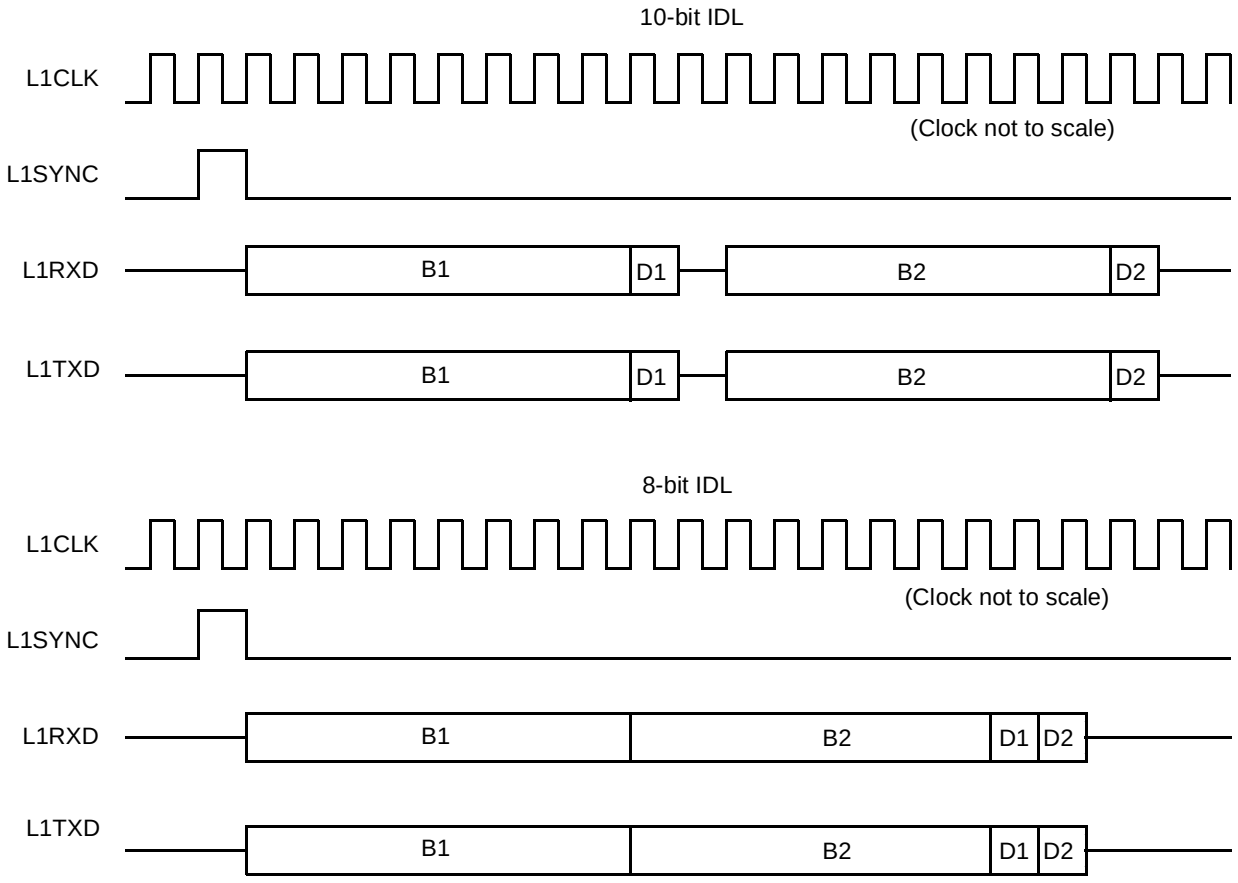

NOTE: L1RQn and L1GRn are not shown.

Figure 36-46. IDL Bus Signals

NOTE

Previous versions of Freescale IDL-defined bit functions, called auxiliary (A) and maintenance (M), were eliminated from the IDL definition when the IDL control channel became out-of-band. They were defined as a subset of the Freescale SPI format called serial control port (SCP). If a user prefers to implement the A and M bit functions as originally defined, the TSA can be programmed to access these bits and route them transparently to a UCC. The QUICC Engine block SPI can perform this out-of-band signaling.

The QUICC Engine block supports all channels of the IDL bus in the basic rate. Each bit in the IDL frame can be routed to every UCC (connected to the specific SI) or can assert a strobe output for supporting an external device. The QUICC Engine block supports the request-grant method for contention detection on the D channel of the IDL basic rate. When the QUICC Engine block has data to transmit on the D channel, it asserts L1RQx. The physical layer device monitors the physical layer bus for activity on the D channel and indicates that the channel is free by asserting L1GRx. The QUICC Engine block samples the L1GRx signal when the IDL sync signal (L1RSYNCx) is asserted. If L1GRx is high (active), the QUICC Engine block transmits the first zero of the opening flag in the first bit of the D channel. If a collision is detected on the D channel, the physical layer device negates L1GRx. The QUICC Engine block then stops sending

and retransmits the frame when L1GRx is reasserted. This procedure is handled automatically for the first two buffers of a frame.

For the primary rate IDL, the QUICC Engine block supports up to four 8-bit channels in the frame, determined by the SI RAM programming. To support more channels, the user can route more than one channel to every UCC and the UCC will treat it as one high-speed stream and store it in the same data buffers (this approach is appropriate only for transparent data). Additionally, the QUICC Engine block can be used to assert strobes for support of additional external IDL channels.

The IDL interface supports the CCITT I.460 recommendation for data-rate adaptation since it separately accesses each bit of the IDL bus. The current-route RAM specifies which bits are supported by the IDL interface and by which serial controller. The receiver only receives bits that are enabled by the receiver route RAM. Otherwise, the transmitter sends only bits that are enabled by the transmitter route RAM and three-states L1TXDx.

36.9.5 IDL Interface Programming

The user can program the channels for the IDL bus interface to the appropriate configuration. First, the SIxMR should be programmed to the IDL grant mode for that channel through the GMx bits. More than one channel can be programmed to interface with the IDL bus. If receive and transmit sections are used for interfacing to the same IDL bus, the user can internally connect the receive clock and sync signals to the SI RAM transmit section, using the CRTx bits. The RAM section for the IDL channels must be programmed to the preferred routing. See Section 36.9.1, “SI RAM Programming Example.”

Next, define the IDL frame structure to be a delay of 1-bit from frame sync to data, to falling edge sample sync, and the clock edge to transmit on the rising edge of the clock. The L1TXDx pin should be programmed to be three-stated when inactive (through the parallel I/O open-drain register). To support the D channel, the user must program the appropriate CMXS1CR[GRx] bit and program the RAM entry to route data to that serial controller. The two definitions of IDL, 8 and 10 bits, are supported only by modifying the SI RAM programming. In both cases, L1GRx is sampled with the L1TSYNCx signal and transferred to the D channel UCC as a grant indication. The same procedure is valid for supporting an IDL bus in the second channel.

Chapter 37
Point-to-Point Protocol (PPP)

37.1 Overview

The QUICC Engine implementation of the PPP is compliant with the RFCs 1661, 1662, 1990, 2686, and 3153. This chapter describes the functionality and data structures of the PPP protocol, the Multilink-Multiclass PPP (ML-MC) protocol, and the PPP mux protocol.

The Multilink (ML) protocol maximizes the bandwidth for real time multimedia flows over low-bit rate links, while minimizing the end-to-end delay. The ML protocol provides packets to be split into fragments that run over several TDM links that are part of a bundle. As shown in Figure 37-1, each TDM link can be configured as a single link running the PPP protocol or configured as part of a bundle running the ML-MC protocol.

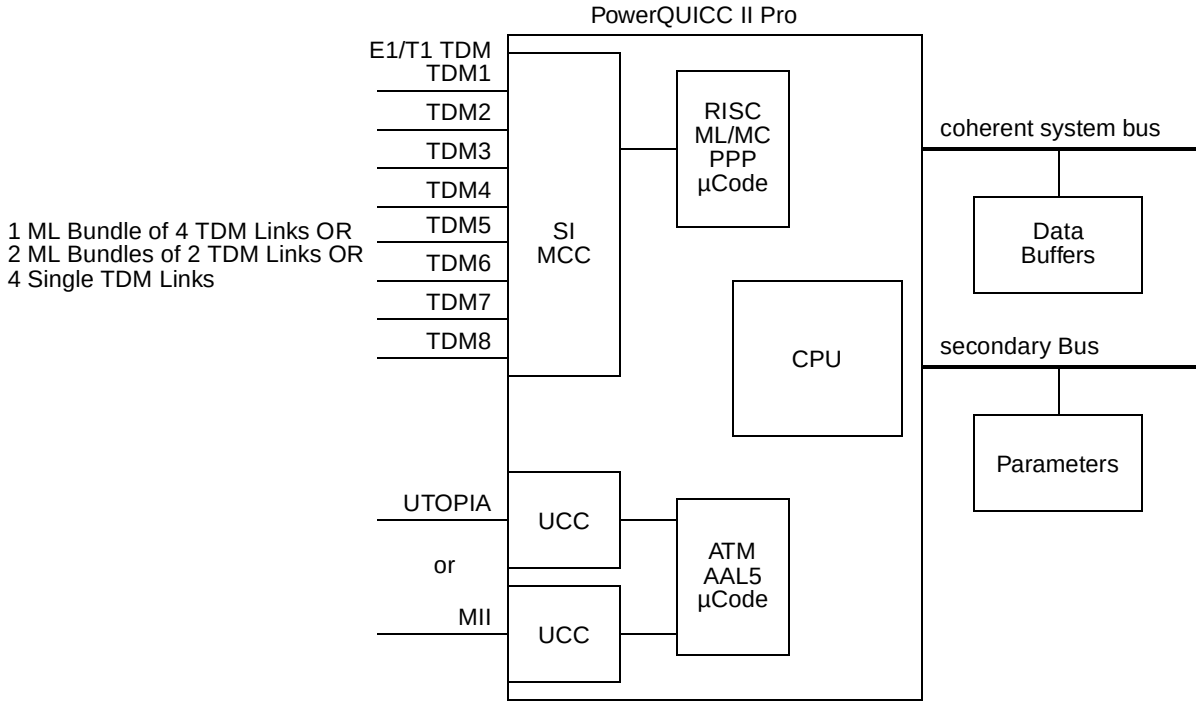

Figure 37-1. Example ML-MC PPP System

37.2 Terminology

This section defines the terms used in this document. When applicable, the RFC number in which the term is used is specified.

Figure 37-2 shows the frame structures that can be processed by the PPP/MLMC/PPP mux protocol stack.

Plain PPP Frame Received on a Link

Address & Control	PID	Information (Up to 1500 Bytes)	FCS

PPP MUX Superframe Received on a Link

ML/MC PPP Fragment Received on a Link

Address & Control	ML/MC Header	PID	Information	FCS

PPP MUX Superframe Over ML/MC Received on a Link

Address & Control	ML/MC Header	PPP MUX	PPP Subframe Information	PPP Subframe Information	PPP Subframe Information	FCS

Figure 37-2. Typical Frames Handled by the RISC

Table 37-1. Terminology

Term	Definition
Frame	The unit of transmission at the data link layer (RFC 1661).
Packet	The basic unit of encapsulation, which is passed across the interface between the Network Layer and the Data Link layer (RFC1661). **Note:** The terms “packet” and “frame” are used in this document interchangeably.
MultiLink (ML) Fragment	A portion of a Network Layer packet sent as a frame over a link belonging to a MultiLink bundle. The MultiLink bundle is a virtual PPP link-layer entity (RFC1990).
Maximum Receive Unit (MRU)	The maximum size of a ML Fragment on a given Link.
Maximum Received Reconstructed Unit (MRRU)	The maximum number of octets in the Information fields of reassembled packets.
Subframe	A PPP encapsulated frame when concatenated into a single PPP multiplexed frame (RFC3153).
PPP Mux super frame	A frame which contains multiple PPP Subframes.
Link queue	An ingress or egress queue which is directly associated with a link and does not belong to the ML/MC traffic. This queue is for Plain PPP frames. It could also be a PPP Mux frame with no ML/MC header.
Queue Descriptor	Data structure which has the management parameters of a queue of BDs. Each BD ring is managed by such a structure, both, for egress and ingress traffic.

37.3 Features

- Conformance to RFC 1661—Point-to-Point Protocol (PPP)
  - PFC protocol field compression mode—Dynamically tested
  - PID is copied to BD
- Conformance to RFC 1662—PPP in HDLC like Framing
  - Receives both kinds of interframe fill: contiguous 1 and flag sequence
  - User-defined FCS: either 16 bit FCS or 32 bits FCS
  - Programmable address and control characters—The user may program one ACC in addition to 0xFF03
  - Address and control field compression (ACFC) is supported
  - Programmable MRU (maximum received unit)
  - No support for Shared Zero Mode
- Conformance to RFC 1990—The Multilink Protocol (MP)
  - User-defined sequence number: either 12 bit or 24 bit
  - Fragment loss detection
    - User-programmable fragment loss window size
    - Frame is discarded in detection of lost fragment
    - Fragment lost counter
  - Programmable MRRU
  - No support of self-describing padding
  - No support of prefix elision
- Dynamic addition and removal of link in a bundle
  - Addition of link.
  - Supports dynamic removal of link from a bundle.
- Conformance to RFC2686 MultiClass extension to Multilink PPP
  - Supports up to 8 classes
  - User-defined class field: either 2 CLS bit or 4CLS bit
  - Frames are enqueues in separate queues by class
- LCP frames handling
  - LCP frames from all links are enqueued in the dedicated LCP Link core queue which uses a dedicated BD ring
  - LCP frames received as ML-MC frames are enqueued in the class core queue
- Free buffer pools (FBPs)
  - Single FBP on ingress
  - Multiple buffer pools on egress
- Supports channelized MCC and PPP
- Statistics

  - The following statistical information per link is provided:
    - FCS error counter
    - Invalid address and control characters counter
    - Aborted fragments/frames counter
    - Illegal fragments/frames counter
    - Transmit and receive plain PPP frames counter
    - Transmit and receive MLMC PPP fragments on this link
    - Transmit and receive byte count per link (32 bit counter)
    - Transmit idle counter
    - MRU exceeded counter
    - Link queue busy counter
  - The following statistical information per class is provided:
    - Fragment loss counter
    - Window full counter
    - Class queue busy counter
    - Demultiplexer queue busy counter
    - MRRU exceeded counter
    - Receive frames counter
- Connectivity to up to 8 T1/E1 TDM interfaces
- Conformance to RFC 3153, PPP MUX handling
  - Supports up to 256 Sub-Frames per fragment
- Decapsulating received PPP Mux frames into sub frames, extracting PID information automatically
- Support aging discard for PPP Subframes
- Support time-out for stopping encapsulation process in PPP MUX frames
- Support up to eight queues per link
- Weighted fair queuing algorithm for class and queue selection
- Automatic removal of empty queue from queue selection process
- LCP transmission
- Packet insertion on a link when working in ML/MC mode
- No data copying

37.4 Operation

37.4.1 Receive (Rx)

When a link begins to receive a fragment, the received data is stored in an internal memory buffer pointed to by Rx_IB_ptr within the Link Parameter table. After a sufficient amount of data is received, the microcode begins parsing the content of the frame.

The address and control fields are checked, and then the PID is compared. There are four possibilities: MLMC-PPP fragment, plain PPP frame, PPP MUX frame and LCP frames. The receiving process continues until the whole frame/fragment is received and checked for correct FCS. After FCS verification, the frame is enqueued into the appropriate queue.

In the case of plain PPP traffic, the Rx process enqueues the received frame to a BD ring for handling by the Host. It is referred to as a Link queue. In the case of ML/MC, the Rx receives on each link of the bundle a fragment and re-assembles all the fragments of the same frame. After reassembling, the Rx enqueues the complete frame to a BD ring for handling by the host. Every fragment is received in a separated buffer. This is referred to as ML/MC queue. The Rx detects and supports fragment loss according to RFC 1990.

The following types of packets are discarded. A counter for each type of error is updated:

- Packets with address and control characters that do not match the characters negotiated for the link
- Packets that are too short
- Packets with a bit stuffing error
- Packets with bad FCS.

37.4.1.1 Reception of Plain PPP, LCP and PPP MUX Frames on a Single Link

There are three receive queues for each link. These queue frames do not have the PPP ML MC header. Each of the three queues is dedicated for a specific type of frame: one is for plain PPP frames, one for PPP mux frames, and one for LCP frames. The host has two methods of handling data buffer pointers. One is to use a Free Buffer Pool (FBP) where buffer pointers are fetched from the FBP. In this case all the BDs in a queue do not contain a valid pointer upon initialization. The other option is to have an initialized BD which contains a data pointer. The RISC will swap the pointers between a BD and the buffer currently used by the receiver. Only for the first queue (plain PPP frames), the host can select which of the methods is being used.

For the LCP queue the host prepares a BD Ring where the BDs do contain data buffers pointers. The RISC swaps the pointers in the BD with the one currently used for reception of the frame.

Plain PPP frames are enqueued into the plain PPP queue and PPP mux frames are forwarded to the PPP demultiplexing (Demux) process described later.

37.4.1.2 Reception of Multi Link-Multi-Class PPP Fragment

In ML/MC-PPP frames, the RISC expects two kinds of packets: data packets and PPP mux packets. The reconstruction of a complete frame from its fragments is done in two stages: the front-end and back-end. The front-end process collects the fragments of each class, detects a completion of a frame or a fragment loss, and then forwards each completed frame into the back-end process—the packet reconstruction task—for enqueuing into the appropriate queue.

Each fragment is stored in the queue only if it was completely received with the correct FCS and no other violation of the setup. After a successful reception of a complete frame, the back-end parses the frame and checks if it's a PPP mux frame or not according to the PID. In the case of PPP mux, the receiver enqueues the frame to the demultiplexer; otherwise the frame is enqueued to a BD ring for handling by the host.

37.4.1.3 Reception of PPP Mux Frame

The demultiplexer (demux) is a stand alone centralized process which handles PPP mux frames. It takes a received frame, from the back-end of the receiver, analyzes its content and de-multiplexes a PPP mux frame by assigning each of its encapsulated subframes to a host queue.

37.4.2 Transmit (Tx)

The transmitter also has also two separate sources for transmission. One is transmission from a Link queue of plain PPP frame or a PPP MUX frame, and the other is transmission of a ML/MC fragment from a bundle.

For each of these sources there is a dedicated process for building and encapsulating a valid frame.

37.4.2.1 Transmission of Plain PPP, LCP, and PPP MUX Frames on a Single Link

Each link has an associated queue structure that supports transmission of plain PPP frames (typically LCP frames) and PPP MUX frames. The Link queue has a higher priority than the ML MC queue of a bundle.

There is an option to define up to eight queues that are related to each link. Selection of a queue is done by the weighted Fair Algorithm (WFQ).

37.4.2.2 Transmission of ML/MC PPP

This process is divided, as on the receiver, to two stages: the front-end and back-end.

The front-end is responsible for transmission and HDLC framing of fragments which are prepared by the back-End process. The back-end is responsible for scheduling among classes if applicable, and preparing valid fragments for transmission.

The microcode supports up to eight different classes per a ML/MC bundle. Selection of each class for transmission is also done by a WFQ algorithm. The class field (CLS field) for the ML/MC header is taken from a Class Parameter Table, as is the incremental sequence number.

Each transmit class contains only one QD under it, which can be of type ML-MC MUX or ML MC non MUX.

37.4.2.3 Transmission of PPP MUX

The MUX encapsulation is a stand alone centralized process which generates PPP mux super-frames. Each bundle could have one of its associated classes assigned as a MUX queue. The process is an upper layer in the PPP transmission. Once a superframe is built, it is handled by the back-end of the transmitter for fragmentation if this is a Multi-Link queue, or by the link itself if this is a Link queue. For PPP mux frame the procedure for encapsulating subframes into a PPP mux frame is stopped if one of the following happens:

- The next subframe to be added to the frame will cause the total length to exceed the maximum value allowed for a super-frame. (This maximum value is programmable.)
- A time-out timer has elapsed.

Each sub-frame could have a time stamp and an aging mechanism timer is defined in order to ensure that “older” sub frames are not transmitted. When the encapsulation process starts building a new superframe, the time stamp of each BD is examined. If the difference between the current time and the time stamp has exceed the allowed time the sub-frame is discarded and will not be queued into the superframe. A counter increments for each subframe discarded due to aging.

The code fully complies to RFC 3153 with respect to PFF and LXT handling. PFC is also supported.

37.4.3 Supporting Channelized MCC and PPP

Running channelized MCC and PPP configurations is possible. The PPP microcode data structure is combined with the MCC data structure as follows:

- The Link Parameter Table of each PPP link has the size of 4 MCC channel specific parameter RAMs. The user must reserve 4 contiguous channel specific parameter RAM for each PPP link.
- The PPP Global Parameter RAM is placed in the MCC page in the location MCCbase+0x90.
- The rest of the parameter tables can be located in MURAM, as long as they do not overlap MCC channelized resources (i.e the channel specific parameter RAM and the channel extra parameter RAM).
- The receiver distinguishes between a MCC channel and a PPP link according to the programming of RSTATE. The user should initialize the RSTATE/LRSTATE to 0x HH80_0000 for non MLMC PPP MCC channel. For ML MC PPP operation a dedicated host command will initialize RSTATE/LRSTATE to the appropriate value.

37.5 Data Structures

The following sections briefly describe the data structures defined by this package. A global parameter table contains general parameters for the MCC operation, under which this PPP microcode package runs, and matches the existing MCC global parameter page. This page has been expanded for the operation of this package.

In addition to the global page expansion, other dedicated parameter tables have been added for ML/MC support. These additional tables are described in following sections.

37.5.1 Link Parameter Table

The Link Parameter Table (LPT) contains parameters that are link-related. The location of this table is determined by mapping of a TDM link by the serial interface into a specific MCC channel. The size of this table is larger than the MCC channel specific parameters. Therefore, this table consumes several traditional MCC channels. The LPT is accessed by the RISC on each receive and transmit request, and the initial frame/fragment parsing is done on the link level. The LPT assigns each link with a number and associates each link to a bundle parameter table (BPT). The LPT also contains various link level statistics and management parameters for the receive queues.

37.5.2 Bundle Parameter Table

The Bundle Parameter Table (BPT) contains pointers and parameters that are valid for a bundle: Free Buffer Pool Parameter Table pointer, Class management and tables, Bundle mode bits.

NOTE

If a link is not a member of any bundle, a Bundle Parameter Table still has to be initialized. In such a case the Bundle Parameter Table will be smaller. The purpose for this is to remove redundant parameters on a link and a bundle level and to avoid duplication of parameters in a multi-link setup.

37.5.3 Class Parameter Table (CPT)

The class parameter table (CPT) manages the reconstruction of fragments and the fragment loss using a buffering queue. The buffering queue is represented by an external ring of BDs (WBD ring) and an internal status ring. After reconstruction, the ML/MC PPP frames are stored in a queue, managed by the CPT. The CPT also contains various class level statistics.

Each queue is managed by a queue descriptor. The user initializes a BD ring, leaving the data pointer of each BD blank. A free buffer pool is used to manage the memory allocations of the system.

37.5.4 Free Buffer Pools

The transmitter is capable of handling selection of Tx buffers from four pools. This is useful when the traffic mix contains small sub-frames and bigger data frames. The application designates to each type it's own pool and the transmitter returns the buffer to the specified pool once transmission is done.

The receiver interacts with one buffer pool. This size of the buffers is of the size of MRU in the ML/MC setup.

Note that LCP frames are received into a BD ring where BDs contain data pointers, so reception of LCP frames does not interact with the Free Buffer Pool.

37.5.5 Weighted Fair Queue (WFQ) Table

This is a structure which controls the selection of one queue from up to eight queues on a link or one class of up to eight classes. In a situation where the application requires such differentiation the user defines this structure for each set of queues. Priorities can be set as WFQ, Round Robin, or fixed priority.

37.5.6 Queue Descriptor (QD)

This data structure is associated directly with a queue and contains all the parameters managing it. It points to a buffer descriptor ring (the queue) and defines the mode of operation for this queue. There are a few modes of operation and each queue has its attributes. It is a resource which is shared between the RISC and the host.

37.5.7 Data Structures for RISC Usage

On top of the above data structures there are data structures which are for RISC usage. Some do not have to be initialized and only the memory space should be allocated. Fragment descriptors which are used by the transmitter back-end process is one example for this type of data structures. On the receiver side, a window BD (WBD) is an example for such a data structure. They are described in detail later.

Figure 37-3 and Figure 37-4 illustrate all the data structures described above.

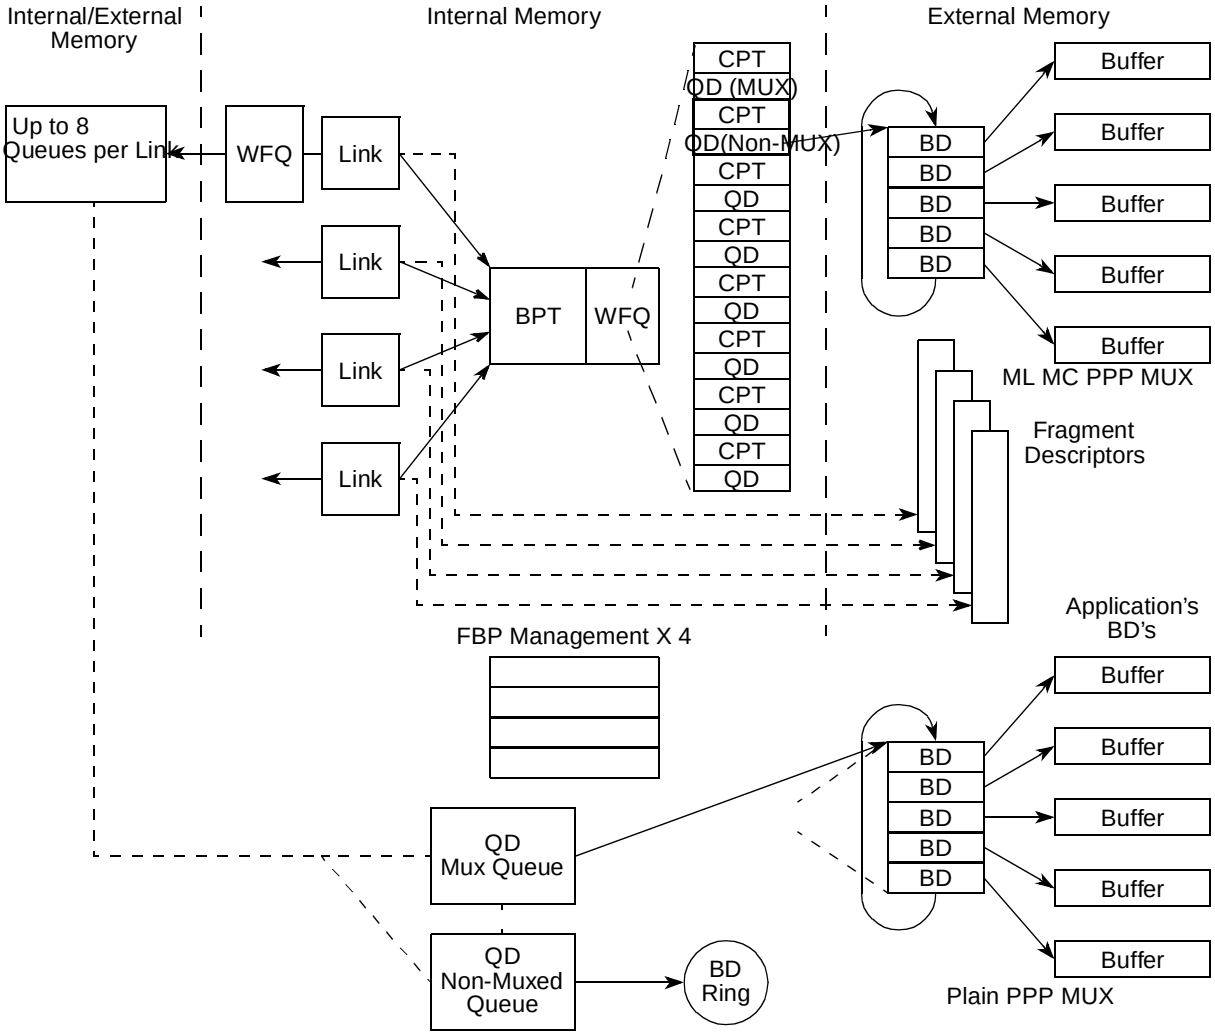

Figure 37-3. PPP Tx Parameter Structures

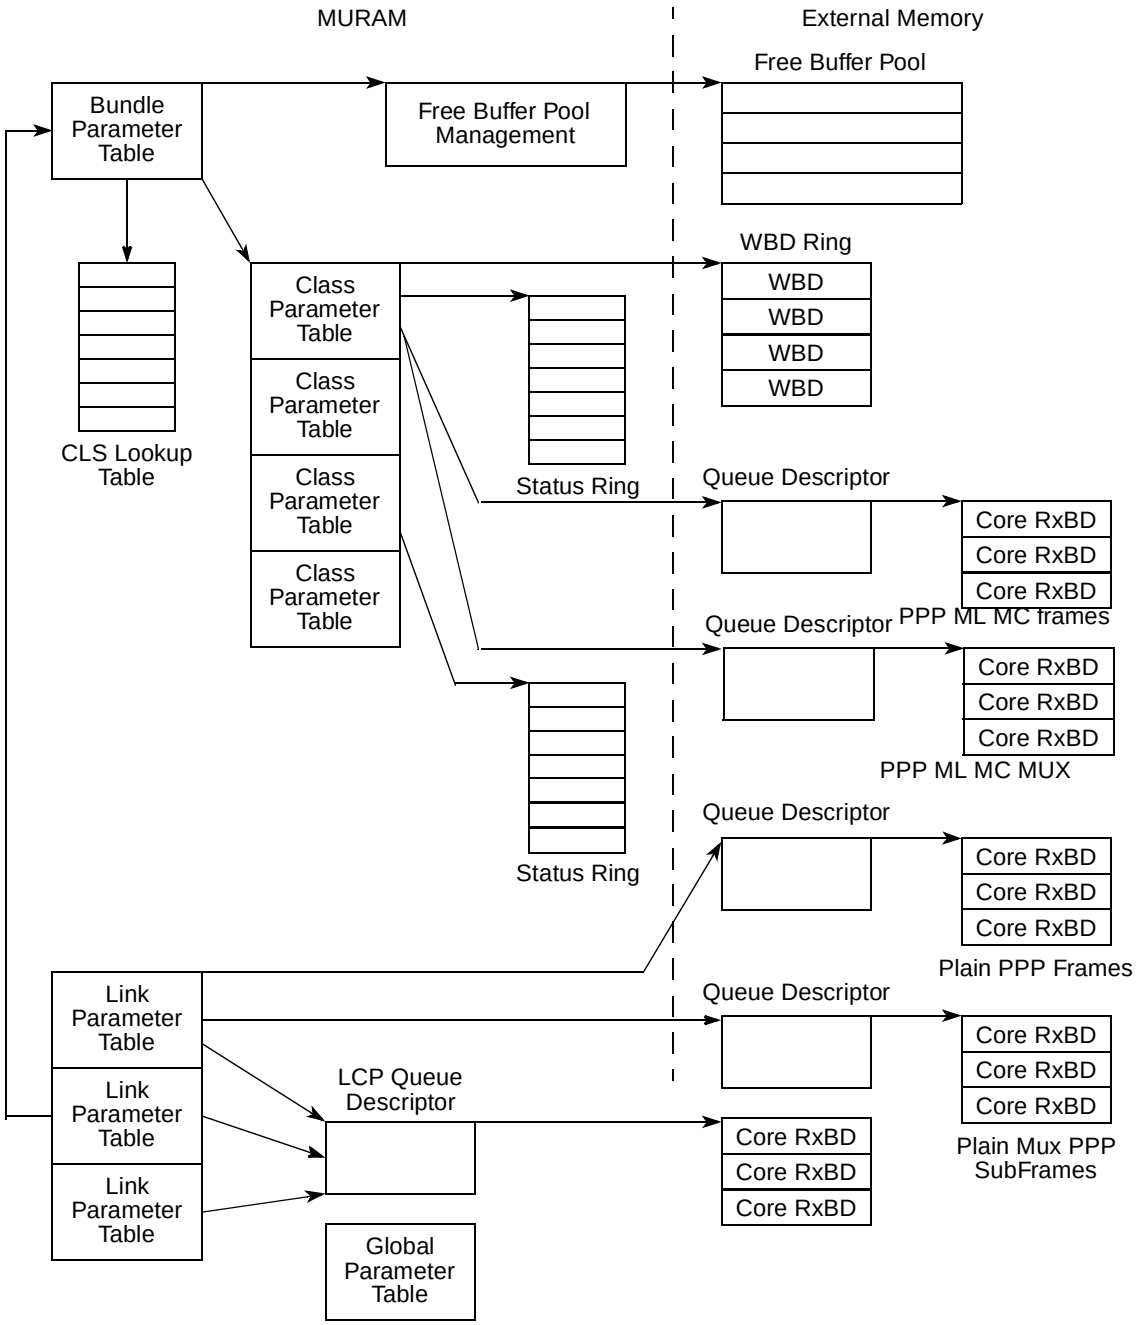

Figure 37-4. PPP Rx Parameters Structures

37.6 Receive Process

37.6.1 Address and Control Characters

This section describes the handling of address and control characters. The default ACC characters are 0xFF03. The user may negotiate other values for each link. The default address and control characters are always recognized.

The user may program other values using the RxACC field in LPT (refer to Section 37.11, “Link Parameter Table (LPT)”). When the user wishes to use only the default address and control characters, initialize the ACC field to 0xFF03. This user programmable ACC is compared when a packet is received. The received ACC is first compared to default Address and Control characters, and then to the ACC field.

When the first two received bytes do not match the default or the ACC programmed value, and RxACFC bit it set, the frame is regarded as a frame with compressed ACC, otherwise the frame is regarded as containing unrecognized address and control characters. Frames containing unrecognized address and control characters are discarded and the counter Rx_IACCNT increments.

The following figure describes the address and control handling on receive side.

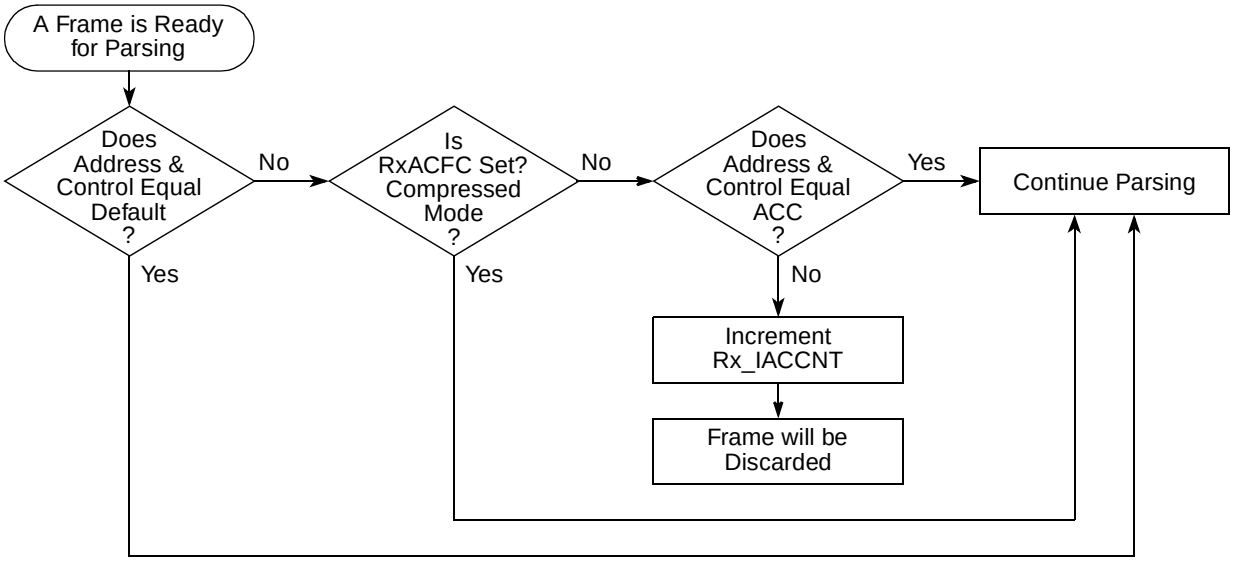

Figure 37-5. Rx ACC Flow

37.6.2 PID on Receive

The PID may or may not be compressed. The receiver handles this dynamically. The receiver checks the LSB bit of the first byte of the PID field. If it is set, the PID is regarded as compressed and it is decompressed for further checks by adding 0x00 as the MSB. If it is cleared the PID is regarded as non-compressed, and all further checks are done on the 2-byte PID field. The PID is not treated as part of the data and is being isolated and put in the BD for host handling. The receiver recognizes several types of PID and acts accordingly. Recognized PIDs include: plain PPP, PPP mux, ML/MC PPP and LCP. The following sections discuss the receive processing for each of the packet types.

37.6.3 Receive of Plain PPP Frames

Plain PPP frames are placed into Link queues. The Link queue is described by a queue descriptor (QD) and a BD ring. Both are initialized by the host. If working in Free Buffer Pool mode enabled (QD[FBP]=1), each BDs in the Link RX BD ring is prepared without any data pointer. The Link Parameter Table includes a valid data pointer from the ML/MC Free Buffer Pool. All Non LCP packets are using the FBP (which has smaller buffers size). The buffers are filled and once the FCS is checked and there are no other errors during reception, the Rx retrieves a free BD from the Link queue, updates its status bits (i.e E, PID), length and inserts the pointer into the BD. Afterwards, new pointer is taken from the pool for the next frame on the link.

If working in Non-Free Buffer Pool mode, the BD ring is initialized with valid data pointers and the RISC swaps the pointer from the BD with the pointer currently used for receiving the frame, and which is also initialized by the application.

37.6.4 Receive of LCP Frames

Once the address and control characters are checked and the PID is identified as a LCP packet the packet is routed to a dedicated queue common to all the links in the bundle if applicable.

This queue is also described by a queue descriptor (QD) and a BD ring. Both are initialized by the host. The BDs are smaller than the plain PPP BDs and each BD in the Link Rx LCP BD ring is initialized with a data pointer. The Link Parameter Table has a dedicated data pointer for LCP packets. All LCP packets use buffers which could have larger size to accommodate default 1500 bytes packets. Once the buffer is filled and after the FCS is checked and there are no other errors during reception, the Rx retrieves a free BD from LCP queue and updates its status bits (i.e E, PID) and swaps the pointer currently in the Link with the one in the BD. The pointer taken from the BD is used for the next LCP packet reception.

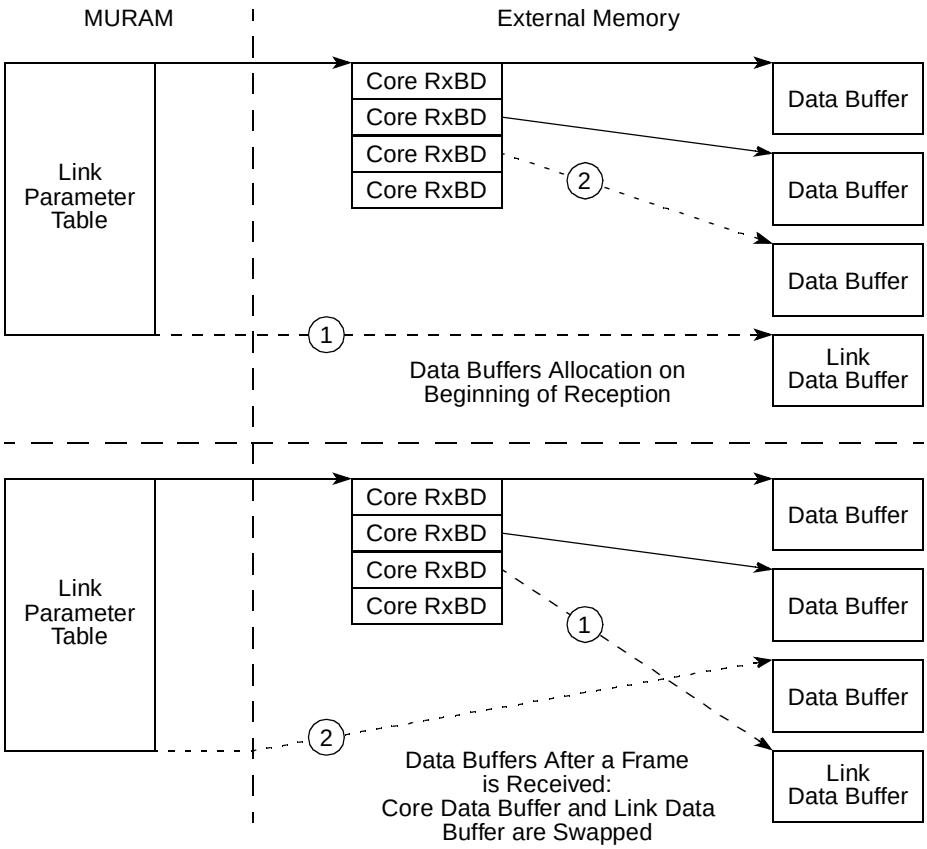

Figure 37-6. LCP Buffers Handling

37.6.5 Reception of ML/ MC PPP Fragments

Reception of ML/MC traffic is done in two independent processes—the front-end and the back-end. Once the front-end has finished processing a PPP packet it activates the back-end for further processing and interfacing to the Host. The front-end uses data structures prepared by the host but are completely managed by the RISC. Those structures and the flow of the process are described later. See Section 37.6.5.1, "WBD and Status Ring."

The receiver fills a data buffer pointed by a valid pointer from the FBP which resides in its table. Once the FCS is checked and no other errors are found, the receiver updates the appropriate WBD in external memory along with its associated status entry in the internal MURAM memory. Location in the WBD is determined by the sequence number of each fragment which is maintained by the receiver on a per class basis. Each WBD has a status nibble in the internal memory. The Valid bit is set in the appropriate status nibble. If this fragment is the beginning of frame, the B bit will be set. In case of an ending fragment, the E bit is set. The WBD is updated with the length of fragment and with the inner PID in case of a beginning fragment. If the Full bit (which is updated automatically by the QUICC Engine block: set upon an error in the fragment) is not set in the Status Ring, the RX writes the data buffer pointer to the WBD and brings a new data buffer from the Free Buffer Pool. Otherwise, the RX swaps data pointers—the data buffer pointer (which points to the received data) is copied to WBD and the data pointer currently in the WBD is copied

to the Link Parameter Table as the next Rx data buffer pointer. In FBP mode the host has to return each processed BD pointer back to the FBP.

Another mode of operation for the QUICC Engine block is not using the FBP- swap mode. Instead the host has to initialize the BDs in the BD ring with valid data pointers. The WBDs should also be filled with valid data pointers and the status ring for each class should be initialized with the Full (F) bits set. In this mode the host swaps the data pointers in the BD ring with new pointers on each receive operation. The QUICC Engine block will swap pointers between the BD ring the WBD ring and the link pointer dynamically.

When a complete frame is found (see Section 37.6.5.2, “Complete Frames Handling”) it is enqueued to a Class Queue. Each BD is updated with the buffers status, fragment’s length and the data buffer pointer. After the Host processes the fragments, the Host clears the empty bit in the BD and returns the pointer to the FBP.

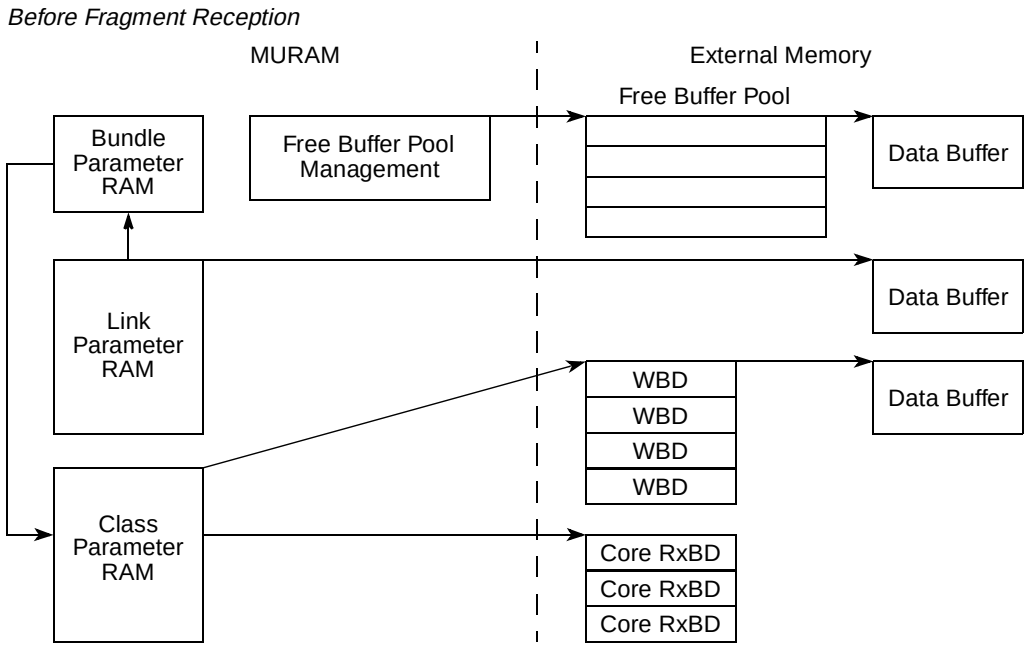

Figure 37-7. Data Buffer Pointers State Before Fragment Reception

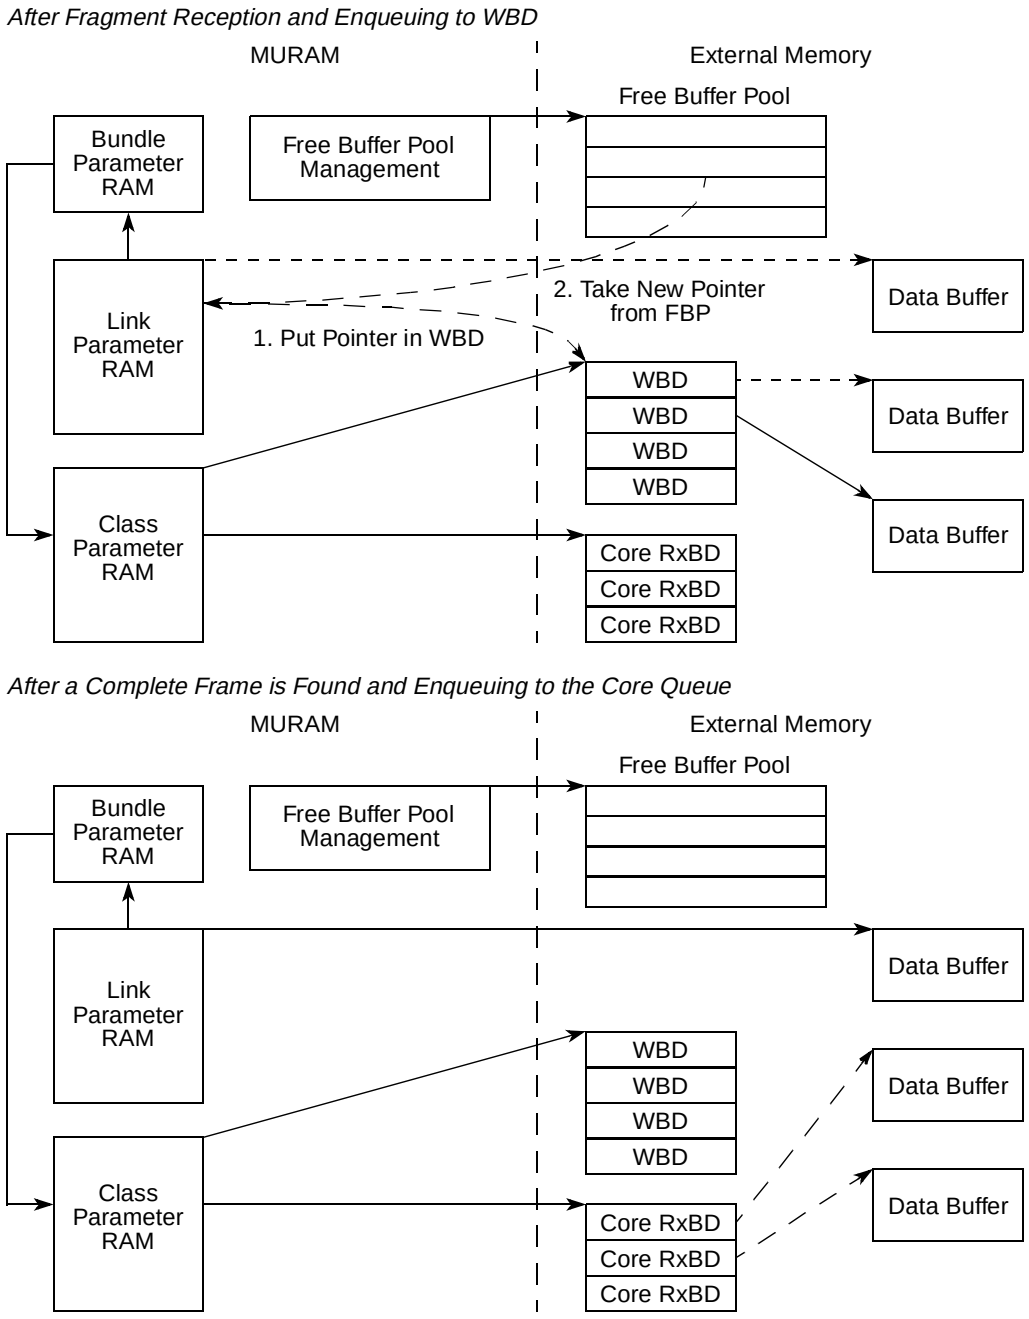

Figure 37-8. Data Buffer Pointers State After Fragment and Frame Reception

37.6.5.1 WBD and Status Ring

37.6.5.1.1 WBD Ring

The WBD structure is designated for the RISC usage and is not visible to the application. It serves as an intermediate buffer handling to store the fragments until a complete frame is assembled. Its purpose is to manage differential delays between links on a bundle so that it would be transparent to the host application.

- WBDs are located in external memory, status parameters are stored in the MURAM to simplify the management and to improve performance.
- Each WBD entry represents a single fragment.
- The status of every fragment is stored in the Status Ring.
- The allocation of a WBD entry is done according to the fragments sequence number. Before a fragment is placed in the queue, its sequence number is checked to see if it fits into the current window.
- Only complete frames will be enqueued to the Host queue or to the Demultiplexer.
- Each class has its own WBD ring.
- The size of a window must be a power of 2.

37.6.5.1.2 Status Ring

The status ring indicates which fragments were received and their status. It has the same number of entries as the WBD ring. Each entry has an associated WBD entry and is located in MURAM.

For best memory efficiency, each entry in the status ring has the size of a nibble (4 bits) and represents a fragment. The status ring is initialized to zeros (if working in FBP mode). When a fragment is received, the Valid bit is set and the bits representing begin and end of frame are updated. The fourth bit is the Full bit, indicating if there is a valid data buffer pointer in the WBD entry. This bit is set by the RISC in case of fragment invalidation.

The Class Parameter Table (CPT) holds a pointer to the beginning of the status ring (Status Ring Base). The management of the fragments reassembly process requires two pointers:

- BF_index—Begin Fragment Index which represents the beginning of current frame.
- EF_index—Empty Fragment index which represents the next empty fragment. Both pointers are stored in CPT.

The number of entries in the status ring (like the WBD ring) should be a power of 2.

Figure 37-9 illustrates the WBD ring and the status ring:

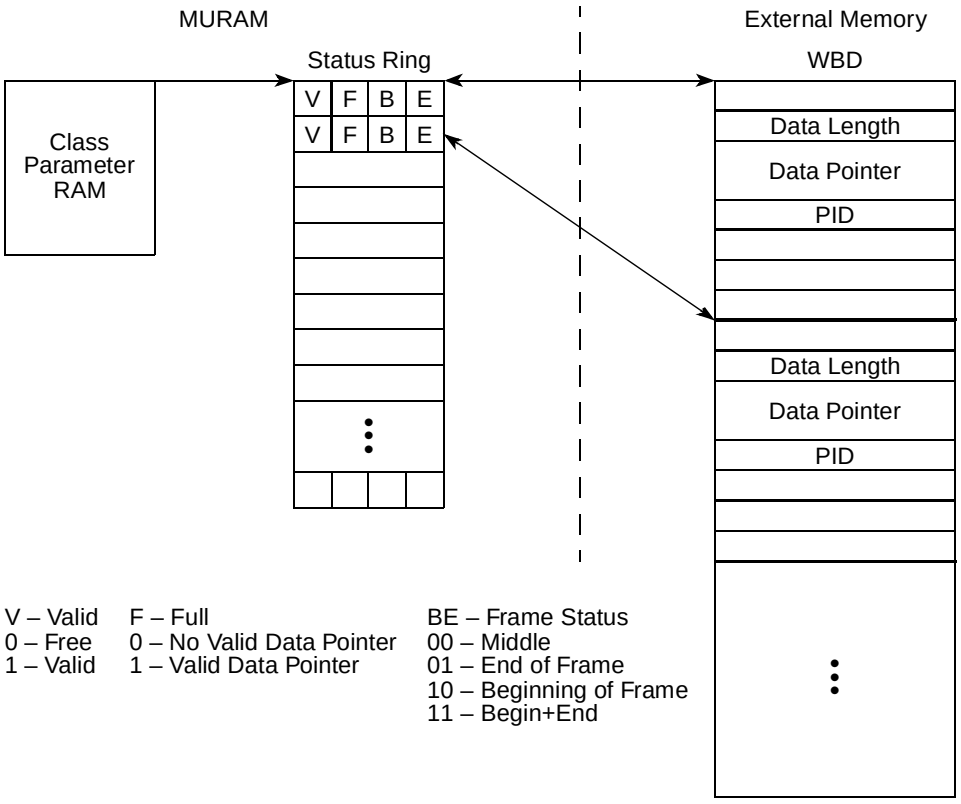

Figure 37-9. Status Ring and WBD Ring Correlation

37.6.5.2 Complete Frames Handling

Whenever a fragment whose sequence number corresponds to the location of the first empty index (EF_index) is received, the process of searching a complete frame is triggered. The process scans through the status table and updates the First_Empty_index parameter to a new value. As the scan is ongoing on the status ring, each entry is checked for its valid bit and B/E bits. When a correct and complete sequence of middle fragments and end fragment is found, a complete frame is found. The first fragment of the frame is pointed to by Begin_fragment_index. The location of Begin_fragment_index and the number of fragments are registered for the back-end process—the packets reconstruction task, via the Packets Reconstruction Table (refer to Section 37.16.2.1, “Rx Packets Reconstruction Entry”).

After a complete frame is found the Begin_fragment_index is updated to the next beginning of frame and the first empty index (EF_index) moves on till the next found end of frame. The process stops when EF_index reaches an empty fragment. The scan process can detect multiple completed packets, but it fills an entry in the Packet Reconstruction Table for each packet.

If an unexpected fragment is encountered during the process, such as B when E or middle are expected, all fragments starting from Begin_fragment_index up to the next valid Begin_fragment_index are invalidated.

The invalidation of a fragment is done by clearing the Valid bit, the Begin bit and the End bit and also by setting the Full bit in the appropriate status nibble. When a fragment is invalidated, the data pointer is not

returned to the Free Buffer Pool. On the next time a data buffer pointer is required, this pointer will be used instead of a pointer out of the FBP.

Figure 37-10 shows the process.

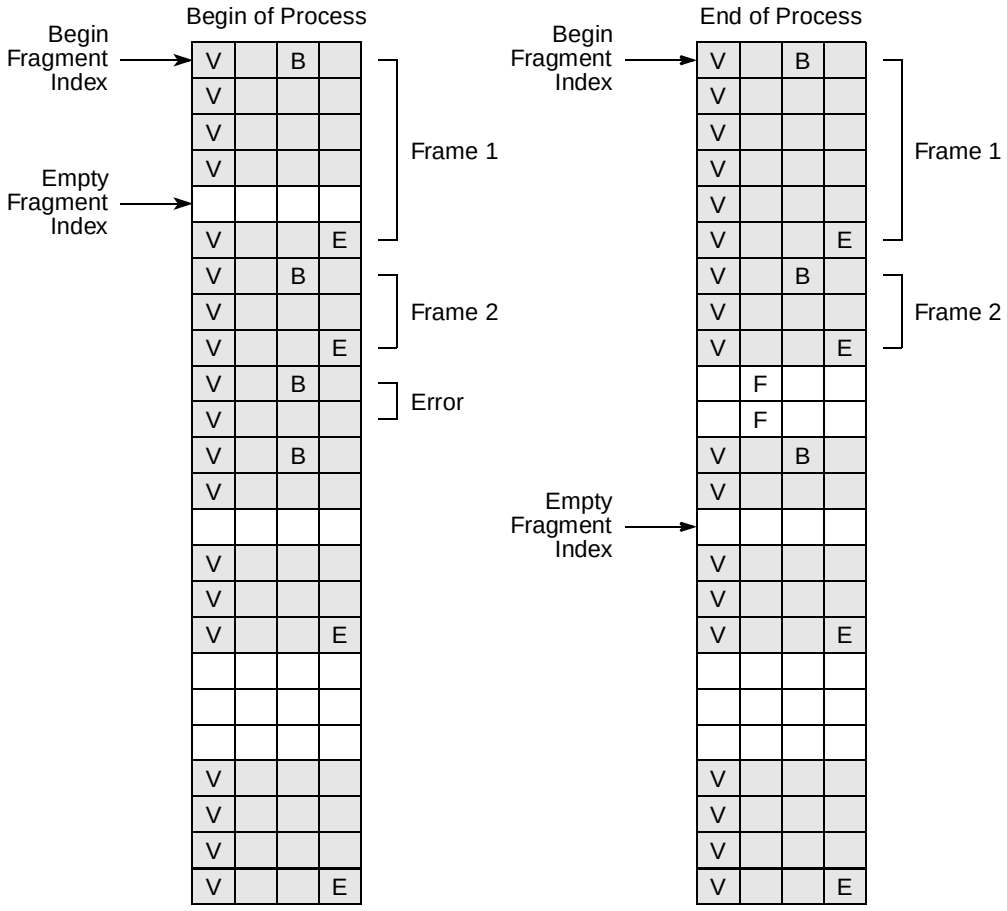

Figure 37-10. Status Ring Pointers Handling

37.6.5.3 Fragment Loss Process

RFC 1990 suggests the following algorithm: the receiver keeps track of the incoming sequence numbers on each link in a bundle and maintains the current minimum (M) of the most recently received sequence number over all the member links in the bundle. The minimum and the tracking of the incoming sequence numbers are kept per class. The receiver records the sequence number of fragments marked E. The sequence numbers are represented as offsets in the WBD ring. It always keeps the lowest sequence number of an ending fragment of a not complete frame (E). A fragment loss is detected when M advances past E.

The goal of the process is to identify fragment loss as soon as possible in order to prevent handling of many frames at a time. The receiver indicates the next empty fragment that is expected (EF_index). When M increments past the sequence number of an empty fragment, a fragment loss can already be detected. There is no need to wait for M to advance past E: since M is higher than the sequence number of the next empty fragment, and since the sequence numbers are always incrementing, the empty fragment is not expected on the link anymore. This condition also triggers a fragment loss process.

After a fragment loss is detected, Begin_fragment_index (BF_index) and Empty_Fragment_index (EF_index) are updated. First, all fragments between Begin_fragment_index and Empty_Fragment are invalidated. Empty_Fragment (EF_index) is updated to the next fragment, its status is checked. If it is empty both offsets will indicate this location. If it is B, the Begin_fragment_index is updated to it and Empty_Fragment_index increments to the next fragment location. The process continues until Empty_Fragment_index reaches an empty fragment location.

The algorithm described above works well when the fragments of the same class are distributed on all links of a bundle. If they are concentrated on fewer links, the value of M may stay unchanged because M is calculated on all the links in the bundle. This could cause the WBD ring to overflow in case of fragment loss. (Since M is the minimum of recent sequence numbers of ALL links, M will point to the last sequence number, received on the links, on which fragments are not transmitted.) To prevent that from happening, an additional mechanism is defined. A MX parameter holds the maximum value of recently received sequence number of all links. LSQN holds the last contiguous sequence number (i.e the sequence number before the one, EF_index represents) A threshold value is defined—SQN_TH. Whenever MX exceeds LSQN by more than the threshold, a fragment loss is detected. The frame containing the lost fragment (indicated by EF_index) will be discarded: BF_index will be moved to the next B, EF_index will be moved to the next empty fragment after BF_index, LSQN, M are updated.

37.6.5.4 Packet Reconstruction Task (PRT)

The packet reconstruction task (PRT) collects complete frames from the WBD ring and enqueues them to their destination queues. In the case of a muxed PPP frame, the PRT enqueues the frame to the demultiplexer queue—the demux fragment table. The PRT is triggered in case of fragment loss as well. Its purpose in that case is to clean all old fragments, collect complete frame, and synchronize the fragment pointers required to the continue of fragment reception and fragment loss monitoring.

This process is done in the background and is triggered by the front end process, utilizing a special interface which is described later. The information is passed to this task via a dedicated table—the Packets Reconstruction Table. The front end process writes a Packet Reconstruction Table entry when it wishes to trigger a complete frame search. The packet reconstruction task gets an entry from the table and searches for a complete frame. The frame is enqueued to the host or to the demultiplexer task according to the PID of the packet. If the front-end does not find a valid entry in this table, a busy interrupt is sent to the host. This could indicate some overloading in the system since the background is not able to keep up processing with the front-end.

The packet reconstruction task handles a single entry of the Packet Reconstruction Table at a time.

When enqueuing to the host queue, the task calculates how many BD’s are required for the complete frame since each fragment resides in a separate BD. Then it fetches the queue descriptor of the host. It checks if there are enough free BDs in the queue to accommodate the new frame. This check is based on the difference between the offset-in and offset-out values in the queue descriptor. If there are enough BDs, the Packet reconstruction table writes the BDs to the host queue and places the data buffers pointers into the BDs. Host processing of the BDs depends on the mode of operation. If FBP is active the host should return

the buffer pointers which were in the BDs or new buffer pointers to the Free Buffer Pool. If FBP is not active- swap mode, the host should put valid buffer pointers in the BDs which were processed. If there are not enough BDs to enqueue the complete frame, the frame is discarded and an interrupt is issued (Busy).In this case the corresponding entries in the Status Ring are invalidated (Valid bit =0); the Full bit of the entry is reset in the case of successful enqueuing and is set in case of a Busy condition.

When enqueuing to the demultiplexer, the packet reconstruction task reads an entry from the Demux Frame/Fragment Table (DFT). If this entry is valid, it enqueues a fragment to this table for de-multiplexing and continues to do so until it enqueues the last fragment of the packet. If an entry is not valid, the RISC discards all of the fragments for the reconstructed packet.

The Packets Reconstruction Table is allocated in the MURAM. The Packets Reconstruction Table size is programmable by the user, each entry representing a frame.

Figure 37-11 illustrates this process.

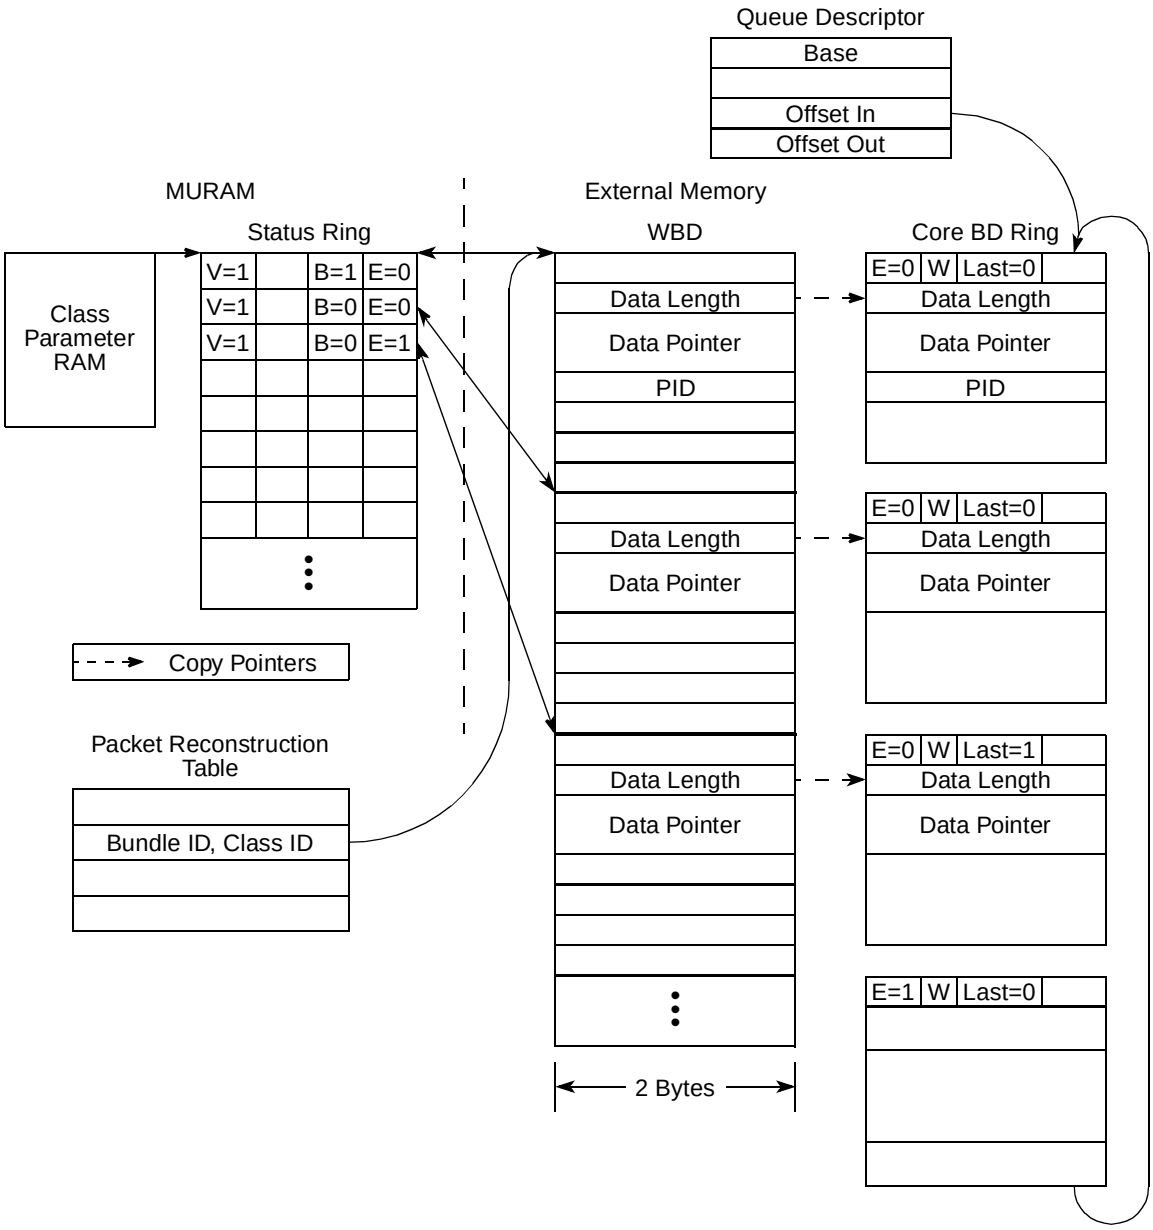

Figure 37-11. Packet Enqueuing Process

37.7 Transmission Process

37.7.1 Plain PPP Transmission

For plain PPP traffic related to a specific TDM link, utilizing Link queue (packets which are not fragmented over multilink), the framing process and the transmitting itself are done by the front-end process. The transmitter always checks if it has data to be transmitted on the Link basis; if it has none, it transmits the data for ML/MC traffic.

37.7.2 ML/MC Transmission

37.7.2.1 Fragmentation Process Structure

The process of preparing a ML-PPP fragment is also partitioned into two independent processes. The front-end deals with the actual transmission on the link, and the back-end process prepares the fragments. The background process is called the fragmentation process. Each fragment can consist of several BDs (typical when encapsulating PPP mux frames) or on the other hand may be a single BD which is transmitted over several fragments.

The back-end requires data structures to be prepared and initialized by the host. These are completely managed by the RISC during normal operation. Each bundle points to a structure of several fragments in external memory. These data structures are called Fragment Descriptors. The number of these data structures is twice the number of potential links in the bundle. Each bundle also points to a Fragment Pool Table, which manages the order of preparing and transmitting the fragments.

37.7.2.2 Fragment Descriptor Structure

Each Fragment Descriptor structure contains the information needed for transmitting a fragment. It is located in external memory and is for RISC usage only. The application should only allocate the memory required for these structures.

The user determines the size of the fragment structure according to the maximum number of BDs that constitute a fragment. For small size PPP mux subframes and a large fragment size, one can expect to have more BDs on each fragment. The size allocated must be a power of 2. The formula for calculating Fragment Descriptor size as a function of the maximum number of BDs is:

Fragment_Size = (Max No. BDs * 16) + 16.

For example, a maximum number of 7 BDs requires a 128 bytes Fragment Descriptor.

A fragment structure of 128 bytes is described in Figure 37-12 for illustration purposes only. As stated, these structures are for RISC usage only. The host should only allocate the memory for those structures.

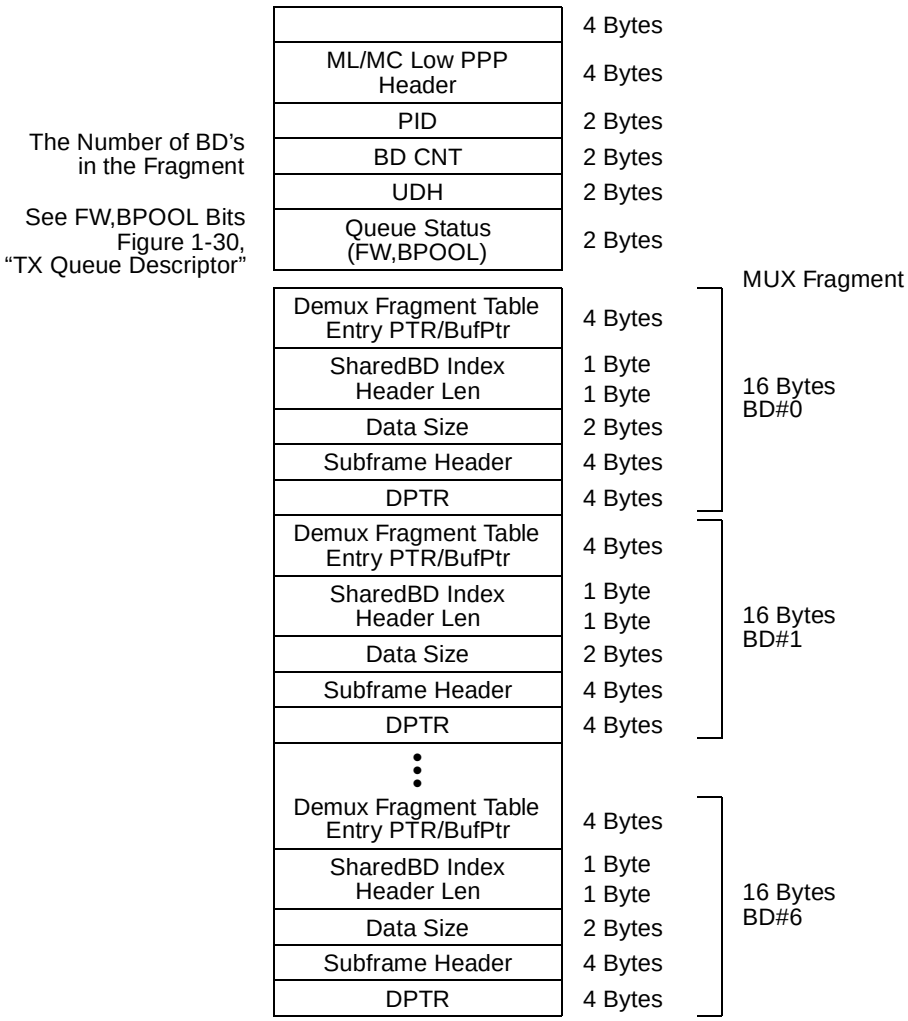

Figure 37-12. Fragment Descriptor

Figure 37-13 and Figure 37-14, illustrate the fragmentation process for two links in a bundle. Figure 37-13, part A, shows two fragments (index=0 and index=1) which are ready for transmission, therefore the Fragment Ready Count is equal to two. In Figure 37-13, part B, the first two fragments (index=0 and index=1), are transmitted by link X and link Y, and a new fragment (index=2) is ready for transmission; therefore the Fragment Ready Count is equal to one. In Figure 37-14, part C, link Y has finished to transmit fragment (index=1), and has started to transmit next fragment (Index=2), also a new fragment is ready for transmission (index=3), therefore the Fragment Ready Count is equal to one. Link Fragment Offset In is advanced, because one fragment was already transmitted, and entry 0 in the table was updated with index=1. In Figure 37-14, part D, link X has finished to transmit fragment (index=0), and started to transmit fragment (Index=3), also a new fragment is ready for transmission (index=1), therefore the Fragment Ready Count is equal to one. Link Fragment Offset In is advanced, because one fragment was already transmitted, and entry 1 in the table was updated with index=0.

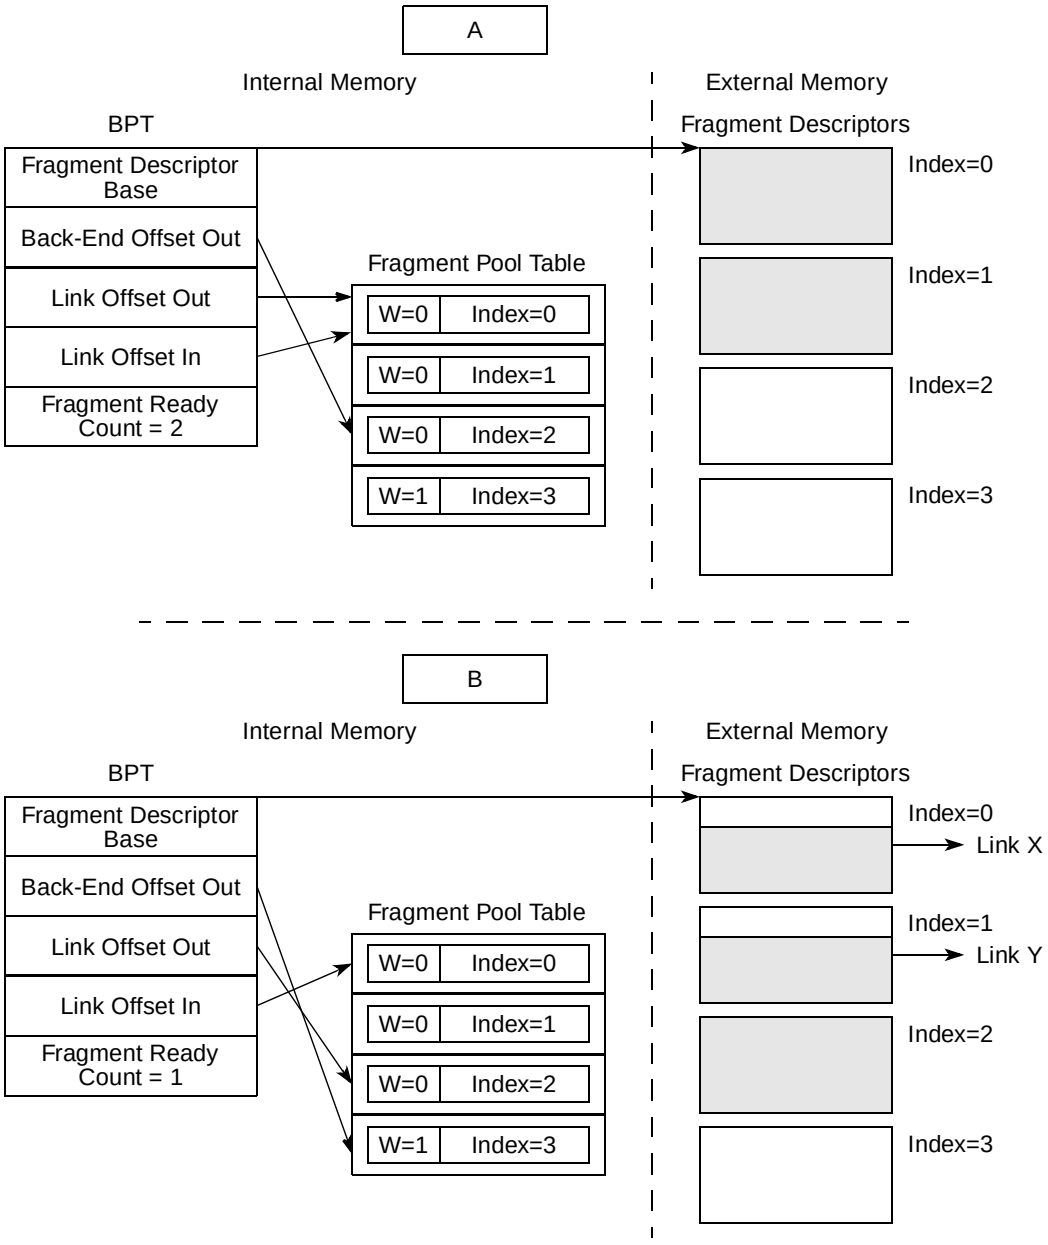

Figure 37-13. Fragmentation Structures (for 2 Links per Bundle)

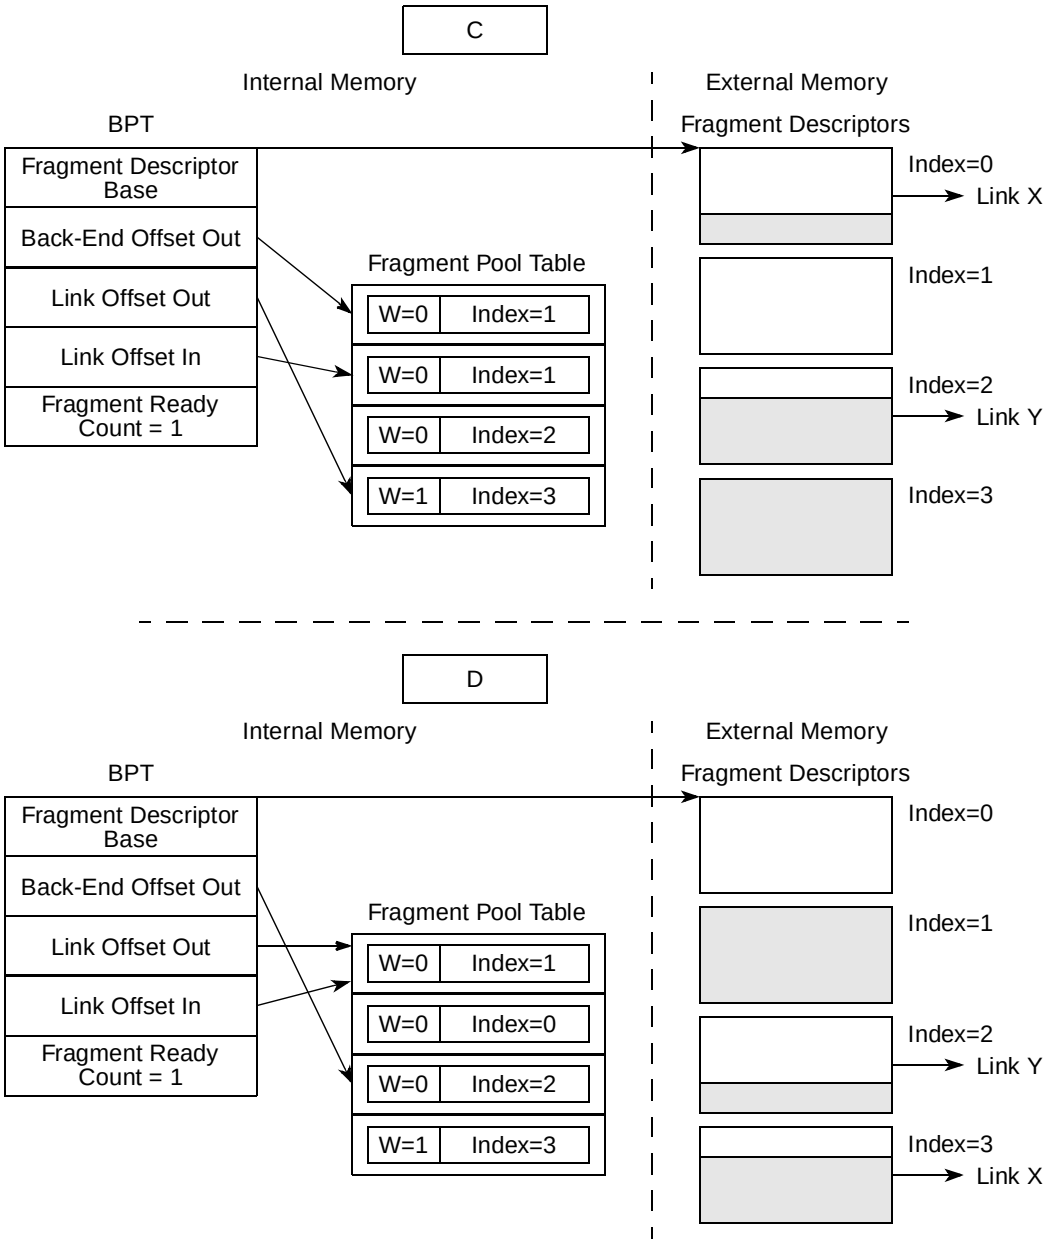

Figure 37-14. Fragmentation Structures (for 2 Links per Bundle)—Continued

37.7.2.3 Shared Buffer Handling

In ML-PPP, several links may attempt to transmit fragments from a common buffer. This happens when a packet which is larger than MRU size resides in a single buffer. This requires special handling of the BD related to this buffer. Only the last link that transmits the last fragment from this buffer should return the buffer pointer to the Free Buffer Pool.

This process is done by the RISC using a dedicated management routine. Up to 32 shared BDs can be handled by the system. The application must allocate the space for this management table for each bundle.

37.7.3 Weighted Fair Queueing (WFQ)—Selection of Queues/Classes

Weighted fair queueing (WFQ) is a mechanism for scheduling a queue or a class for transmission. The selection process is done in a few levels according to a predetermined order. As described in Figure 37-3, there are two sources for transmission, the Link and the ML/MC. Priority of the link queue is higher than ML/MC queues.

On the link queue there is an option to define up to eight queues where selection is done by the WFQ algorithm. If there is no need for multiple queues this data structure and process are omitted. On the ML/MC there is a need to select a class out of up to 8 classes. This is done also by a WFQ algorithm. The WFQ management resides in the internal ram (MURAM) for best efficiency and coherency. For each queue/class represented in the WFQ scheduling scheme there is a status bit indicating the status of the queue (i.e. is the queue full or empty). This bit is embedded in the WFQ structure. In each queue descriptor there is a pointer pointing to the location of this bit in the internal memory. In all of the cases if there is no need for multiple queues the WFQ data structures are omitted. In this case there will be only a single bit indicating queue empty/full. This bit should be handled by the host as described below. (See Section 37.7.3.5, “Management of the Queue Empty (QE) Bit”).

Each queue has an associated weight, which is translated to a parameter called INC (Increment) programmed in the WFQ data structure. INC is inversely proportional to the weight value. The higher the weight (lower the INC) value, the higher the bandwidth for the queue.

In weighted fair queueing, all queues are examined and the queue with the smallest finish time is selected. The relative data rate for the queue is determined by the WINC parameter as programmed in the Weighted Fair Queueing Table (see Section 37.5.5, “Weighted Fair Queue (WFQ) Table”). The Queue Empty bit of a queue that has no frames/fragments to transmit is set, and as a result this queue will not be selected.

The following sections describe different scheduling schemes that can be obtained by the WFQ algorithm.

37.7.3.1 WFQ Among All Queues

The WFQ mechanism can be used to implement many scheduling schemes of weighted fair queueing (WFQ) among all 8 queues, as the example in Table 37-2 shows.

Table 37-2. Example of WFQ among All Queues

	Queue0	Queue1	Queue2	Queue3	Queue4	Queue5	Queue6	Queue7
INC	3	5	2	30	2	5	30	20

The formula for the allocated bandwidth of each queue out of the total bandwidth, assuming Queue#i has an INC=Ki value associated with it, is as follows:

$$\text{QueuePriority}_i = \frac{1}{K_i} \times \sum_{\text{all queues}} \frac{1}{K_j}$$

For the above example Queue0 has priority of 18%, Queue1 receives 10%, and so on. The algorithm implements WFQ algorithm in the sense that at any given time all queues are examined, and the one with

the smallest finish time is chosen. Finish time is updated for the selected queue by adding the queue INC value to the finish time.

37.7.3.2 Strict Priorities among All Queues

Strict priority is a mode in which, whenever a high priority queue has a frame to be transmitted, this queue is chosen. To implement strict priority among all queues (Queue0 is highest and Queue7 is lowest priority) program all INC values to zero.

37.7.3.3 Round Robin Algorithm

To implement Round Robin the application must program the same INC value (greater than 0) for all queues. In this way all queues get the same relative weight.

37.7.3.4 Mixed Mode

To implement mixed mode where a number of queues are in strict priority and others are scheduled with WFQs: The strict priority queues are assigned to the low numbered queues (starting from Queue number 0—Queue0), these queues are assigned INC=0. Other queues are assigned INC according to their relative weight.

Table 37-3. Example of mixed mode WFQ

	Queue0	Queue1	Queue2	Queue3	Queue4	Queue5	Queue6	Queue7
INC	0	0	2	30	2	5	30	20

In this example Queue0 and Queue1 are strict as long as Queue0 has a queue with a BD that is ready to transmit. If it has no ready BD, Queue 1 is chosen. If it is also empty (The BD are not ready), one of Queue2 to Queue7 is chosen. according to their relative weight.

37.7.3.5 Management of the Queue Empty (QE) Bit

Each queue/class has a status indicating if it is full or empty, so that it can be scheduled for transmission if full and removed from the selection automatically, when it is empty. The RISC and the host change the QE bit according to the state of the queue. When reaching a point where there are no BD’s in the queue, the RISC sets the QE (Queue Empty or CE Class Empty) bit. The host, when filling up a queue of BD’s for transmission, should clear this bit in order to put the queue into the scheduling process. When clearing a Link/Class empty bit the host should follow the procedure described in Figure 37-15:

1. Set the BD[R] bit for the corresponding BD’s under the queue.
2. Check if the QE bit is set, and only if it is set clear it, in order to enable the queue.

The user may desire only one queue instead of 8 queues. In this case the Weighted Fair Queueing Table is not necessary. There are four possible modes that determine the location of the QE and the CE bits that are described in Section 37.5.5, “Weighted Fair Queue (WFQ) Table.”

Table 37-4. Queue Empty Bit Management

Case	PPP Mode	Number of Classes	Number of Queues	Queue/Class Empty Bit Location
1	Link	not applicable	1	LPT[LMR]->QE
2	Link	not applicable	>1	Queue WFT[QE]
3	ML	1	not applicable	BPT[BMR]->CE (Offset 0x0E in BPT)
4	MLMC	>1	not applicable	Class WFT[QE]

For example, in the case of MLMC with multiple classes (case 4 in the table), the host/RISC needs only to manage the Class WFQ[QE] bit. The QD[QE_PTR] parameter would be initialized to the relevant Class WFT entry pointer.

See the host flow in Figure 37-15.

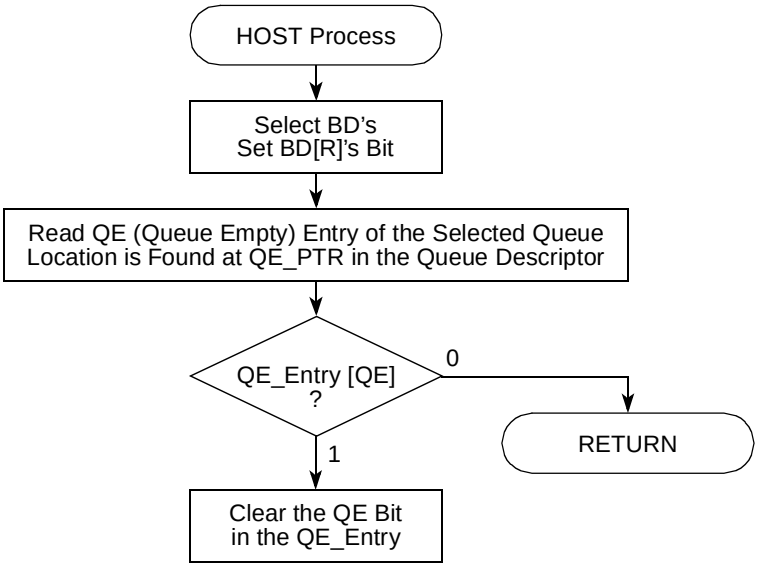

Figure 37-15. Activating a Queue by the Host

37.8 Background Processes Interface

As described earlier, both the receiver and the transmitter have background activities done in parallel to the MCC activities. Because it is possible to have a system with multiple bundles running concurrently there is a need to indicate to these background processes on which bundle their services are required.

The transmitter and receiver have different activation process because of the difference in the tasks done by each of those background processes.

37.8.1 Transmitter Background interface

The task of the transmitter background is to perform a selection between the classes in a ML/MC setup and to generate the fragments for transmission. This should be done on a bundle basis since fragments are

prepared for each bundle. For doing this there is a special table defined used by the transmitter. The table contains a list of valid bundles in the system which require the background task services. It is filled by the host. Up to four bundles are allowed in the system. Last entry is marked with a Wrap indication.

The table consists of up to four entries for four available bundles. Each entry contains a pointer to a bundle parameter table (BPT) in the system which is a ML/MC bundle. The front-end generates requests to the back-end. Upon request the back-end processes an entry in its table. It steps to the next entry upon completion of a full fragment for the current bundle. Service is done in a round robin method Figure 37-16 describes this handshake between the back-end and the front-end process.

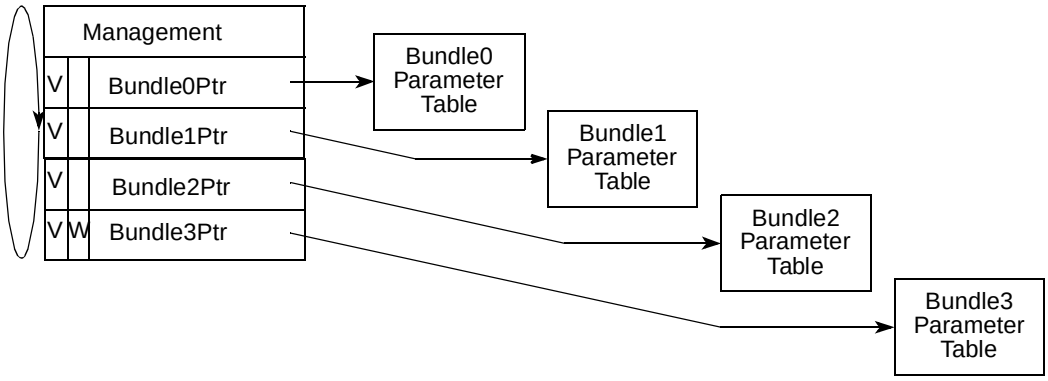

Figure 37-16. Fragmentation Process interface

37.8.2 Receiver Background interface

The packet reconstruction task which is a receiver background task provides services on a class and bundle basis. Therefore upon each packet reception which can consist of several fragments, the front end writes a request in a centralized request table (Packet Reconstruction Table). Each entry in this table contains all the information needed for the reconstruction task. The size of the table is determined by the application and last entry is marked with a Wrap indication. Management of the process is located in the MURAM.

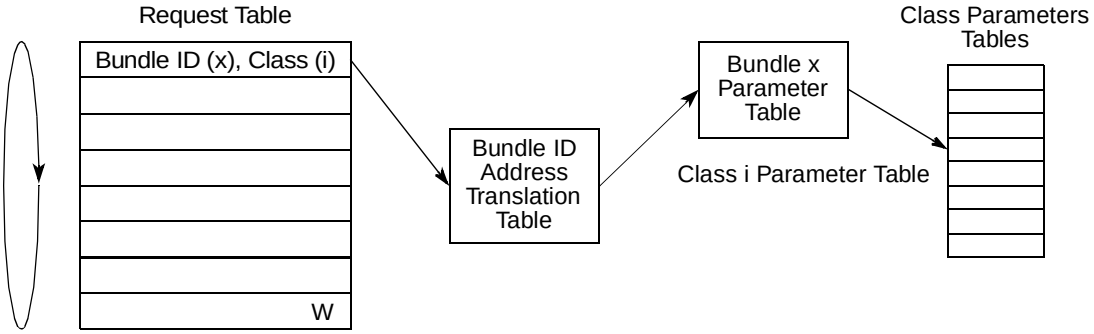

Figure 37-17. Packet Reconstruction Process interface

37.9 PPP Mux Process

The RISC is capable of processing PPP mux superframes. The process is a stand alone process having its own page. It can be looked as an upper layer of handling this service. It is called by the back-end processes of the receiver and the transmitter and has a dedicated interface and handshake for doing that.

On the ingress the RISC detects and analyzes a PPP mux superframe arriving as part of a ML/MC multi fragment superframe or on a link as a plain PPP mux packet. Once the frame is identified as a muxed frame, it is forwarded to the Demux process which parses through the frame, breaks the superframe into the encapsulated sub-frames and puts the subframes into their queues with all information needed.

On the egress side the RISC encapsulates superframes for all the queues which are listed as requiring MUX services. This process is also done in the background and upon completing a superframe it is taken by the transmitter back-end process for fragmentation into the ML/MC traffic.

37.9.1 PPP/ML-MC Demultiplexing

Three program entities are involved in the demultiplexing process—the PPP mux detection, the demux process, and the host. The receiver detects that a PPP mux frame was received based on the PID information. If the PPP mux frame was received over ML or ML/MC connections then each fragment of the frame resides in a single data buffer. All parameters of that fragment (e.g Length, Data buffer pointer, etc.) are passed to an entry in the Demux Fragment Table. A time stamp (stamped on fragment basis) is also passed to this Table (DFT). At this point the receiver requests the services of the demux process, The Demux scans through the superframe, extract the information for each of the subframes within the fragment, and assign each subframe its own BD. No data is ever being copied in this process. When the demux becomes active it first fetches a DFT entry, then a queue descriptor for a BD ring which is, in fact, empty data structures ready to be used by the RISC. The RISC processes the fragment, extracts and analyzes subframe headers and put the necessary parameters into the BDs. Once all the subframes are processed, the demux generates an interrupt to the host, containing information on the location of the queue descriptor and the DFT entry index. The host handles the BD ring. Since each BD contains a pointer which points into the original fragment buffer there is a unique way for returning a buffer to the FBP after ALL of its sub-frames BDs were processed.

Once the demux has finished processing all DFT entries it becomes inactive and will be activated by another request from the receiver.

Figure 37-18 illustrates the mechanism described above.

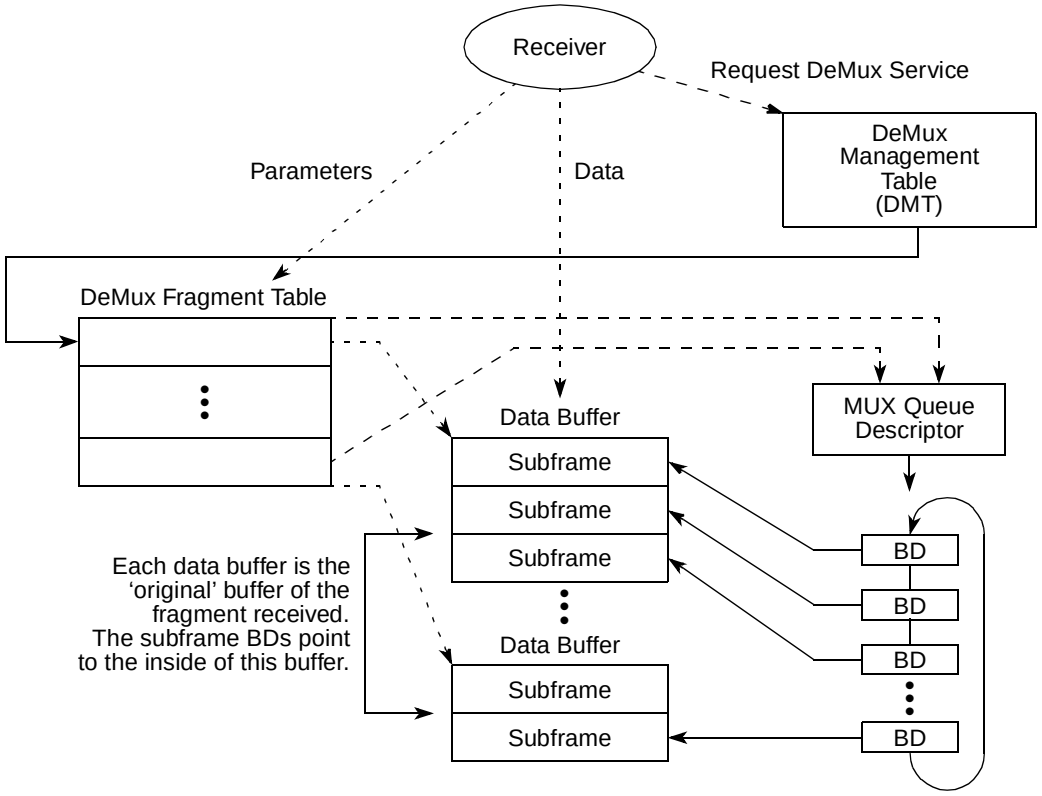

Figure 37-18. Demux Operation

37.9.2 PPP/ML-MC Muxing Encapsulation

This centralized process provides encapsulation services to all the muxed queues in the system.Note that there can be up to 16 Mux queue in the system.The host puts on each of the queues sub-frames. The mux process scans through the queues list and builds a superframe. Each of these queues can have different super-frame size and attributes. The process starts building the super-frame by scanning the BD ring of each of the queue and upon getting a valid BD it modifies the BD so it can be processed later by the transmitter back-end (or by the Link itself if this is a Link queue). This implies that there are three entities dealing with this queue—the host, the mux process, and later, the transmitter back-end or the Link itself transmitting the frame. The queue descriptor, for this reason, has a unique description. The process continues as long as the BD's are ready. When the desired super-frame size is reached or when the time-out period has expired (if enabled) the superframe is handled to the transmitter. An aging mechanism can also be activated so that an "old" packet is not encapsulated into the super-frame.

The mux process does not start generating the next superframe as long as the previous one has not been taken for fragmentation. Once this is done it has a new request and starts the process again. The list of queues for this process is located in the Mux Parameters Table which contains entries for each muxed QD. It is a static list which can be modified by the host. The mux processing scans through the list in a round robin fashion so the bigger the list is, the higher is the latency for building a super-frame. Management of processing the entries in this table is located at the Mux Management Table.

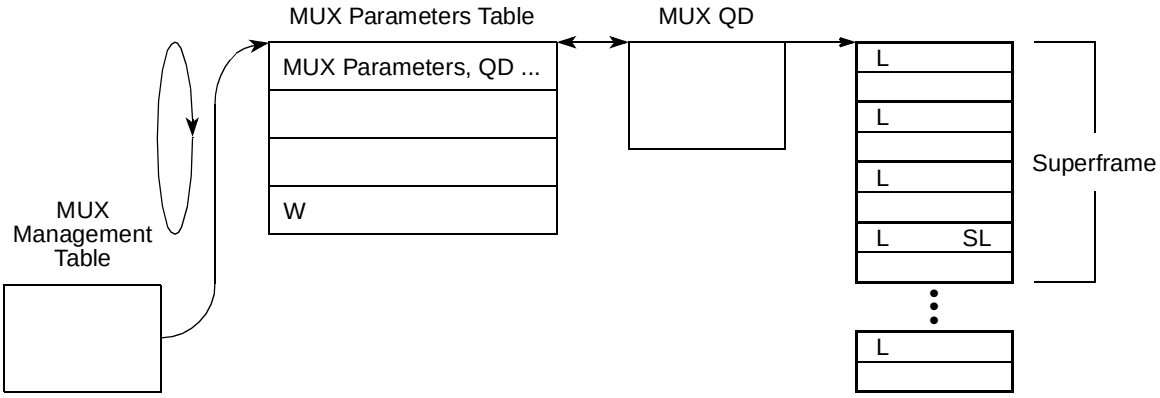

Figure 37-19. Mux Operation

37.10 Programming Model

37.10.1 Global Parameter RAM

For ML/MC operation the Global Parameter RAM is extended and has some extra parameters besides those that are already defined in the MCC page.

The following table indicates the PPP Global Parameter Ram for the MCC page.

NOTE: Important

For any pointer value to a MURAM location (noted as internal pointer) the user should put the offset to the MURAM and not the full address of the data structure. In case of an interrupt event where such a pointer is part of the information provided in the interrupt entry it is the offset value and not the address itself.

Offset + 0x90	PPP_INTBASE			
Offset + 0x94	—			
Offset + 0x98	—			
Offset + 0x9C	—			
Offset + 0xA0	Bundle ID table	Bundle0PTR		
Offset + 0xA4		Bundle1PTR		
Offset + 0xA8		Bundle2PTR		
Offset + 0xAC		Bundle3PTR		
Offset + 0xB0	Packet Reconstruction Management pointer			
Offset + 0xB4	—			
Offset + 0xB8	Tx_BG SNUM	Rx_Packet Reconstruction_SNUM	Tx_Mux SNUM	Rx_De-Mux SNUM
Offset + 0xBC	Demux Management Table base			
Offset + 0xC0	Mux Encapsulation Management Table base			
Offset + 0xC4-Offset+ 0xFF	—			

Figure 37-20. Global Parameter RAM

Table 37-5 describes the Global Parameter RAM fields.

Table 37-5. Global Parameter RAM

Offset	Name	Width	Description
0x90	PPP_INTBASE	Word (internal)	Pointer to the base address of the interrupt queue parameter tables. Should be 0x20 bytes aligned. Up to 14 queues are available.
0x94–0x9F	Reserved	12 Bytes	Should be cleared.
0xA0	Bundle0PTR	4 words	Bundle ID Table. Should be initialized only if Rx or Tx ML MC PPP operation is needed. Each entry contains a BPT offset, and the entry location is determined according to the BPT's BMR[BundleID]. e.g. entry that points to BPT with it's BMR[BundleID]=2 should be located in third place. Entry description: bit 0 -Valid bit. Should be marked by the user. An entry which has its valid bit cleared will not get serviced. bit 1 - Wrap bit. Last entry should have its Wrap bit set to 1. bits 2-7 - Reserved set to 0. bits 8-31 - BPT offset.
0xA4	Bundle1PTR		
0xA8	Bundle2PTR		
0xAC	Bundle3PTR		
0xB0	Packet Reconstruction Management pointer	Word (Internal)	Pointer to the Packet Reconstruction Management table. Valid only if ML MC PPP frames are in use or when PPP Mux frames are received. Note that even if the PPP Mux is received on the Link with out ML MC functionality, this table should be allocated. The user must assign value to the Rx_Packet Reconstruction_SNUM in these cases. Should be 64 bytes aligned and it's size is 64 bytes. Refer to Table 37-24.

Table 37-5. Global Parameter RAM (continued)

Offset	Name	Width	Description
0xB4	Reserved	Word	RISC internal use. Should be cleared.
0xB8	Tx_BG SNUM	Byte	Tx background process SNUM. The SNUM is taken from the available SNUMs described in Table 20-15. Should be set only if Tx ML-MC functionality is needed, otherwise should be cleared.
0xB9	Rx_Packet Reconstruction_SNUM	Byte	Rx Packet reconstruction process SNUM. The SNUM is taken from the available SNUMs described in Table 20-15. Should be set only if Rx ML-MC functionality is needed or if PPP Mux is enabled, otherwise should be cleared.
0xBA	Tx_Mux SNUM	Byte	Tx Mux encapsulation process SNUM. The SNUM is taken from the available SNUMs described in Table 20-15. Should be set only if Tx Mux functionality is needed, otherwise should be cleared.
0xBB	Rx_De-Mux SNUM	Byte	Rx De-Mux process SNUM. The SNUM is taken from the available SNUMs described in Table 20-15. Should be set only if Rx Mux functionality is needed, otherwise should be cleared.
0xBC	Demux Management Table base	Word (internal)	This field holds the pointer to the DeMux Management Table (DMT). The DMT resides in internal memory. User should allocate 64 bytes for this table, and it should be 64 bytes aligned. See Table 37-30.
0xC0	Mux Encapsulation Management Table base	Word (internal)	This field holds the pointer to the Mux Management Table (MMT). The MMT resides in internal memory. User should allocate 56 bytes for this table, and it should be 64 bytes aligned. See Table 37-33.
0xC4–0xFF	Reserved	-	Should be cleared.

37.11 Link Parameter Table (LPT)

Link-related parameters are stored in the Link Parameter Table (LPT). It contains a pointer to the bundle that the LPT related link is a member of, pointers, and parameters of the Link Host Queue.

The Link Parameter Table (LPT) is an extension to the MCC Channel-Specific HDLC Parameters. It is accessed on each MCC Transmit or Receive request. The size of the LPT is 256 bytes so it consumes the space of four MCC channel specific parameters. Location in the MURAM is determined by 64*CH_NUM (relative to the MURAM base address). The CH_NUM is the channel number, and must be a multiply of 4. (8 bits alignment) Any PPP host command should use this channel number as a command parameter (MCN).

NOTE

If a link is configured as a single link (not Multilink-Multiclass), the user still has to initialize the first 28 bytes (0x1C) of a Bundle Parameter Table related to this link.

Table 37-6 describes the Link Parameter Table.

Table 37-6. Link Parameter Table (LPT)

Offset[1]	Name	Width	Description
0x00	TSTATE	Word	Tx internal state. It is initialized by the host command. Refer to Table 37-44.
0x04	ZISTATE	Word	Zero-insertion machine state. (User-initialized to 0x1000_0207 for regular channel, and 0x3000_0207 for inverted channel)
0x08	ZIDATA0	Word	Zero-insertion high word data buffer (User-initialized to 0xFFFF_FFFF)
0x0c	ZIDATA1	Word	Zero-insertion low word data buffer (User-initialized to 0xFFFF_FFFF)
0x10	Bundle_Shared_ptr	Word (internal)	Bundle & Link Shared Parameters Pointer. The Bundle & Link Shared Parameters pointer points to the bundle parameter table in case of ML/MC PPP. In case of Plain PPP it points to a table of parameters that are used by the Link and by the ML so that this is an extension of the LPT table. **Note:** Should be 64 bytes aligned.
0x14	Reserved	Hword	Reserved, should be cleared.
0x16	LINTMSK	Hword	Link interrupt mask flag. See Figure 37-21.
0x18	LMR	Word	Link Mode Register. See Table 37-7.
0x1C	Reserved	Word	Reserved, should be cleared.
0x20	RSTATE	Word	Rx internal state. It is initialized by the host command. Refer to Table 37-44.
0x24	ZDSTATE	Word	Zero-deletion machine state (User-initialized to 0x80ffffe0 for regular channel and 0xA0FF_FFE0 for inverted channel)
0x28	ZDDATA0	Word	Zero-deletion high word data buffer (User-initialized to 0xFFFF_FFFF)
0x2C	ZDDATA1	Word	Zero-deletion low word data buffer (User-initialized to 0x8000_FFFF)
0x30	Reserved	Word	Reserved, should be cleared.
0x34–0x3B	Reserved	12 Bytes	Reserved, should be cleared.
0x3C	Rx_Swp_Data_ptr	Word	If a FBP is used by the receiver this entry should be initialized with the value 0xFFFF_FFFF. In case when only some of the RxQDs under this link use FBP mode and other RxQDs uses swap mode, then the host still need to initialize this entry with the value 0xFFFF_FFFF, and the buffers pointers allocated for the swapped RxQDs should match the size of the buffer pointers in the FBP. Once the INIT PPP Rx link (see 0xPPP Commands) command is issued this value is changed by the RISC to a valid data pointer from the FBP. It must be used as an acknowledge for enabling traffic on a link If a FBP is not in use by the receiver, this pointer is swapped with the existing pointer in the BD. It should be initialized with a valid data pointer. In this case the WBD and status ring should be initialized as described in 37.16
0x40	MRU	Hword	Maximum Receive Unit bytes length. Must be bigger than 16 bytes. For Plain PPP it includes the information field and any padding; but not the protocol, address, control or FCS fields.
0x42	Rx_ACC	Hword	Receive Address and Control Characters.

Table 37-6. Link Parameter Table (LPT) (continued)

Offset[1]	Name	Width	Description
0x44	Tx_LWFQ_ptr	Word (internal)	Transmit Link Weighted Fair Queue Pointer. This entry points to the Link Weighted Fair queue structure, which occupies 32 bytes, and should be 32 bytes aligned. This parameter should be initialized to 0 if there are not any queues for this link or there is a single queue for this link (in this case the link is located in Tx_LQDB parameter).
0x48	Tx_LQDB	Word (external or internal)	Transmit Link Queue Descriptor Base Pointer. Point to the base address of the Link queue descriptors. Could be address to external or internal memory. Should be 16 bytes aligned. When working in WFQ mode the Link queue descriptors are placed consequently and each queue occupies 16 bytes. When working in a single queue mode, if LMR[LQE]=1 the Link queue is empty and therefore will not be scheduled for transmission. When the user clears this bit the queue will be scheduled with highest priority.
0x4C	Reserved	Word	Reserved, should be cleared.
0x50	Rx_IB_ptr	Word (internal)	Points to the Receive Internal Buffer. The size and alignment of this buffer is determined by the Rx_IB_Size entry in this table. The buffer enables parsing of received data before copying to external memory.
0x54	Tx_LInt_Frg_Ptr	Word (internal)	Transmit Link Internal Fragment Base Pointer. Allocate 64 bytes in Multi-user RAM for the current fragment which is transmitted by the link. Should be aligned to 64 bytes.
0x58-0x73	Reserved	32 Bytes	Reserved, should be cleared.
0x74	Rx_LCP_Data_ptr	Word	Rx data pointer used by RISC to receive LCP packets. When the receiver identifies this type of packet it will use this pointer to store the data. The LCP data buffers may differ in size from the data buffers, therefore after receiving a complete frame, this pointer is swapped with a buffer pointer from the LCP Queue. Note: The data buffer, which the Rx_LCP_Data_ptr refers to, should fit the LCP queue data buffer size.
0x78	Rx_LMuxQDP	Word (external or internal)	Rx Link Mux Queue Descriptor pointer. Can reside in external memory or internal memory. Points to the Queue Descriptor of the Link Mux Queue. When a common queue descriptor for all the links in the bundle is used, the Queue Descriptor should reside in internal memory. All plain PPP mux messages will be stored in this queue by the Demultiplexer.
0x7C	Int_TxQD_PTR /Cur_IntQD_PTR	Word (internal)	Internal Tx QD Pointer. The user should allocate 16 bytes for this entry. Pointer to Multi-user RAM for the location where the external Tx QD is fetched, when external Tx QD is used (LMR[TxExtQ]=1). Should be 16 bytes aligned. If LMR[TxExtQ]=0 the user should initialize to 0.
0x80	Rx_LQDP	Word (external or internal)	Rx Link Queue Descriptor pointer- Points to the receiver Queue Descriptor of the Link. Can reside in external memory or internal memory. When a common queue descriptor for all the links in the bundle is used, the Queue Descriptor should reside in internal memory. All plain PPP messages will be stored in this queue.
0x84	Reserved	Word	Reserved, should be cleared.

Table 37-6. Link Parameter Table (LPT) (continued)

Offset[1]	Name	Width	Description
0x88	Rx_LSR	HWord	RISC usage. Internal state of the RISC when processing a PPP packet. Initialize to 0x0007
0x8A	Rx_IB_Size	Byte	Receive Internal Buffer Size. Initialized by the user to 32.
0x8B	Reserved	Byte	Reserved, should be cleared.
0x8C–0x9B	Reserved	16 Bytes	Reserved, should be cleared.
0x9C	Link_Statistics_Table_Ptr	Word (internal)	Pointer to a table in the Multi-Port RAM which contains statistic information about this link. See Table 37-8 for details. The address should be 0x40 byte aligned.
0xA0–0xAB	Reserved	12 Bytes	Reserved, should be cleared.
0xAC	Rx_LState	Word	RISC usage. Internal state of the RISC when processing a PPP packet. It is initialized by the host command. Refer to Table 37-44
0xB0	Rx_CState	Word	RISC usage. Internal state of the RISC when processing a PPP packet. It is initialized by the host command. Refer to Table 37-44
0xB4	Reserved	Word	Reserved, should be cleared.
0xB8	Rx_LQDP_internal	Word (internal)	Internal Rx QD Pointer. The user should initialized this field in case of LMR[RxExtQ]=1 or in case of Mux traffic on the link. The user should allocate 32 bytes. Should be 32 bytes aligned.
0xBC-0xFF	reserved	68 Bytes	Reserved should be cleared.

[1] The offset is relative to Multi-user RAM base address + 64*CH_MUM

37.11.1 Link INTMSK Register (LINTMSK)

The link interrupt mask register (LINTMSK) is a user-initialized register, shown in Figure 37-21.. It provides enabling/disabling events defined in the Interrupt queue table entry.

	0	1	2	3	4	5	6	9	10	11	15
Interrupt entry	—		MRU	—	NIDL	IDL	—		UN	—	
Mask	—		Mask bit	—	Mask bit	Mask bit	—		Mask bit	—	

Figure 37-21. Link INTMSK Register (LINTMSK)

To enable an interrupt, set the corresponding bit in this register. If a bit is cleared no interrupt will be issued.

37.11.2 Link Mode Register (LMR)

The link mode register (LMR) is a user-initialized register, shown in Figure 37-22.

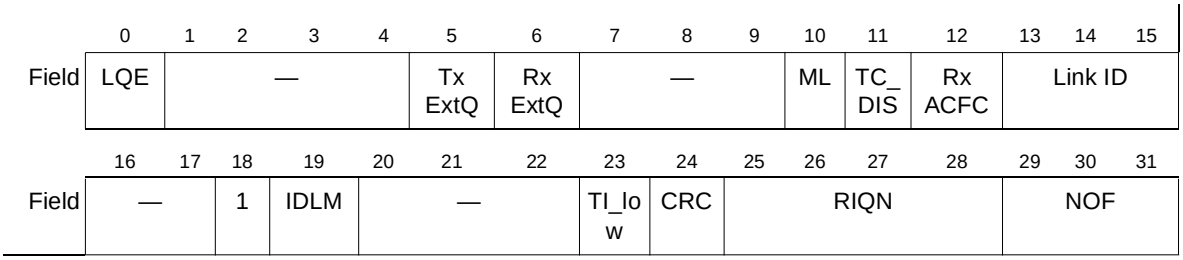

Figure 37-22. Link Mode Register (LMR)

LMR fields are described in Table 37-7

Table 37-7. LMR Field Descriptions

Bits	Name	Description
0	LQE	Link Queue empty bit. Initialized to 1. Valid only when there is one queue per Link in this bundle. 0 The Link queue is not Empty. Cleared by the core only after setting the [R] bit. 1 The Link queue is empty. Set by the RISC when there is not Valid buffer in the queue. **Note:** If the Link queue is a MUX queue, this bit will be handheld automatically by the RISC. The host shouldn't change this bit after initialization to 1. The MUX encapsulation process will clear this bit upon completion preparation of a super-frame.
1–4	—	Reserved.
5	TxExtQ	Transmit external link queues. 0 The Link queues are located in internal memory. 1 The Link queues are located in external memory.
6	RxExtQ	Receive external link queues. 0 The Link queues are located in internal memory. 1 The Link queues are located in external memory.
7-9	—	Reserved. Should be cleared.
10	ML	Tx MultiLink mode. It defines if there is a background process for fragments generation. 0 There is no ML/MC traffic generation e.g. there is no need for fragmentation process. Fragments will not be generated when this bit is cleared. 1 There is ML/MC traffic generation on the Tx ML bundle pointed by the LPT(BNDLPTR) parameter.
11	TC_DIS	Tx CRC disabled. 0 Transmit the CRC sequence after the last data byte. 1 Transmit the closing flag after the last data byte. This setting can be used for testing purposes to send an erroneous CRC after the data.
12	RxACFC	Receive ACFC (address and Control Field Compressed) mode. 0 ACFC disabled on receive side. 1 ACFC enabled on receive side.
13–15	LINK ID	Link ID. The host should assign each link with a serial number. This number will be used when a link is part of a bundle. **Important**: The number of links supported per bundle is limited to 8 or 16. When assigning a link ID to a link which is a part of a bundle the application should be aware that only the 3 or 4 least significant bits are taken for fragment lose detection as appears in Table 37-15. This implies having on each bundle up to 8 or 16 links with non overlap in the 3 or 4 lsb.

Table 37-7. LMR Field Descriptions (continued)

Bits	Name	Description
16–17	—	Reserved. Should be cleared.
18	1	Must be set.
19	IDLM	Idle Mode. 0 No idle patterns are sent between frames. 1 At least one idle pattern is sent between adjacent frames.
20–22	—	Reserved. Should be cleared
23	TI_low	Transmit Interrupt low event register. Use lower part of MCCE. 0- The interrupts associated with a Link events resides in queue #4 1- The interrupts associated with a Link events resides in queue #11 (0xB)
24	CRC	Selects type of CRC. 0 16 bit CCITT-CRC 1 32 bit CCITT-CRC
25–28	RIQN	Receiver interrupt queue number. Specifies the interrupt queue number. On the link level events are logged into the interrupt queues associated with the link. It is not related to the bundle. Numbering of the interrupt queues is described in Section 37.20.4, “MCC Event and Mask Registers” which is different than that of the legacy MCC. Since interrupt queues 4,5 and 11,12 are designated for transmitter usage, the interrupt queues that are available for the receiver are 0-3, 6-10 and 13: 0000 Rx Interrupt queue number 0 0001 Rx Interrupt queue number 1 0010 Rx Interrupt queue number 2 0011 Rx Interrupt queue number 3 0110 Rx Interrupt queue number 6 0111 Rx Interrupt queue number 7. 1000 Rx Interrupt queue number 8 1001 Rx Interrupt queue number 9. 1010 Rx Interrupt queue number 10 (0xA) 1101 Rx Interrupt queue number 13 (0xD)
29–31	NOF	Number of flags. NOF defines the minimum number of flags before frames 000 At least 1 flag 001 At least 2 flags ... 111 At least 8 flags.

37.11.3 Link Statistics Table

This table contains statistics information for the specific link in the multi link system.

Table 37-8. Link Statistics Table

Offset[1]	Name	Width	Description
0x00	Rx_FCSECNT	Word	FCS error counter. Initialized to 0.
0x04	Rx_MRUCNT	Word	Longer than MRU frame/fragment counter. Initialized to 0.
0x08	Rx_LQBSY_CNT	Word	Link Queue Busy counter: Discarded frames counter due to lack of empty BDs in the Host BD Ring. Initialized to 0.

Table 37-8. Link Statistics Table (continued)

Offset[1]	Name	Width	Description
0x0C	Rx_FRM_CNT	Word	PPP plain Frames counter. Initialized to 0.
0x10	Rx_FRG_CNT	Word	Multi Link Fragments counter. Initialized to 0.
0x14	Rx_BYTCNT	Word	Byte Count - counts the number of bytes received on link. Initialized to 0.
0x18	Tx_FRM_CNT	Word	Transmitter Frame counter. Initialized to 0. Counts the number of transmitted frames on this link.
0x1C	Tx_FRG_CNT	Word	Transmitter Fragment counter. Initialized to 0. Counts the number of transmitted fragments on this link.
0x20	Tx_Byte_CNT	Word	Transmitter bytes counter. Initialized to 0. Counts the number of transmitted valid frame/fragment bytes from this link.
0x24	Rx_AB_FCNT	Word	Counts the number of frames received with abort occurrence. Initialized to 0.
0x28	Rx_ILL_FCNT	Word	Counts the number of illegal frames. Illegal frame example include: short fragment with less than 13 bytes. Initialized to 0.
0x2C	Rx_IACCNT	Word	Invalid Address & Control character counter. Initialized to 0.

1 Offset from base address pointer

37.12 Bundle Parameter Table (BPT)

The Bundle Parameter Table contains bundle related parameters and a pointer to the Class Parameter Table. User should allocate 0x80 bytes for the BPT in case of ML MC mode of operation.

The first 28 bytes of the Bundle Parameter Table (up to offset 0x1C) is common to the bundle and to the links which are members of this bundle. This bytes should be initialized even when ML MC mode is not enabled, since they are used as extension to the LPT.

Table 37-9 describes the RX Bundle Descriptor fields.

Table 37-9. Bundle Parameter Table Fields

Offset	Name	Width	Description
0x00	Rx_LCP_QD_ptr	Word (Internal)	Pointer to the queue descriptor for the LCP packets for all the links in the bundle. This QD must reside in internal memory.
0x04	Rx_LCP_MRU	Hword	Maximum size of an LCP frame on a link. The buffers on an LCP QD should be of this size.
0x06	—	Hword	Reserved. Should be cleared.
0x08	TXFBPT_BASE	Word (Internal)	Points to the TX Free Buffer Pool Parameter Tables Base. Up to 4 different FBP can be supported for the transmitter, and the actual address of each table is calculated by: FBP parameter table = TXFBPT_BASE + TQD[Tx_FBP_Sel]. Each FBP management table occupies 16 bytes.
0x0C	BMR	word	Bundle Mode Register. See Section 37.12.1, “Bundle Mode Register (BMR).”

Table 37-9. Bundle Parameter Table Fields (continued)

Offset	Name	Width	Description
0x10	TxACC	Hword	Transmitter address and control characters. According to RFC1662 should be initialized to 0xFF03. Only 2 bytes length of Address and Control characters are supported.
0x12	De-Mux Default PID	Hword	User should initialize the De-Mux Default PID. This is the default PID for usage of the De-mux process when PFF=0 in a sub-frame header.
0x14	Tx MUX UDHBase	Word	MUX User Defined Header Base, resides in external memory. Address to the UDH is (UDH_Index*0x100+Bundle_UDH_Base). The Index parameter is taken from the Queue Mode field in the Queue Descriptor. See Figure 37-32.
0x18	Rx_FBPT_BASE	Word (Internal)	Points to the Rx Free Buffer Pool Parameter Table Base. This is the FBP which is used for ML/MC traffic. Should be 0x10 bytes aligned. Each FBP management table occupies 16 bytes. Buffer's size allocated should be big enough to accommodate the maximum size specified in LPT[MRU].
0x1C	CPT_BASE	Word (Internal)	Class Parameter Table Base. Pointer to the first Class Parameter Table of this bundle. Points to the base address of Class 0 Parameter Table. Should be 128 bytes aligned. When WFQ mode is used to select class, the CPT should be located consequently, each one occupies 0x80 bytes.
0x20	Rx_CLS Lookup Table PTR	Word (Internal)	Pointer to a table that indicates which classes are available in this bundle. Since only 8 classes are supported, in case of 4 bits class number, this table also converts the 4 bits class to 3 bits class. This is a 4 entries table in case of 2 bits of class and this is a 16 entries table in case of 4 bits of class. Each entry in both cases is a single byte. see Section 37.12.2, "Class Lookup Table."
0x24	Tx_CWFQ_ptr	Word (Internal)	Transmit class weighted fair queue pointer. This entry points to the Class Weighted Fair queue structure, and should be 32 bytes aligned. In case there is a single class in this bundle this parameter should be initialized to 0. In this case the class is located in **CPT_BASE** parameter. Also the CMR[CLSID] of the class must be equal to zero.
0x28	—	Hword	Reserved. Should be cleared.
0x2A	—	Byte	Reserved. Should be cleared.
0x2B	Tx_FD_Size	Byte	Fragment Descriptor Size. Initialized to the power of two of the fragment descriptor size (for example if initialized to 7 then the actual size is 128). This size is determined by number of optional BD's in one fragment. The formula of calculating fragment descriptor size as a function of maximum number of BD's is as follows: Fragment_Size = (Max No. BD's * 16) + 16. Note: the maximum value of this parameter is 0x0B.
0x2C	No_Links	Byte	Number of links. User initialized to the number of links, which are part of the bundle.
0x2D	—	Byte	Reserved. Should be cleared.
0x2E–0x4F	—	34 bytes	Reserved. Should be cleared.

Table 37-9. Bundle Parameter Table Fields (continued)

Offset	Name	Width	Description
0x50	Tx_FDB	Word	User initialized to Fragment Descriptor Base. Pointer to the first Fragment Descriptor, which is located in the external memory. The Maximum number of the Fragment Descriptors is the number of links belonging to this bundle multiplied by 2. Should be 8 bytes aligned.
0x54	—	Word	Reserved. Should be cleared.
0x58	Tx_ShB_mngt_tbl_Base	Word (Internal)	Shared Buffer management Table Pointer. Pointer to an array of 32 Counters, each of a single byte. This is for the internal usage of the RISC and controls the shared Buffer mechanism of returning the buffer pointer back to the Free Buffer Pool. Should be 32 byte aligned.
0x5C	—	Hword	Reserved. Should be cleared.
0x5E	MFS	Hword	Max fragment size that is transmitted over the link. This includes the information field and any padding; but not the protocol (ML PID), address, control or FCS fields.
0x60	MRRU	Hword	Maximum Reconstructed received frame.
0x62–0x6F	—	14 bytes	Reserved. Should be cleared.
0x70–0x7F	Fragment Pool Table	16 bytes	Fragment Pool Table. Allocate 2*number of Links bytes (for a maximum of 8 links in a bundle, we get 16 bytes). Contains information for managing the order of preparing and transmitting the fragments. The Fragment Pool Table should be initialized with sequential index numbering of the Fragments. see description in Section 37.12.3, “Fragment Pool Table.”

37.12.1 Bundle Mode Register (BMR)

The Bundle Mode Register (BMR) is a user-initialized register, shown in Figure 37-23.

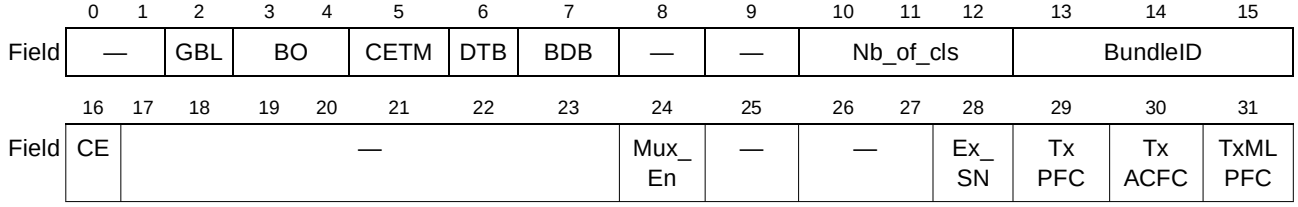

Figure 37-23. Bundle Mode Register (BMR)

BMR fields are described in Table 37-10.

Table 37-10. BMR Field Descriptions

Bits	Name	Description
0–1	—	Reserved
2	GBL	Global. Setting GBL enables snooping of data buffers, BD’s, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”

Table 37-10. BMR Field Descriptions (continued)

Bits	Name	Description
3-4	BO	Byte ordering. Set BO to select the required byte ordering for the buffer. If BO is changed on-the-fly, it takes effect at the beginning of the next frame or at the beginning of the next BD. 00, 01, 11 Reserved 10 Big-endian
5	CETM	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1 and Section 5.4.3.7, “Debug Configuration.”
6	DTB	Data buffers bus Selection 0 Resides on the coherent system bus. 1 Resides on the secondary bus.
7	BDB	WBD, Interrupt, Queue Descriptor, Free Buffer Pool bus Selection 0 Resides on the coherent system bus. 1 Resides on the secondary bus.
8	—	Reserved. Should be cleared.
9	—	Reserved. Should be cleared.
10–12	Nb_of_cls	Number of Classes associated to this bundle.
13–15	BundleID	Bundle ID. Distinguishes between several bundles. It is applicable for interrupt information, and for the management of the TxBundleIDTable (see Table 37-5).
16	CE	Class empty bit. Initialized to 1. Valid only when there is a single Class under the Bundle. 0 - The Class is not Empty. Cleared by the core only after setting the BD[R] bit within a queue under this class. 1 - The Class is empty. Set by the RISC when there is no data ready in the queue under the class. **Note:** If the class queue is a MUX queue, this bit will be handheld automatically by the RISC. The host shouldn’t change this bit after initialization to 1. The MUX encapsulation process will clear this bit upon completion preparation of a super-frame.
17–23	—	Reserved. Should be cleared.
24	MUX_En	Defines if there is a Tx PPP MUX queue operation. 0 No Tx PPP MUX process needed. 1 Tx PPP MUX process is needed and should called by the Link front-end process.
25	—	Reserved. Should be cleared.
26–27	—	Reserved. Should be cleared. Used by the RISC
28	Ex_SN	Extended Sequence Number Mode 0 12 bits sequence number and 2 bits for CLS id 1 24 bits sequence number and 4 bits for CLS id
29	TxPFC	Transmit PID Compressed for the Original PPP packet. (inner PID of the fragment) 0 PID transmitted is 2 bytes length. 1 PID transmitted is 1 byte length (only if MSB byte of the PID is 0).

Table 37-10. BMR Field Descriptions (continued)

Bits	Name	Description
30	TxACFC	Transmit ACFC (address and Control Field Compressed) mode. 0 ACFC disabled on transmit side. 1 ACFC enabled on transmit side.
31	TxMLPFC	Transmit ML header PID Compressed. 0 PID is 0x003d. 1 PID is 0x3d.

37.12.2 Class Lookup Table

The Class Lookup Table, shown in Figure 37-24, indicates which classes are available in this bundle in order to filter an unwanted incoming traffic. Fragments with a non-valid class number will be discarded. Also this table maps the class number in ML/MC-PPP header to the actual class number that is implemented. This mapping is required since 4 CLS bits allow 16 classes but the receiver supports only up to 8 classes. The table is 4 bytes long - single byte per entry in case of 2 bits of CLS in ML/MC PPP header or it is 16 bytes long - single byte per entry in case of 4 bits of CLS in ML/MC PPP header. The access to the table is according to the CLS of the ML/MC PPP header.

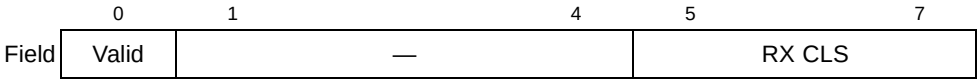

Figure 37-24. Class Lookup Table Entry

Table 37-11. Class Lookup Table Entry Fields

Bits	Name	Description
0	Valid	0 - This class is not valid in this bundle. 1 - This class is valid in this bundle.
1–4	—	Reserved. Should be cleared.
5–7	Rx CLS	The class number which is used by Rx.

37.12.3 Fragment Pool Table

This table is used by the transmitter front-end and back-end processes. The size of this data structure in bytes is twice the number of links in the bundle. Each entry contains an index to the fragment descriptor currently being used by each of the processes. An example is described Figure 37-14.

The user should allocate enough entries to accommodate the maximum number of links in the bundle. The table should be initialized in a sequential order. Last entry should be marked with a Wrap bit. See Table 37-12 for a 2-link bundle. In cases where the user would like to dynamically add links to a bundle, allocate and initialize a table which fits the maximum links possible in this bundle.

Table 37-12. Fragment Pool Table

0x00
0x01
0x02
0x83

NOTE

Since each entry is associated with a fragment descriptor which reside in external memory, the higher the number of entries (above the minimum required= 2* number of links) in the table the bigger is the memory allocated externally for the fragment descriptors.

37.13 Class Parameter Table (CPT)

All class-related parameters are stored in the Class Parameter Table. The Class Parameter Table contains the pointer to the Class Queue Descriptor and to the Mux Queue Descriptor.

Table 37-13. Class Parameter Table

Offset	Name	Width	Description
0x00	CMR	word	Class Mode register.See Table 37-14.
0x04	—	Word	Reserved. Should be cleared
0x08	Tx_QD_ptr	Word (Internal)	Transmit MLMC Queue Descriptor Pointer. Points to the Queue Descriptor of the class, which is located in internal RAM and occupies 16 bytes. Should be 16 bytes aligned.
0x0C	—	Word	Reserved. Should be cleared.
0x10	Tx_FSBD_offset	Byte	Fragment Shared Buffer offset. Initialized to 0xff. For RISC use only.
0x11	—	Byte	Reserved. Should be cleared.
0x12	—	Hword	Reserved. Should be cleared.
0x14	Cls_Ext_PTR	Word (internal)	Class Extension pointer. Allocate 32 bytes. Points to a data structure which is an extension to the CPT table. See Table 37-15.
0x18–0x2D	—	22 Bytes	Reserved. Should be cleared.
0x28	—	Word	Reserved. Should be cleared.
0x2E	WBD Size	Hword	Number of entries in the Window BD/Status Ring. The size indicates the number of fragments stored in the WBD/Status ring. This entry must be initialized with a number which is a power of 2 and the value that is written in this entry is 2^n -1. For example: for 128 entries it should be initialized to: 0x7F. See 37.16.1 for details.
0x30	WBD Base	Word	Window BD base pointer. Pointer to external memory.

Table 37-13. Class Parameter Table (continued)

Offset	Name	Width	Description
0x34	Status ring Base	Word (Internal)	Pointer to the Status Ring Table described in 37.6.5.1.2. The table should be aligned to it's size in bytes.
0x38–0x3D	—	6 Bytes	Reserved. Should be cleared
0x3E	Rx_Updating_M_Link	Byte	RISC internal use. Initialize to one of the links ID which are part of the bundle for this class.
0x3F	—	Byte	Reserved. Should be cleared
0x40	Rx LSQN	Word	Should be initialized to 0x01. Internal use. Sequence number of the fragment represented by EF_index.
0x44	Rx Max	Word	Internal use. Initialize to 0x0. The current maximum of the most recently received sequence number over all member links in bundle. This entry is copied by the host when adding a link dynamically. see Section 37.22.2.2, "Addition of Link."
0x48	—	Word	Reserved. Should be cleared.
0x4C	Rx_Queue Descriptor pointer	Word (external or internal)	Points to the Queue descriptor associated to this Class. This queue is for non Mux traffic. Can reside in external or internal memory.
0x50	Rx_Mux Queue Descriptor pointer	Word (external or internal)	Points to the Queue Descriptor used by the De-Mux processing for enqueuing PPP Mux sub-frames. Can reside in external or internal memory.
0x54	RXFRM_CNT	Word	Received frames counter. Initialize to 0.
0x58	Rx FRLCNT	Word	Fragment Loss counter- Counts the number of times window moved due to fragment lost. Initialize to 0.
0x5C	Rx WFCNT	Word	Window Full counter- Counts the number of fragments that were discarded due to lack of space in WBD. Initialize to 0.
0x60	Rx CQBSY_CNT	Word	Class Queue Busy counter: discarded frames counter due to lack of empty BD's in the Core BD Ring. Initialize to 0.
0x64	Rx MRRU_CNT	Word	Longer than MRRU frame counter. Initialize to 0.
0x68	—	Word	Reserved. Should be cleared.
0x6C	DMXBSY_CNT	Word	Demux Busy counter: discarded frames counter due to Busy occurrence in the Demultiplexer Table. Initialize to 0.
0x70	—	Word	Reserved. Should be cleared.
0x74	Rx SQN_TH	Word	Sequence number threshold. Whenever MX exceeds LSQN by more than a threshold value, a fragment loss is detected. See description of threshold register in Section 37.13.1, "Threshold register." See explanation at Section 37.6.5.3, "Fragment Loss Process."
0x78	—	8 Bytes	Reserved. Should be cleared.

37.13.1 Threshold register

This value represents the threshold that will trigger a fragment lose indication due to a big differences between links. It has a different format when working in 12 bit sequence number in the ML PPP or 24 bits for the sequence number.

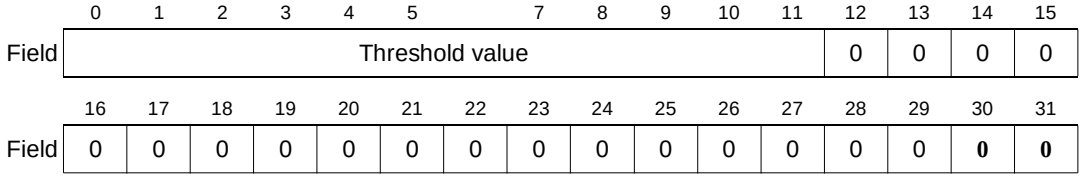

Figure 37-25. Rx Threshold register for 12 bit SN (RX SQN_TH)

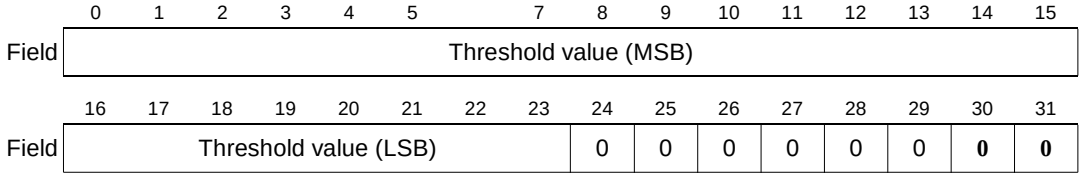

Figure 37-26. Rx Threshold register for 24 bit SN (RX SQN_TH)

37.13.2 Class Mode Register (CMR)

The class mode register (CMR) is a user-initialized register, shown in Figure 37-27.

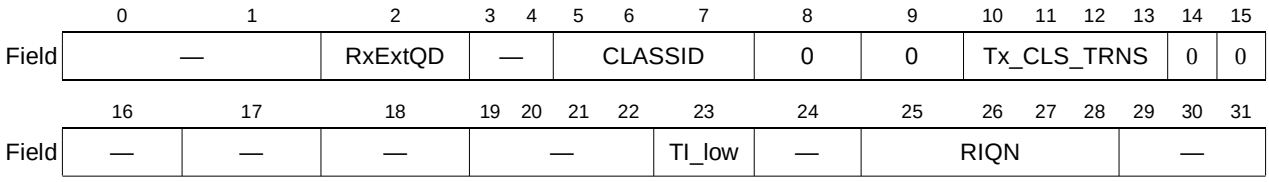

Figure 37-27. Class Mode Register (CMR)

CMR fields are described in Table 37-14.

Table 37-14. CMR Field Descriptions

Bits	Name	Description
0-1	—	Reserved. Should be cleared.
2	RxExtQD	Receiver Queue Descriptors location.(Mux and non Mux) 0 The Queue descriptor is located in the Multi-user RAM 1 The Queue descriptor is located in the external memory
3–4	—	Reserved. Should be cleared.
5–7	CLASSID	Class ID. Assign an ID number for this class, according to the location of the class. Used by the RISC for interrupt information.
8–9	0	Should be cleared.

Table 37-14. CMR Field Descriptions (continued)

Bits	Name	Description
10–13	Tx_CLS_TRNS	Transmit Class Translation. The user should program the CLS bits that will be actually transmitted in the MLMC header. For Short sequence mode: bits 12-13 have to be cleared and bits 10-11 represent the 2 class bits that will be transmitted. For Long sequence mode: bits 10-13 represent the 4 class bits that will be transmitted. Note that there is no obligation that the Tx_CLS_TRNS will match the CPT[ClassID]; for example, the user can assign the CLS=12 (for Long sequence mode) for the class no. 1 (CLASSID=1).
13–15	0	Should be cleared.
16–22	—	Reserved. Should be cleared.
23	TI_low	Transmit Interrupt low event register. Use lower part of MCCE. 0- The interrupts associated with a Multi-Link/Class events resides in queue #5 1- The interrupts associated with a Multi-Link/Class events resides in queue #12 (0xC)
24	—	Reserved. Should be cleared.
25–28	RIQN	Receiver interrupt queue number. Specifies the interrupt queue number on a class level event.- Numbering of the interrupt queues is described in Section 37.20.4, “MCC Event and Mask Registers” which is different then the one of the legacy MCC. Since interrupt queues 4,5 and 11,12 are designated for transmitter usage, the interrupt queues that are available for the receiver are as follows: 0000 Rx Interrupt queue number 0 0001 Rx Interrupt queue number 1 0010 Rx Interrupt queue number 2 0011 Rx Interrupt queue number 3 0110 Rx Interrupt queue number 6 0111 Rx Interrupt queue number 7. 1000 Rx Interrupt queue number 8 1001 Rx Interrupt queue number 9. 1010 Rx Interrupt queue number 10 (0xA) 1101 Rx Interrupt queue number 13 (0xD)
29–31	—	Reserved. Should be cleared.

37.13.3 Class Extension Table

This table is an extension to each CPT table so that each CPT consumes only (0x80) 128 bytes. The size of the extension table is (0x20) 32 bytes

Table 37-15. Class Extension Table

Offset	Name	Width	Description
0x00	Rx_CL0_SQ	Word	Receiver Class Link x Sequence Number: most recently received sequence number over link x of the bundle.See Table 37-16.. This is for the RISC internal use. The Host should initialize these entries with 0.
0x04	Rx_CL1_SQ	Word	
0x08	Rx_CL2_SQ	Word	
0x0C	Rx_CL3_SQ	Word	
0x10	Rx_CL4_SQ	Word	
0x14	Rx_CL5_SQ	Word	
0x18	Rx_CL6_SQ	Word	
0x1C	Rx_CL7_SQ	Word	

37.13.4 Class Link Sequence Number (CLx_SQ)

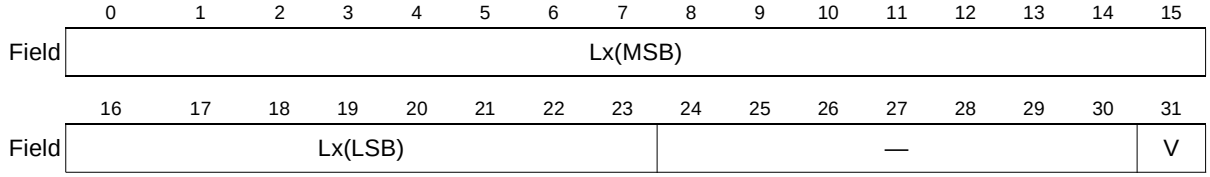

Figure 37-28. Class Link Sequence Number (CLx_SQ)

Table 37-16. CL x_SQ Field Descriptions

Bits	Name	Description
0–23	Lx	Most recently received sequence number over link x of the bundle. Initialize to 0.
24–30	—	Reserved. Should be cleared.
31	V	Valid bit. 0 Link x is not a part of the bundle associated to this class 1 Link x is a part of the bundle associated to this class

37.14 WFQ Table

There are two locations where WFQ tables are used: On the Link level for selection of queue on the link and in the bundle level for class selection. The pointers to the WFQ table are located in LPT(Tx_LWFQ_ptr) and BPT(Tx_CWFQ_ptr).

Table 37-17 describes the WFQ table fields for Link WFQ (LWFQ) or Class WFQ (CWFQ).

Table 37-17. WFQ Table

Offset	Name	Width	Description
0x00	WFT0	Hword	WFTx- Weighted Finish Time. Eight 16 bit FTMs, one for each Queue. The FTM is used to determine the finish time of the next Frame being transmitted from the queue. FTM at offset zero corresponds to Queue0, FTM at offset 0x0E corresponds to Queue7.
0x02	WFT1		
0x04	WFT2		
0x06	WFT3		
0x08	WFT4		
0x0a	WFT5		
0x0c	WFT6		
0x0e	WFT7		
0x10	WINC0	Hword	WINCx- Weighted Increment. Eight 16 bit increments, one for each Queue. INC at offset 0x10 corresponds to Queue0, INC at offset 0x1E corresponds to Queue7.
0x12	WINC1		
0x14	WINC2		
0x16	WINC3		
0x18	WINC4		
0x1a	WINC5		
0x1c	WINC6		
0x1e	WINC7		

37.14.1 WFQ Finish Time Entry (WFT)

Figure 37-29 shows the format of the Weighted Fair Queueing (WFQ) Finish Time entry in the WFQ Table. There are 8 such entries in the table, one for each queue. These entries are initialized by the CPU.

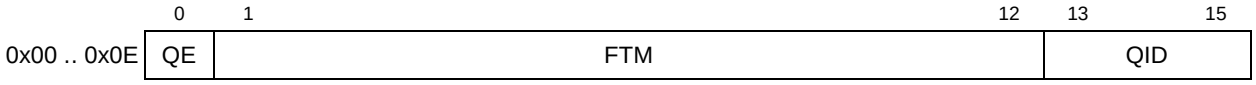

Figure 37-29. WFT Entry

Table 37-18 describes the WFT entry fields.

Table 37-18. WFT Entry Field Descriptions

Bits	Name	Description
0	QE	Queue Empty. Initialized to 1. The CPU clears this bit ONLY if this bit is already set, and after it set the related BD[R] bits of this queue. This bit is set automatically by the RISC if the corresponding Queue has no BD[R] set for this queue. **Note:** If the queue is a MUX queue, this bit will be handheld automatically by the RISC. The host shouldn't change this bit after initialization to 1. The MUX encapsulation process will clear this bit upon completion preparation of a super-frame.
1–12	FTM	Finish time. This bit is automatically updated by the RISC. Initialize with WINC[INC] value.
13–15	QID	Queue ID. The CPU initializes the number of the Queue in these bits. Offset values are as follows: 0000 - 000 0010 - 001 0100 - 010 0110 - 011 1000 - 100 1010 - 101 1100 - 110 1110 - 111

37.14.2 WFQ Increment Entry (WINC)

Figure 37-30 shows the format of the Weighted Fair Queueing (WFQ) Increment entry in the WFQ Table. There are 8 such entries in the table, one for each queue. These entries are initialized by the CPU.

Figure 37-30. WINC Entry

Table 37-19 describes the WINC fields.

Table 37-19. WINC Field Descriptions

Bits	Name	Description
0	—	Reserved. Should be cleared.
1–12	INC	Weighted Increment value. This value determines the Priority for the queues. If all queues are backlogged the Priority of each queue is 1/INC. If some of the queues do not have something to transmit, the total Priority of the port is divided among the backlogged queues according to their relative INC values. INC=0 for all 8 queues - Queue 0 has the highest priority (Fixed Priority). See Example 37.7.3.4.
13–15	—	Reserved. Should be cleared.

37.15 Queue Descriptors (QD)

37.15.1 RX Queue Descriptor

The RX Queue Descriptor is a table which describes the BD Ring associated to a Class or to a Link.

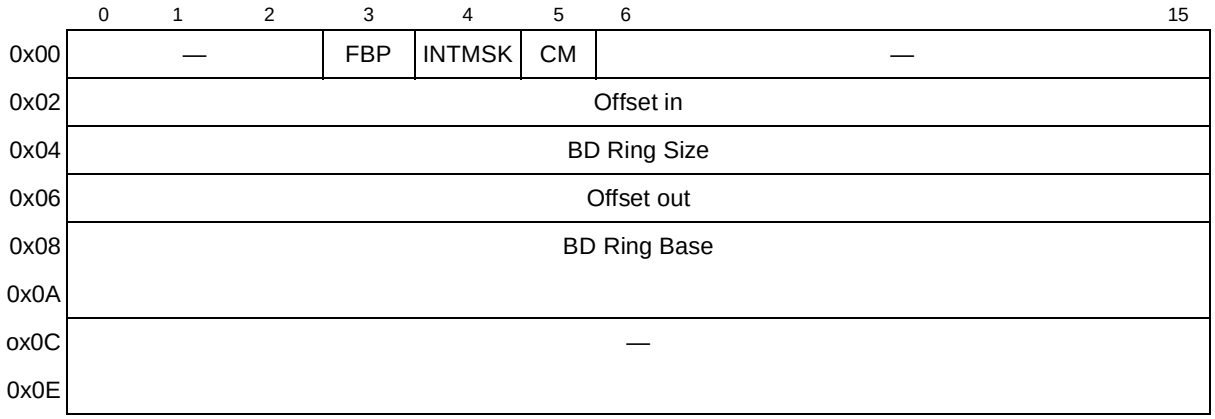

Figure 37-31. RX Queue Descriptor

Table 37-20. RX Queue Descriptor Fields

Offset	Bit	Name	Description
0x00	0–2	—	Reserved. Should be cleared.
	3	FBP	Free Buffer Pool Queue. 0 The BD's of this queue contain Data pointers which are swapped upon reception with the new data pointers. 1 The BD's of this queue do not contain any Data pointer. The Data pointers are located in the Free buffer pool associated to this RQD. For PPP Mux queues and LCP this bit is not valid. **Note:** Mux operation always requires FBP and LCP frames are always using swap operation.
	4	INTMSK	Receive frame mask. 0 Disable interrupt related to this queue (RXF for non Mux, LE and FRG for muxed queue). 1 Enable interrupt related to this queue (RXF for Non Mux, LE and FRG for muxed queue).
	5	CM	Continuous mode 0 Normal operation. 1 The RISC does not clear the ready bit after this BD is closed.
	6–15	—	Reserved. Should be cleared.
0x02	0–15	offset IN	Points to the next BD in the BD ring. Initialize to 0
0x04	0–15	BD Ring Size	Number of BD's in the Ring.
0x06	0–15	Offset out	Pointer to the next BD to be fetched by the Host. Updated by the host. Initialize to zero.

Table 37-20. RX Queue Descriptor Fields (continued)

Offset	Bit	Name	Description
0x08	0–31	BD Ring Base	BD Base Address. Address of first BD in the queue.
0x0C	0–31	—	Reserved. Should be cleared

37.15.2 TX Queue Descriptor

As shown in Figure 37-3, there are up to 8 Link queues under each link. Also there are optionally up to eight ML queues, one for each class. Each queue has its priority level, which is described in the WFQ section.

The TX Queue Descriptor (TQD) length is 16 bytes. For the Link queues, it could reside in internal or external memory. For the ML queues, it is located in the internal memory. The QD contains the information about the current BD handled. The BD base address and BD currently being transmitted. It also contains mode bits for selecting the mode of operation.

For Muxed TQD the RISC needs additional parameters for proper operation. This information, such as User Defined Header (UDH), resides in the PPP Mux Parameter Table.

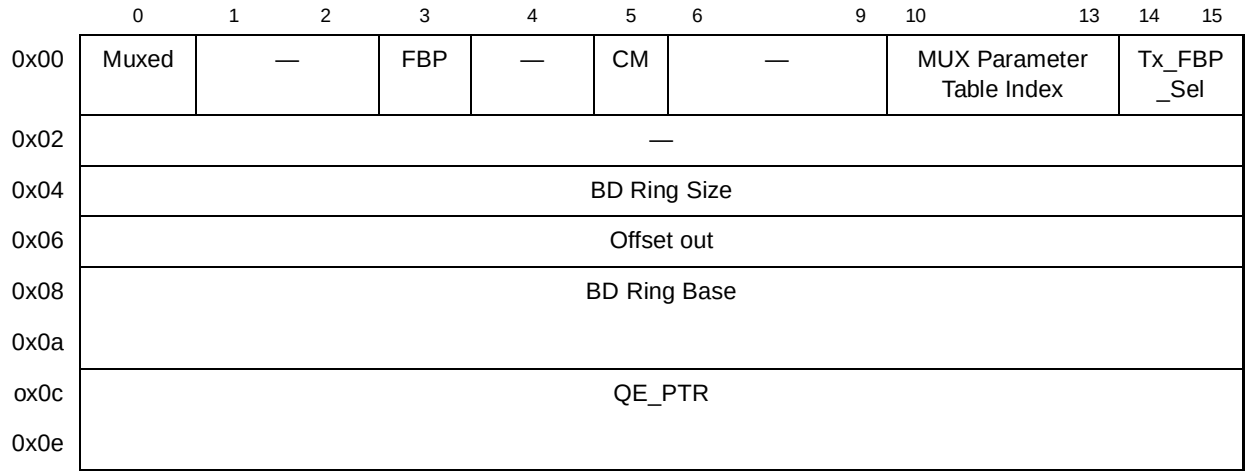

Figure 37-32. TX Queue Descriptor

Table 37-21 describes the TQD fields.

Table 37-21. TX Queue Descriptor Fields

Offset	Bit	Name	Description
0x00	0	Muxed	PPP Multiplex Mode. 0 - PPP Multiplexing is disabled for this QD. 1 - PPP Multiplexing is enabled for this QD.
	1–2	—	Reserved. Should be cleared.
	3	FBP	Free Buffer Pool Mode enabled. Important: This mode is valid for link queues only. When the queue is a ML/MC queue FBP operation is always needed regardless of the setting of this bit. 0 Data pointers in the BDs are not returned to the FBP after transmission 1 Data pointers are returned to the FBP after transmission.
	4	—	Reserved. Should be cleared.
	5	CM	Continuous mode 0 Normal operation. 1 The RISC does not clear the ready bit after this BD is closed.
	6–9	—	Reserved. Should be cleared.
	10–13	MUX Parameter Table Index	Index of the Mux encapsulation parameter table which is associated with this queue. see 37.19.6
	14–15	Tx_FBP_Sel	Selects one of 4 available Free Buffer Pools. The actual address to the FBP table is BPT(FBPT_BASE)+BPOOL*16. See Section 37.17.2, “TX Free Buffer Pool.”
0x02	0–15	—	Reserved. Should be cleared
0x04	0–15	BD Ring Size	Number of BD’s in the Ring.
0x06	0–15	Offset out	Pointer to the next BD to be fetched by the RISC. Updated by the RISC. Initialize to zero.
0x08	0–31	BD Ring Base	BD Base Address. Address of first BD in the queue.
0x0C	0–31	QE_PTR	This is a pointer to the queue Empty /Class Empty bit depending on the setup. The address of this bit is specified in 0xQueue Empty Bit Management

37.16 Receive Window BD (WBD) Ring and Status Ring

In the process of receiving ML/MC traffic each class has a Status ring and a WBD ring associated with it. This status ring is located in internal memory and each entry of it represents a WBD entry from the ring which resides in external memory. All these structures are for RISC internal use and the application should allocate the memory required for each data structure. Each status ring entry is 4 bits width (A nibble) and the WBD entry is 16 bytes long.

NOTE

When working in the free buffer pool mode (QD[FBP]=1), the status ring table has to be initialized to ALL zeros at the beginning of ML/MC operation. If QD[FBP]=0, each entry in the status ring table has to be initialized to 0x4 (this bit indicates full buffer). By doing so the RISC swaps the data pointers from the WBD to the BD ring and vice versa. In this case, all the WBD should naturally be initialized with valid data pointers.

The WBD ring described below is for information only and the application does not have to initialize or handle any of it.

Figure 37-33 shows an entry of the WBD ring.

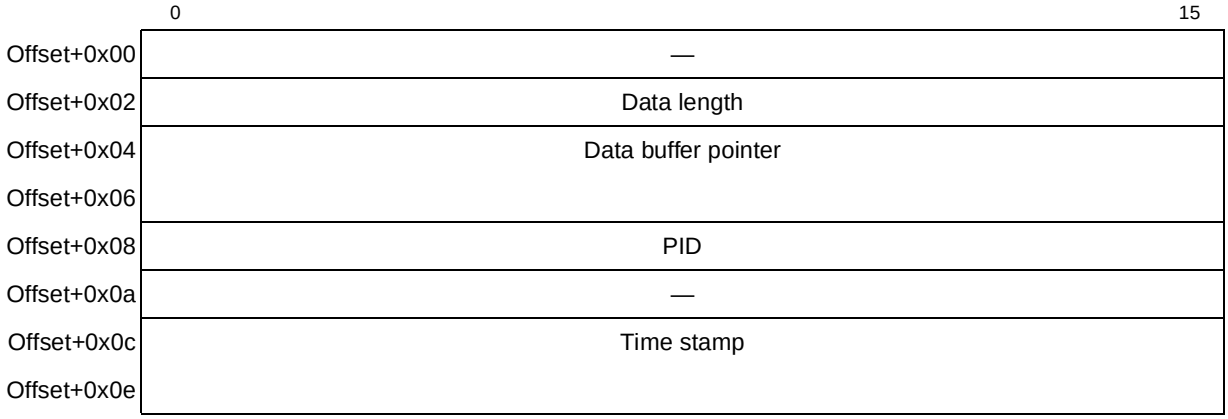

Figure 37-33. WBD Entry

Table 37-22 describes the WBD entry fields.

Table 37-22. WBD Entry Fields

Offset	Bit	Name	Description
0x00	0–15	—	Reserved
0x02	0–15	Data length	Length of the Data received in this fragment Data buffer.
0x04 0x06	0–15	Data buffer pointer	Need to be initialized only if RxQD[FBP] is cleared. Points to the data buffer associated with this WBD entry. In this case each entry in the StatusRing table has to be initialized with 0x4.
0x08	0–15	PID	Protocol ID associated with this WBD entry. Valid only for an entry marked B in the Status Ring.
0x0A	0–15	—	Reserved
0x0C 0x0E	0–15	Time stamp	Time Stamp copied from the QUICC Engine Time-Stamp Register (CETSR) after receiving the complete fragment, see Section 20.3.10, “QUICC Engine Time-Stamp Registers (CETSRn).”

37.16.1 WBD Ring and Status Ring Size

The user must allocate a sufficient place for the WBD ring according to the requirements of the system. The minimum size of the WBD ring has to contain at least a whole packet. In addition, the differential delay between 2 links in a same bundle has to be taken into consideration. This size should be allocated per class on the ML/MC system. Also, the size of the WBD should have enough entries to contain at least one complete PPP packet with the size of MRRU. This defines a minimum size for Window BD. Table 37-23 defines the variables needed to calculate ring size.

Table 37-23. WBD Ring Size Equation Variables

Variable	Definition
Dt	Differential delay between links [seconds]
N	Number of links in the bundle
Ri	Rate of link i [bps]
MRU	Fragment size [bytes]

Thus, the number of entries in the WBD Ring is calculated as follows:

$$\mathrm{Max}\left(\frac{MRRU}{MRU}, \sum_{i}^{N-1} \frac{R_i}{MRU \times 8} \times Dt\right) \times 16$$

This result should be rounded up to the next 2^N value.

Size of WBD in bytes is 2^N*16 [bytes].

Size of Status Ring = (2^N/2) [bytes].

37.16.2 Rx Packets Reconstruction Management

The Packets Reconstruction Management is placed in the MURAM. Table 37-24 describes the Packets Reconstruction Management. This structure size is 64 bytes and it should be 64 bytes aligned.

Table 37-24. Packets Reconstruction Management

Offset	Name	Width	Description
0x00	—	24 Bytes	Reserved, should be cleared.
0x18	Packet Reconstruction Table Base	Word (internal)	Base of the Packet Reconstruction Table (PRT). The size of this table is determined by the application. Should be word aligned. **Note:** When ML MC process is not needed on the receive side, but PPP Mux frames are received on the link, the user still needs to define this base, but only one Rx packet reconstructing entry is needed in this case (this entry in the table should be initialized to 0xc000).
0x1C	—	36 Bytes	Reserved, should be cleared.

37.16.2.1 Rx Packets Reconstruction Entry

The size of the table is determined by the application and last entry is marked with a Wrap indication. Every entry represents a frame. An entry is described in Figure 37-34.

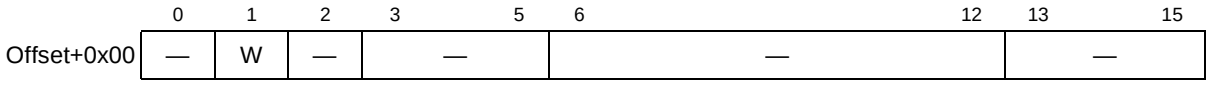

Figure 37-34. Packets Reconstruction Table Entry

Table 37-25. Packets Reconstruction Table Entry Fields

Offset	Bit	Name	Description
0x00	0	—	Must be initialized to 1.
	1	W	Wrap bit. During initialization, the host must set the W bit only for the last entry in the circular table. All other entries should have this bit cleared.
	2–15	—	Reserved, should be cleared.

37.17 Free Buffer Pools (FBP)

37.17.1 Rx Free Buffer Pool

Free buffer Pool structure is located in external memory. It is an array of data pointers as described in Figure 37-35 The buffer Pool has a management table associated with it.

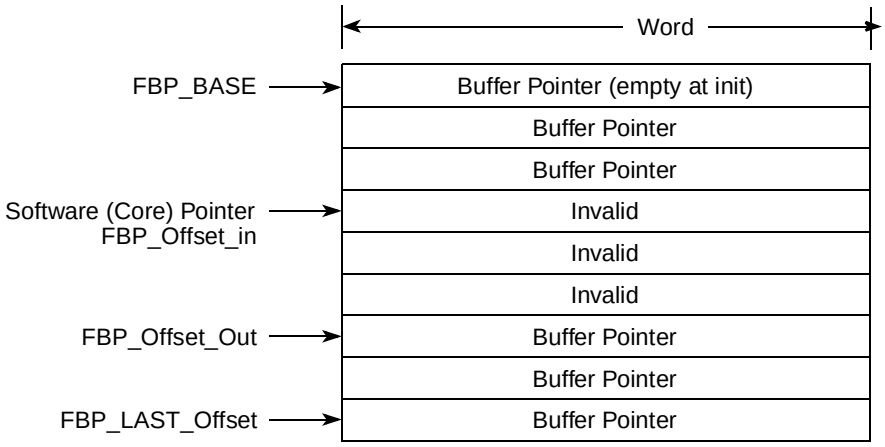

Figure 37-35. Rx Free Buffer Pool per Bundle.

Figure 37-36 describes the Free Buffer Pool Parameter Table. The host should maintain the Offset_In parameter in this table so that the RISC can calculate availability of buffers in the pool.

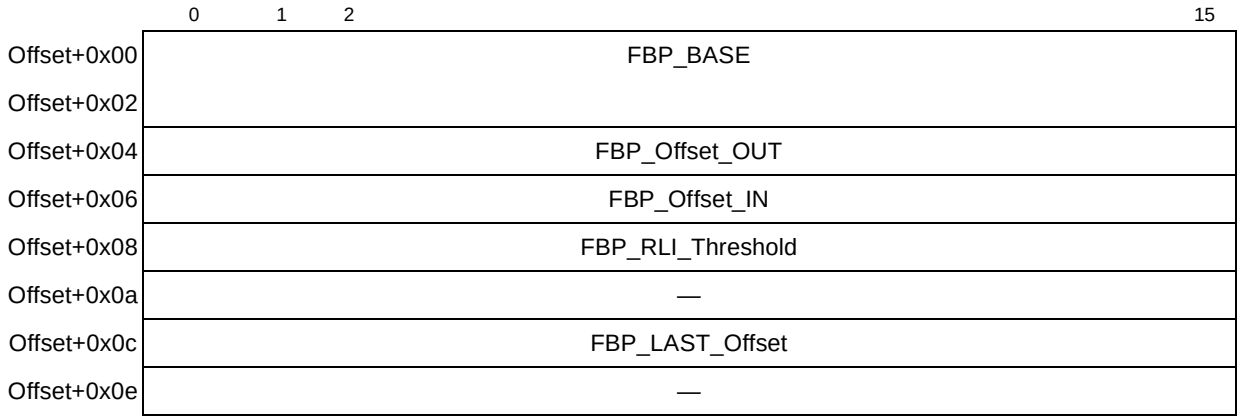

Figure 37-36. RX Free Buffer Pool Parameter Table

The user prepares a BD ring without assigning buffers to them (no Data buffer pointer). The user also prepares a set of free buffers (of size: max LPT[MRU]) in a free buffer pool.

Table 37-26 describes the RX Free Buffer Pool Parameter Table fields.

Table 37-26. RX Free Buffer Pool Parameter Table Fields

Offset	Bit	Name	Description
0x00 - 0x02	0–31	FBP_BASE	Free buffer pool base. Holds the pointer to the first entry in the free buffer pool. FBP_BASE should be word aligned. User-defined.
0x04	0–15	FBP_Offset_OUT	Free buffer pool Receiver pointer. Offset from the FBP_BASE to the current entry used by the receiver. The actual address of the current received FBP entry = FBP_BASE + FBP_Offset_OUT. For termination mode **Initialize to 0x04.** When the Init command is issued the RISC will take the buffer pointer pointed by this entry and will advance the offset to the next entry.
0x06	0–15	FBP_Offset_IN	Free buffer pool host pointer. Offset from the FBP_BASE to the current entry which is being returned to the free buffer pool. **Initialize to 0x0.** This implies this entry is empty and available for a returned pointer. In termination mode The host should maintain this offset **AFTER** each buffer pointer is returned to the pool. **IMPORTANT**: For proper synchronization between the receiver and the host, the host should not advance this entry so it would match the offset out value. (The RISC will advance it's offset_out value to match offset in and in this case the FBP is fully exhausted a BP_BSY interrupt is issued by the RISC)
0x08	0–15	FBP_RLI_Threshold	When the difference between the Offset_In and Offset_Out has reached this value an interrupt is generated. It indicates that the amount of buffers left in the system has reached the low watermark. If the values programmed in this field is 0x0 no interrupt is issued.
0x0A	0–15	—	Reserved. Should be cleared.
0x0C	0–15	FBP_LAST_Offset	Free buffer pool last pointer. User initialized to the offset of the last entry in the FBP. The actual address of the last FBP entry = FBP_BASE + FBP_LAST_Offset.
0x0E	0–15	—	Reserved. Should be cleared.

Each entry of the Free Buffer Pool is located in the external memory.

37.17.2 TX Free Buffer Pool

Four pools are available for the transmitter. The structure for free buffer pools is located in external memory, and is identical to this of the receiver As described in Figure 37-37. The purpose for this is to enable better memory utilization so different queues could use different sizes of buffers.

Important: When working in ML/MC queues, Free Buffer Pool operation is mandatory and the user should initialize the parameters and data structures for this mode.

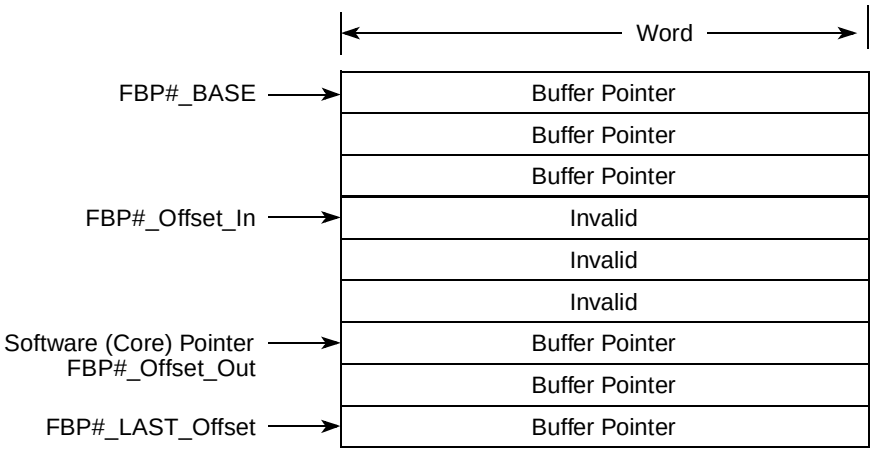

Figure 37-37. Free Buffer Pool Structure

37.17.3 Tx Free Buffer Pool Parameter Tables

The free buffer pool parameters are held in parameter tables in the multi-user RAM; FBPT_BASE in the BPT points to the base address of these tables. Each of the four free buffer pools has its own parameter table with a starting address given by FBPT_BASE+ QD[BPOOL] * 16.

NOTE

FBP is empty at initialization and is being filled by the QE upon completion transmitting of each buffer. Figure 37-38 describes the Free Buffer Pool Parameter Table.

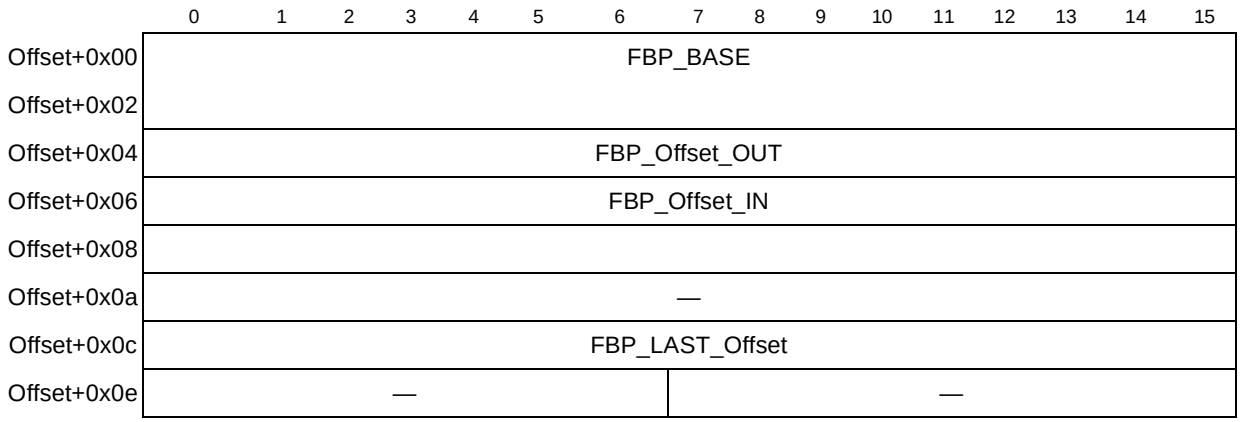

Figure 37-38. TX Free Buffer Pool Parameter Table

Table 37-27. Tx Free Buffer Pool Parameter Table

Offset [1]	Bits	Name	Description
0x00	0–31	FBP_BASE	Free buffer pool base. Holds the pointer to the first entry in the free buffer pool. FBP_BASE should be word aligned. User-defined.
0x04	0–15	FBP_Offset_OUT	Host offset out indicates the pointer entry which the host is currently returning to the application after transmission has finished. The actual address of the current received FBP entry = FBP_BASE + FBP_Offset_OUT. For termination mode **Initialize to 0x00**. The host should maintain this entry in this data structure in order to keep proper buffer management.
0x06	0–15	FBP_Offset_IN	Free buffer pool transmit pointer. Offset from the FBP_BASE to the current entry in the free buffer pool to which the transmitter will return the buffer pointer after it's transmission. *Important*: The transmitter will return a buffer to this offset if the difference between this value and the Offset_Out value is greater than one. The actual address of the current transmitted FBP entry = FBP_BASE + FBP_Offset_IN. For termination mode **Initialize to 0x00**.
0x08	0–15	—	Reserved. Should be cleared.
0x0A	0-15	—	Reserved. Should be cleared.
0x0C	0–15	FBP_LAST_Offset	Free buffer pool last pointer. User initialized to the offset of the last entry in the FBP. The actual address of the last FBP entry = FBP_BASE + FBP_LAST_Offset.
0x0E	0–15	—	Reserved. Should be cleared.

[1] Offset from FBPT_BASE+TQ[BPOOL] × 16

the application should perform the following sequence when getting a buffer pointer from the buffer pool:

-Read offset out value.

-read the buffer pointer located in this offset in the buffer pool. Check if the pointer value is different than zero. If so the pointer is valid and can be reused for transmission again. If it is zero perform a second read of the entry until a non zero value is read.

-After reading a valid pointer the application should clear the entry in the buffer pool. (so on the next time it will be used as indication that a new buffer has been placed by the QE)

37.18 Buffer Descriptors (BD)

37.18.1 Receive Buffer Descriptor (RxBD)

Figure 37-39 shows the RxBD.

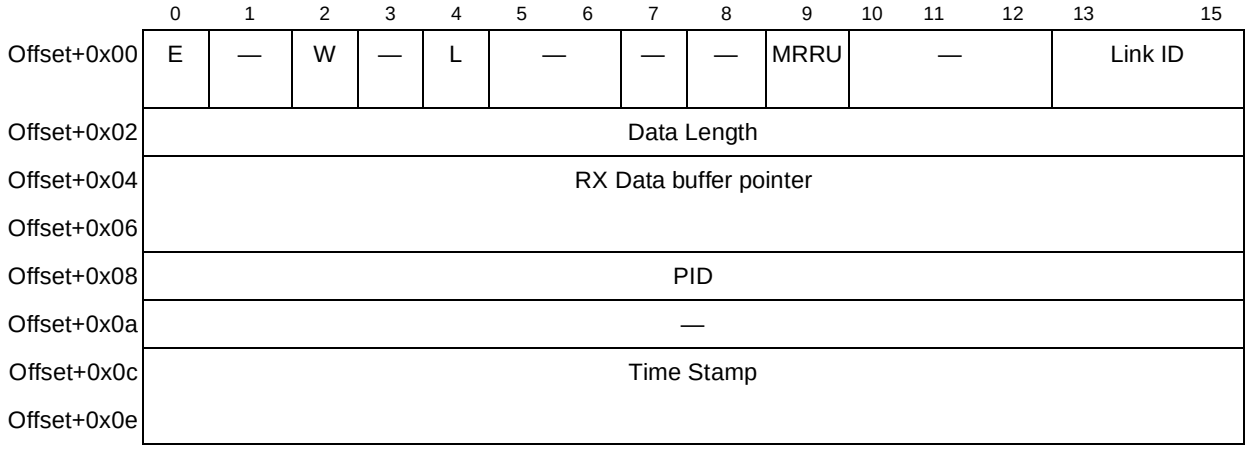

Figure 37-39. Receive Buffer Descriptor

Table 37-28 describes the RxBD fields.

Table 37-28. Receive Buffer Descriptor Fields

Offset	Bit	Name	Description
0x00	0	E	Empty bit. 0 The buffer associated with this RxBD is filled with data. The core can examine or write to this BD. The RISC does not use this BD again while E remains zero. 1 The RX buffer is empty or enqueuing is in progress.
	1	—	Reserved.Should be cleared.
	2	W	Wrap bit 0 This is not the last BD in the RxBD ring. 1 This is the last BD in the RxBD ring.
	3	—	Reserved. Should be cleared.
	4	L	Last. 0 This is not the last buffer in the frame. 1 This is the last buffer in the current frame.
	5–10	—	Reserved. Should be cleared.
	9	MRRU	MRRU exceed. This bit is set by the RISC in the last BD of a frame to indicate that the frame length exceeds MRRU value.
	10-12	—	Reserved. Should be cleared.
	13–15	Link ID	This field is valid only for plain PPP, plain PPP mux & LCP queues. It indicates on which Link the data was received. It is useful when several links use the same queue.
0x02	0–15	Data Length	The data length is the number of bytes stored in this BD's data buffer. If L bit is set this field contains the length of the complete frame.
0x04–0x06	0–31	Rx Data buffer Pointer	Points to the location of the associated buffer. If QD[FBP] = 0, this field must be initialized with a data buffer pointer. **Note:** IF QD[FBP] = 1, this field is ignored by the RISC.
0x08	0–15	PID	PPP PID value of the PPP frame. This entry is valid for the first BD of each PPP frame so that for MLMC PPP frames which takes several BDs only the first BD is valid.
0x0A	0–15	—	Reserved. Should be cleared.
0x0C	0–31	Time Stamp	The RX copies the Time Stamp from QUICC Engine Time-Stamp Register (CETSR) after receiving a complete frame/fragment, see Section 20.3.10, "QUICC Engine Time-Stamp Registers (CETSRn)."

37.18.2 Receive LCP Buffer Descriptor (RxBD)

LCP packets have a dedicated queue and the BDs associated with the queue do not contain the extra information provided by a ML/MC BD. Therefore the size of the BD is smaller.

As described in Section 37.1, "Overview," the LCP BD ring is initialized with valid data pointers and once an LCP packet is received the data pointer which is currently in the link parameter table is swapped with the pointer of the BD currently used by the receiver.

Figure 37-40 shows the RxBD. All the information is identical to the Receive BD.

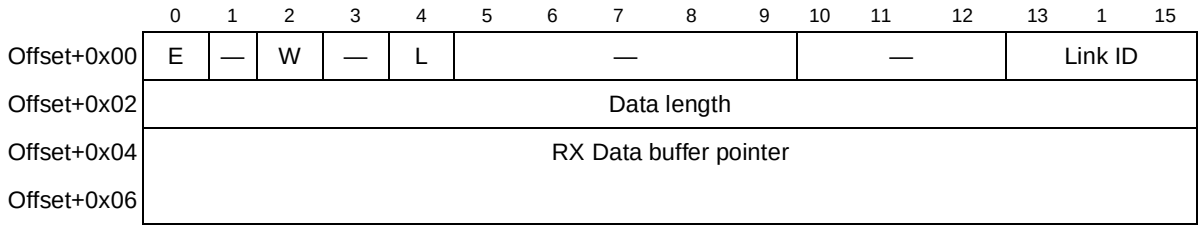

Figure 37-40. Receive LCP Buffer Descriptor

37.18.3 Transmit Buffer Descriptor (TxBD)

Figure 37-41 shows the TxBD.

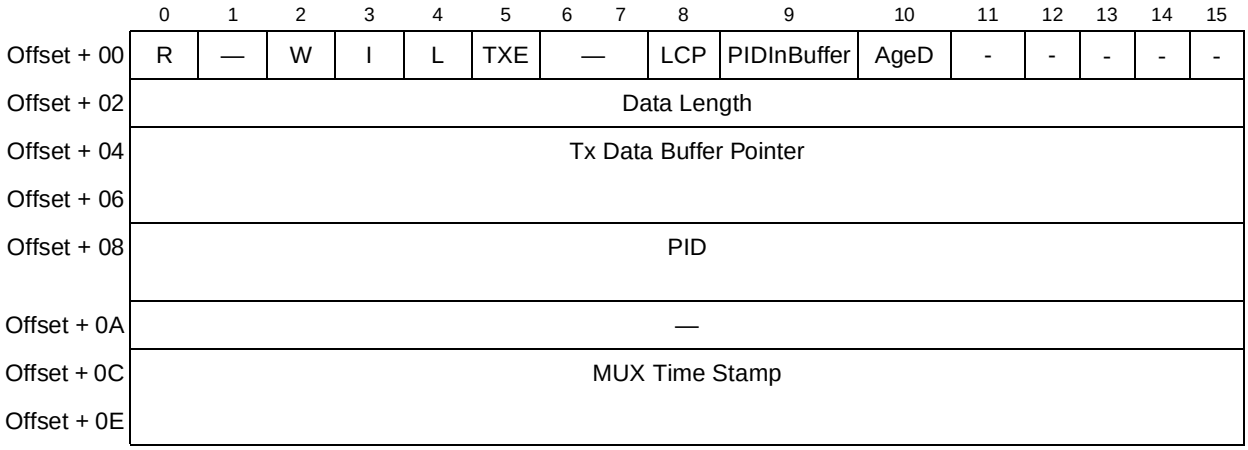

Figure 37-41. Transmit Buffer Descriptor (TxBD)

The TxBD length is 16 bytes. Table 37-29 describes the TxBD fields.

Table 37-29. TxBD Field Descriptions

Offset	Bits	Name	Description Weigthed Fair Queueing (WFQ)
0x00	0	R	Ready 0 The buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated data buffer. The RISC clears this bit after the buffer has been transmitted or after an error condition is encountered. 1 The data buffer is ready to be transmitted. The transmission may have begun, but it has not completed. The user cannot modify this BD once this bit is set.
	1	—	Reserved. Should be cleared.
	2	W	Wrap (final BD in table) 0 This is not the last BD in the TxBD table. 1 This is the last BD in the TxBD table. After this buffer is used, the RISC receives incoming data into the first BD in the table (the BD pointed to by TBASE). The number of TxBD's in this table is programmable and is determined the wrap bit.
	3	I	Interrupt. 0 No interrupt is generated after this buffer has been serviced. 1 TXB in the circular interrupt table entry is set when this buffer has been serviced by the MCC. This bit can cause an interrupt (if enabled).
	4	L	Indicates last BD for the frame. For sub-frames indicate last BD of sub-frame. 0 This is not the last buffer in the frame. 1 This is the last buffer in the current frame.
	5	TXE	Transmit Error indication. Set by the RISC under some error conditions which prevent this BD from being transmitted. Valid in PPP MUX sub frames only. An example for such a case is when a sub-frame length exceeds the MAX Superframe size.
	6–7	—	Reserved. Should be cleared.
	8	LCP	LCP frame. Could be set only for TxBD under a Link queue. LCP packet can split over several BD's. The LCP bit should be marked at the first BD containing the LCP packet. The ACFC characters and the PID are always uncompressed.
	9	PIDInBuffer	PID In Buffer. For PPP MUX Frames the PIDInBuffer must be reset. 0 - The PID is located in the BD. 1 - The PID is located in the buffer.
	10	AgeD	Age Discard. The RISC set this bit if the current BD was not transmitted since it was too old. See AgeEn bit, Section 37.19.7, "Mux Mode Register (MMR)." This is valid for MUX subframes BD's only. Should be cleared by the host.
	11–15	—	Reserved. Should be cleared.
0x02	Hword	Data Length	The data length is the number of bytes that should be transmitted from this BD's data buffer. It is never modified by the RISC. The value of this field should be greater than zero.
0x04	Word	Data Pointer	The transmit buffer pointer, which contains the address of the associated data buffer, may be even or odd. The buffer may reside in either internal or external memory. This value is never modified by the RISC.
0x08	Hword	PID	PPP PID value. PID value for plain PPP frames, or subframe PID in PPP MUX frames or ML/MC frames.

Table 37-29. TxBD Field Descriptions (continued)

Offset	Bits	Name	Description Weigthed Fair Queueing (WFQ)
0x0A	Hword	—	Reserved. Should be cleared.
0x0C	Word	MUX Time Stamp	Mux Time Stamp. The time stamp in which the user had set the Ready bit of this buffer. The user initialize this field with the value written in the QUICC Engine Time-Stamp Register (CETSR), see Section 20.3.10, "QUICC Engine Time-Stamp Registers (CETSRn)." This Time stamp with the SubFrame Age Period parameter, are used by the RISC, in order to determine if the SubFrame packet is too old. In case when the current Time Stamp (when the packet is intended to be transmitted) minus the MUX Time Stamp result is bigger than the SubFrame Age Period, then the packet is discarded.

37.19 PPP Mux Data Structures

The Mux and Demux processes have a page of their own in the parameter RAM.

37.19.1 PPP Mux Process Parameter RAM

The Parameter RAM holds two pointers that points to the management table of the Demux handler and to the Mux handler. The pointers are located in the internal MCC Global Parameter RAM, see at Table 37-5.

37.19.2 Demux Management Table (DMT)

The Demux Management Table (DMT) contains all the parameters needed for the de-muxing process. It resides in internal memory and it's size is 64 bytes.

Note: In systems where the PPP Mux traffic is received on the link level ONLY i.e. not over the ML/MC, it is still required to configure the Packet Reconstruction parameters (management and table) although there is no need for this functionality in the absence of ML/MC traffic.

Figure 37-42. DeMux Management Table (Internal Structure)

Table 37-30 describes the DMT fields.

Table 37-30. DeMux Management Table Field Description

Offset	Bits	Field	Description
0x00	0–1	Reserved	Reserved. Should be cleared.
	2	GBL	Global. Setting GBL enables snooping of data buffers, BD's, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	Reserved	Reserved. Should be cleared.
	5	CETM	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1 and Section 5.4.3.7, "Debug Configuration."
	6	Reserved	Reserved. Should be cleared.
	7	BIB	DeMux Fragment Table bus location. 0 - Reside on the coherent system bus 1 - Reside on the secondary bus
	8–14	Reserved	Reserved. Should be cleared.
	15	IQOV	IQOV Indicates the event of an Interrupt queue Overflow When there is a De-Mux event set in the CEVTER register for the de-Mux process (Based on its selected SNUM), the application should read this status bit which indicates a situation where there is no valid entry in the interrupt queue. The host should never reset this bit. It will be cleared by the QUICC Engine block when the full condition of the interrupt queue is gone.
0x02	Hword	Last entry offset	This field contains the offset to the last entry in the DFT table. It is calculated by 32 * (Number of DFT entries -1).
0x04	Word	External DFT Base pointer	This field holds the pointer to the DeMux Fragment Table (DFT).
0x08	Word	Internal Buffer Pointer (Internal)	Points to a 48 bytes space in Multi-user RAM for temporary storage location. r
0x0C	Hword	Offset in (for receiver)	Internal use. Initialized to zero.
0x0E	Hword	Offset out (for DeMux)	Internal use. Initialized to zero.
0x10–0x1F	16 bytes	Reserved	Reserved. RISC internal use.
0x20	Word	DeMux Interrupt queue base (DIQ)	This field holds the pointer to the interrupt queue base. The interrupt queue is dedicated to the DeMux interrupts. Pointer to external memory.
0x24	Word	DeMux Interrupt pointer (DIP)	Pointer to the DeMux Interrupt queue. The RISC writes the next interrupt information to this entry when an exception occurs. Initialize to DeMux Interrupt queue base pointer. Pointer to external memory.

Table 37-30. DeMux Management Table Field Description (continued)

Offset	Bits	Field	Description
0x28–0x2F	8 Bytes	—	Reserved, should be initialized to zero.
0x30	Hword	DInt_THR	DeMux fragment receive Interrupt threshold.
0x32	Hword	DInt_CNT	DeMux fragment receive count. Internal use. Should be initialize to DInt_THR
0x34–0x3F	12 bytes	Reserved	Reserved. RISC internal use.

37.19.3 Demux Fragment Table Entry (DFT Entry)

The Demux Fragment Table (DFT) is a data structure which defines the interface between receiver, the host and the demux process . It resides in external memory. Each entry of the table is associated with a PPP DeMux frame/fragment and it's parameters are being stored in the DFT entries for further process by the demux. Figure 37-43 describes a DFT entry. User should allocate 32 bytes for this table entry.

NOTE

The number of entries in this table should be large enough to accommodate the largest Super-frame that could possibly arrive on the system (i.e. the number of fragments of the largest super-frame in the system).

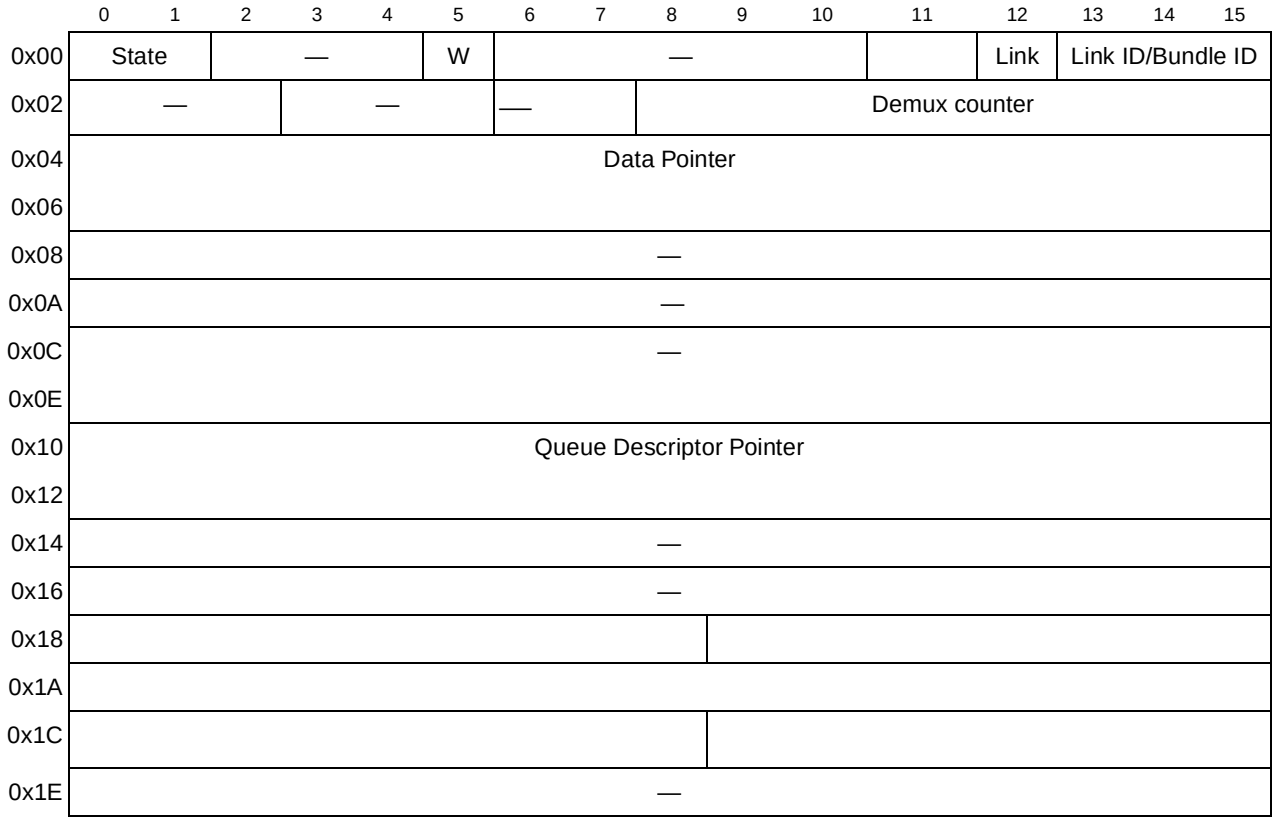

Figure 37-43. DeMux Fragment Table Entry

Table 37-31 describes the Demux Fragment Table entry fields.

Table 37-31. Demux Fragment Table Entry Field Descriptions

Offset	Bits	Field	Description
0x00	0–1	State	00 - This entry is available. The receiver may handle this entry 01 -This entry is now being handled by the DeMux 10 - This entry is now ready for host processing. Once the host finished processing all the SFBD's related to this entry, set the state to 00. 11 - Reserved
	2–4	—	Reserved. Initialized to 0.
	5	W	The Wrap bit indicates the last entry in the DeMux entry table.
	6–11	—	Reserved. Should be cleared.
	12	Link	Initialized to 0. Indicates the host that this entry has been received on a link level and the Link ID information is passed to the BD. 1- Next 3 bits (13-15) indicates the link ID on which this frame has been received. 0- Next 3 bits (13-15) indicates the bundle ID on which this fragment has been received (for ML/MC mode).
	13–15	Link ID/ Bundle ID	Initialized to 0. Link ID from which this fragment has been received. This is valid only for a PPP Mux on a link level and is useful if all links in the bundle use the same DeMux Queue Descriptor i.e. aggregating all the Mux traffic into a single queue. Bundle ID- When the fragment is part of a ML traffic this field indicates the Bundle ID to which this fragment belongs.
0x02			
	0-7	Res	reserved for QUICC Engine block usage
	7-15	Demux counter	Initialized to 0. This field holds the counter of the number of BDs that were processed or are currently processed by the demultiplexer. Once the demux process changes the state field to 0x10 the host has the information of how many sub-frames there are in the specified fragment so it knows how many BD's should be processed before returning the buffer pointer to the FBP. It is used by the host to know how many subframes to process in the superframe, before changing the state from '10' to '00'.
0x04	0–31	Data Pointer	Initialized to 0. Fragment/PPPMux frame data buffer pointer. This data pointer is the "original" pointer from the FBP and should be returned by the host after processing all its sub-frames.
0x08– 0x0F	—	—	Reserved. Initialized to 0.
0x10	0–31	Queue Descriptor Pointer	This field holds the pointer to the Queue Descriptor that handles the BD's to which the subframe of the currently processed fragment should be assigned.
0x14 0x1F	—	—	Reserved. Initialized to 0.

37.19.4 Sub-Frame Rx Buffer Descriptor

The Sub-Frame Buffer Descriptor (SFBD) contains the sub-frame parameters for the host. The data pointer point to the location of the information of sub-frame. This pointer actually points into the original buffer

on which the fragment was stored. No data is being copied so the SFBD do not have any data buffers allocated for their usage. The PID information is extracted and placed in the BD. Figure 37-44 describes the various fields of the SFBD.

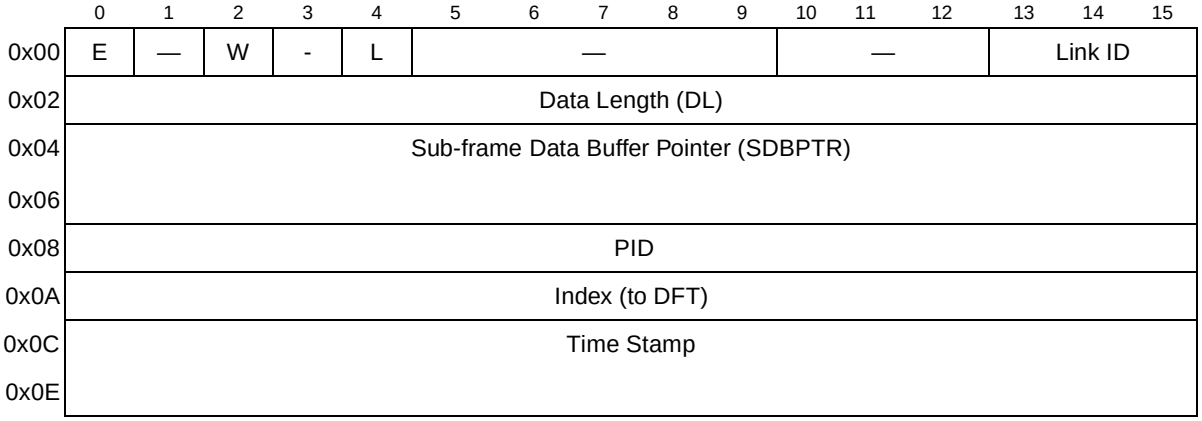

Figure 37-44. Rx Sub-Frame Buffer Descriptor

Table 37-32 describes Sub-frame Buffer Descriptor fields.

Table 37-32. Sub-Frame Buffer Descriptor Field Descriptions

Offset	Bits	Field	Description
0x00	0	E	Empty bit. 0 The buffer associated with this RxBD is filled with data. The core can examine or write to this BD. The RISC does not use this BD again while E remains zero. 1 The RX buffer is empty or enqueuing is in progress.
	1	—	Reserved. Should be cleared.
	2	W	Wrap (final BD in Ring) 0 This is not the last BD in the RxBD table. 1 This is the last BD in the host RxBD ring of this current queue. After this buffer has been used, the RISC receives incoming data for this queue into the first BD in the ring. The number of RxBD's in this table is programmable and is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	-	Reserved.Should be cleared.
	4	L	Last bit. 0-this BD is not the last BD of the sub-frame. 1-this BD is the last BD of the sub-frame.
	5–12	—	Reserved.Should be cleared.
	13–15	Link ID	This indicates the link ID on which this PPP Sub-frame has been received. It is valid only for MUX superframe received in a Link muxed queue. In ML/MC queue this field is cleared.
0x02	Hword	Data Length (DL)	Contains the length of the buffer associated with this BD. This is actually the length of pure data of the packet. All header information is removed.
0x04	Word	SDBPTR	Sub-frame data buffer pointer. Points to the address of the subframe in the data buffer.
0x08	Hword	PID	This field holds the PID of the subframe associated with this BD.

Table 37-32. Sub-Frame Buffer Descriptor Field Descriptions

Offset	Bits	Field	Description
0x0A	Hword	Index (to DFT)	This field holds the index to the DeMUX fragment table (DFT). This direct the host to the fragment on which this sub frame has been received. Once all the sub frames are processed the host has to change the STATE of this entry. The address to the entry is calculated in the following way: External DFT Base pointer+index*32.
0x0C	Word	Time stamp	This field holds the time stamp of the fragment / PPP mux frame.

37.19.5 Mux Encapsulation Management Table (MMT)

This table contains a list of the active queues in the system that are configured to work in PPP mux mode and require building superframes.

Note that there can't be more than 16 Mux queues in the system.

The size of the table is determined by the number of PPP mux active queues. The bigger the size of the table, the higher the latency of building the superframe for each queue.

Figure 37-45 describes the management table for the mux process. It is pointed to from the MCC global parameter RAM (Table 37-5). The table size is 56 bytes.

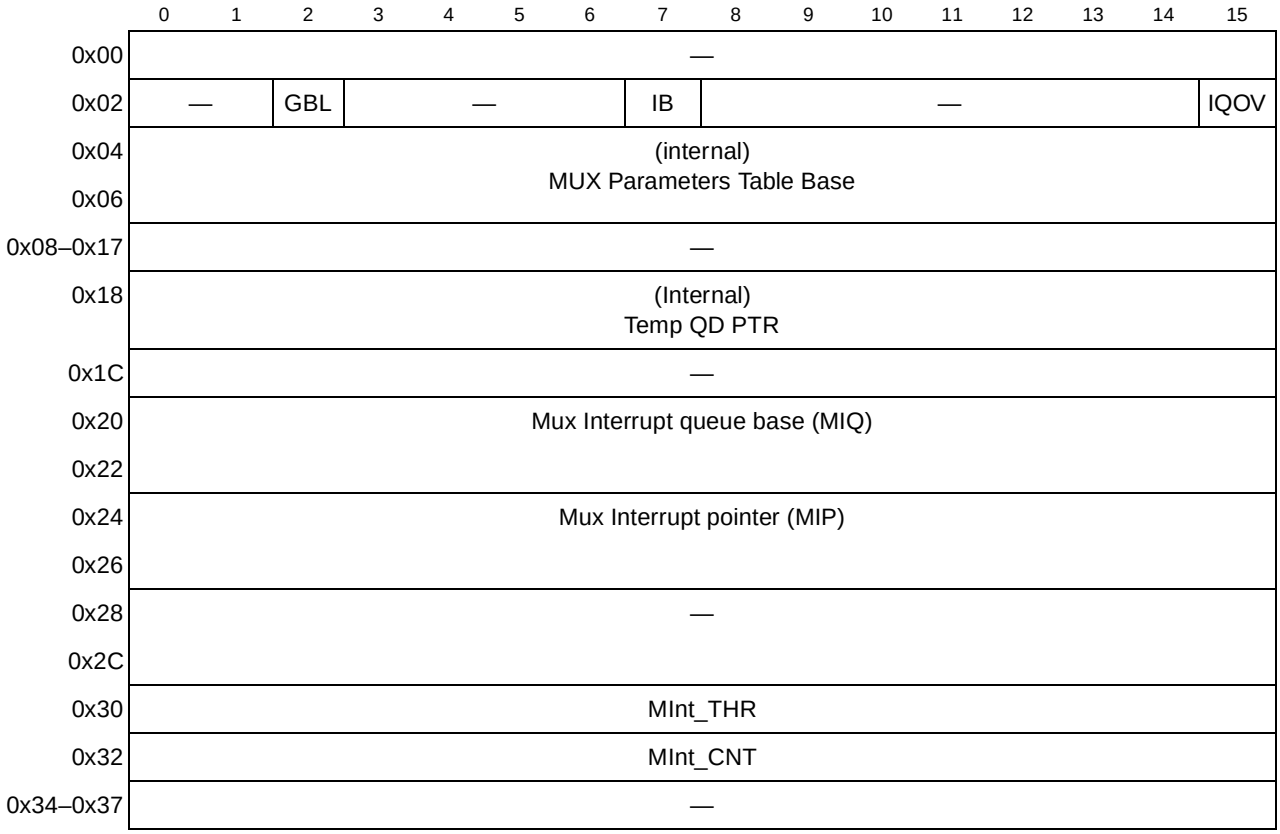

Figure 37-45. Mux Encapsulation Management Table

Table 37-33. Mux Encapsulation Management Table Field Descriptions

Offset	Bit	Size	Name	Description
0x00		Hword	—	Reserved. Initialize to zero.
0x02	0–1	Hword	—	Reserved. Should be cleared.
	2		GBL	Global. Setting GBL enables snooping of Interrupt queues. This should match BMR[GBL]. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–6		—	Reserved. Should be cleared.
	7		IB	IB- Interrupt Bus Selection for the Mux-encapsulation process. 0 Resides on the coherent system bus. 1 Resides on the secondary bus.
	8–14		—	Reserved. Should be cleared.
	15		IQOV	IQOV Indicates the event of an Interrupt queue Overflow. When there is a Mux Encapsulation event set in the CEVTER register for the Mux process (Based on its selected SNUM), the application should read this status bit which indicates a situation where there is no valid entry in the interrupt queue. The host should never reset this bit. It will be cleared by the QUICC Engine block when the full condition of the interrupt queue is gone.
0x04		Word	MPT Base (Internal)	MUX Parameter Table Base. Base address of the MUX encapsulation parameter table described in 37.19.6. Should be 64 bytes aligned.
0x08		16 Bytes	—	Reserved. Initialize to zero.
0x18		Word	Temp QD PTR (Internal)	A pointer to internal memory where the external Queue descriptor is fetched when using external QD. The user should initialize this field with a pointer to 16 bytes in the Multi-user RAM.
0x1C		Word	—	Reserved. Initialize to zero.
0x20		Word	Mux Interrupt queue base pointer (MIQ)	This field holds the pointer to the interrupt queue base. The interrupt queue is dedicated to the mux interrupts. Pointer to external memory.
0x24		Word	Mux Interrupt Queue pointer (MIP)	Pointer to the Mux Interrupt queue. The RISC writes the next interrupt information to this entry when an exception occurs. Initialize to Mux Interrupt queue base pointer. Pointer to external memory.
0x28–0x2F		8 Bytes	—	Reserved. Initialize to zero.
0x30		Hword	MInt_THR	Mux fragment receive Interrupt threshold.
0x32		Hword	MInt_CNT	Mux fragment receive count. Internal use. Should be initialize to MInt_THR
0x34		Word	—	Reserved. Initialize to zero.

37.19.6 Mux Encapsulation Parameters Table

This table resides in the internal multi-user RAM. Each transmit queue (QD) which is designated to work in Mux mode is associated with a PPP Mux Parameters Table, shown in Figure 37-46. Each entry in the

table contains all the information needed for the mux process to generate a PPP mux super-frame.It allocates space for parameters which are initialized by the host and space for the internal state and variables used by the RISC when processing a superframe. The size of the table is determined by the number of PPP mux QDs—one entry per QD. A Wrap bit indicates the last entry in the table. Each entry in the table is 64 bytes long. The Mux encapsulation process will go through the table entries and for each entry, it builds a Mux super-frame.

0x00		Mux Encapsulation Params #1
0x40		Mux Encapsulation Params #2
.....		.....
0xXX	W	Mux Encapsulation Params #N

Figure 37-46. Mux Parameters Table (MPT)

The process scans through the entries in a round robin fashion. When reaching the entry marked with the W indication, the RISC wraps to the first entry for processing. As long as a superframe is not valid the queue which is related to the request entry will be marked as empty. Once it is ready, the QE (Queue Empty) bit is negated and the queue could be selected by the WFQ algorithm.

Table 37-34. MPT Entry

Table 37-35. PPP MUX Parameter Table (MPT) Entry Descriptions

Offset	Bits	Name	Description
0x00	Hword	MMR	Mux Mode Register. See Table 37-36.
0x02	Hword	Def_PID	Subframe default PID. The default value for the subframe PID. If the PID of the first subframe selected is equal to this value, then PFF of the subframe header would be 0, and no PID would be asserted.
0x04	Hword	Super_Frame_Size	MUX super frame size. Defines the maximum transmitted size of a PPP MUX superframe. The size specified in this field does not include the PPP MUX PID which could be of one or two bytes depending on the mode in which the bundle is programmed. In case UDH mode is enabled, the size of the UDH is read from the QD and is subtracted from the value of MUX_Super_Frame_Size. Programming a large value (>MRU) enables encapsulation of multi fragment superframe.
0x06	Hword	—	Reserved, initialized to 0.
0x08	Word	TimeOUT_Period	MUX Time-out Period. The Time-out period for the RISC for stopping the multiplexing process of a superframe. This value is valid when TimeOutEn in the Mux Mode register is on. The user should initialize this field as an integer value of time units which are derived from CETSCR programming, see Section 20.3.9, “QUICC Engine Time-Stamp Control Register (CETSCR).”
0x0C	Word	Age Period	MUX aging Period. This value determines the maximum time allowed for a PPP MUX subframe to be in a queue, before it is discarded. If the Age_En mode is on, this value represents the amount of time allowed. See Table 37-29 in MUX Time Stamp field, for more information. The user should initialize this field as an integer value of time units which are derived from CETSCR programming, see Section 20.3.9, “QUICC Engine Time-Stamp Control Register (CETSCR).”
0x10	Word	Tx_SuperF_Discard_CNT	Transmitter Mux Super Frame Discard counter. Initialized to 0. Counts the number of Super frame that are discarded due to the Link Aging mechanism.
0x14	Word	SuF_Discard_CNT	MUX Encapsulation SubFrame Discard counter. Initialized to 0. Counts the number of SubFrames that were discarded due to the Aging expiration by the MUX process.
0x18	0	—	Reserved. Should be cleared.
	1	UDHEn	User Defined Header (UDH) Enable. 0- No User Defined Header is appended to the MUX fragment/frame. 1- User Defined Header is appended to the MUX fragment/frame. The UDH is appended before the PPP MUX PID (0x0059).
	2–7	UDH_index	Index of UDH. Index from UDH Base. The UDH Base is taken from the BPT, see Table 37-9. Address to the UDH is (UDH_Index*0x100+UDH Base). There are up to 64 different UDH under each bundle.
	8–15	UDH_Size	Size-1 in bytes of the UDH (UDH=255 means UDH of 256 bytes and UDH=0 means UDH of 1 byte). Note that UDH_Size has to be smaller than MFS parameter in case of transmitting ML MC PPP fragments, see field in BPT.
0x1A	Hword	Mux Encapsulation Offset out	Mux Encapsulation Offset out. The Offset in the queue BD ring of the MUX process. Should be initialized to 0.

Table 37-35. PPP MUX Parameter Table (MPT) Entry Descriptions (continued)

Offset	Bits	Name	Description
0x1C	Word	QD_PTR (external or internal)	Queue Descriptor Pointer. This is the pointer to the queue which is requesting the MUX encapsulation services. The queue could be in the internal or external memory and the bus location is determined in the Mux Encapsulation Parameter Table [MMR].
0x20	0	Mux_req	Mux request. Must be initialize to 1. RISC internal use.
	1–10	—	Reserved. Should be cleared.
	11	Link	0- This entry is associated with a ML queue in a bundle specified in bits 12-14. 1 -This entry is associated with a link which is link ID is specified in bits 12-14. This information is initialized by the host.
	12–14	Link ID/ Bundle ID	Specify the Link ID /Bundle ID for this entry. Should be initialized by the host. This information is copied to the interrupt queue upon a MUX event.
	15	W	Wrap (last request in Mux encapsulation request table) 0 This is not the last request in the table. 1 This is the last request in the Mux encapsulation request table.
0x22	Hword	Cur_PID	Current Subframe PID value. Initialized to the MUX_Def_PID parameter. Used by the RISC to determine the PFF value for the next subframe.
0x24	Word	Super Frame Timestamp	Super Frame Timestamp. User initialized to 0. Used by the Mux process to indicate the time stamp of the sub-frame which has the highest timestamp value (enqueued the latest) in the whole superframe. If Aging is enabled and the aging period has elapsed, the complete superframe will be discarded when processed by the transmitter back-end (or the link). This entry which is the MUX process output, is used as input to the transmitter back-end (or the link) and should be used/save by the transmitter back-end (or the link) before raising Mux_req.
0x28	Word	FBPT_PTR (Internal)	Points to the Free Buffer Pool Parameter Tables that this MUX queue is using. Valid only if FBP mode is enabled in the MUX TQD. Four different FBP are supported on the transmitter. The address specified in this entry should match the address calculated by: BPT[TXFBPT_BASE] + TQD[Tx_FBP_Sel]. The MUX encapsulation will use this entry when returning a buffer pointer after discarding a sub-frame due to aging.
0x2C–0x33	8 Bytes	—	Reserved, should be cleared.
0x34	Word	State	RISC internal state for this request entry. Should be initialize to 0x80000000
0x38	8 Bytes	—	Reserved, should be cleared.

37.19.7 Mux Mode Register (MMR)

The Mux mode register (MMR) is a user-initialized register, shown in Figure 37-47.

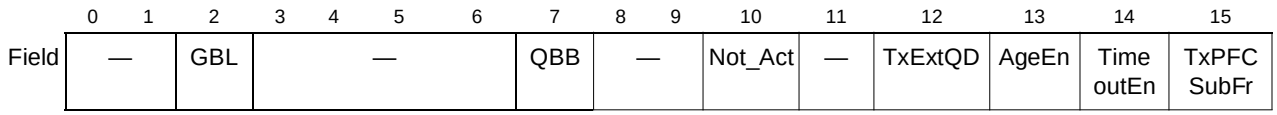

Figure 37-47. Mux Mode Register (MMR)

MMR fields are described in Table 37-36.

Table 37-36. MMR Field Descriptions

Bits	Name	Description
0–1	—	Reserved. Should be cleared.
2	GBL	Global. Setting GBL enables snooping of BD's and QD's. This should match BMR[GBL]. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
3–6	—	Reserved- Should be cleared
7	QBB	Queue Descriptors and Buffer Descriptors bus Selection 0 Reside on the coherent system bus. 1 Reside on the secondary bus. This should match the bus selection of the QD given in BMR[BDB].
8–9	—	Reserved. Should be cleared.
10	Not_Act	Not Active- This bit signals to the QE that this MUX queue is currently not active and there is no need to process a superframe for this queue. The host should clear this bit when the queue is operational.
11	—	Reserved. Should be cleared.
12	TxExtQD	Transmitter External Queue Descriptor. 0- Indicating the MUX process that the queue is in internal memory 1- The queue resides in external memory.
13	AgeEn	Age Enabled. Valid only for PPP MUX superframes. Upon completion the encapsulation of a superframe, before transmission, the current time is compared to timestamp of the "youngest" subframe in the superframe. If the time elapsed is bigger then the Age Period the complete superframe is discarded. 0 - The subframes age algorithm is disabled. 1 - The subframes age algorithm is enabled.
14	TimeoutEn	Timeout Enable. During encapsulation of PPP MUX subframe the QE examines the time stamp value placed by the host on each BD. If the time difference between current time and the BD timestamp value exceeds the Age Period value, the subframe is discarded (and marked as such in the BD) 0 - The time-out MUX mechanism is disabled. 1 - The time-out MUX mechanism is enabled.
15	TxPFCSubFr	Transmit PID Compressed for the PPP MUX sub frame header. 0 - PID transmitted is 2 bytes length. 1 - PID transmitted is 1 byte length (only if MSB byte of the PID is 0).

37.20 PPP Exceptions

The MCC interrupt handling involves two data structures: the MCCE (MCC event register) and the circular interrupt queues.

Fourteen priority interrupt queues are available. The queues are available for legacy MCC usage using the MCC programming model or, alternatively, are available for the PPP application. In this case the programming model is different. It is the application responsibility to use each queue for a unique purpose since the behavior is completely different in each of the cases. If, for example interrupt queue #1 is used for legacy MCC operation it should not be configured in any of the Link or Class parameters LMR/CMR[RIQN] as a queue for PPP usage.

The host controls the number of interrupts sent to the core using a counter in the interrupt queue's parameter table. For each event sent to an interrupt queue, a counter (that has been initialized to a threshold number of interrupts) is decremented.When this counter reaches zero, the global interrupt MCCE[INTx], is set.

37.20.1 Interrupt Queues

Interrupt queues are located in external memory. The parameters of each queue are stored in the Interrupt Queue Parameter Tables.

When the microcode generates an interrupt request, the RISC writes a new entry to the interrupt queue, the valid (V) bit is set and the queue pointer (INTQ_PTR) increments. When INTQ_PTR reaches a location with the W bit set, it wraps to the first entry in the queue.If the RISC tries to overwrite a valid entry (V=1), an overflow condition occurs and the queue's overflow flag of the corresponding queue, MCCE[QOVx], is set.

37.20.2 Interrupt Queue Entry

Each interrupt queue entry is 8 bytes long. Each interrupt queue entry provides detailed interrupt information to the host.

An interrupt queue entry is shown in Figure 37-48.

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0x00	V	W	MRU	Rx BP_BSY	NIDL	IDL	BP_RLI	FLOSS_TH	PRT_BSY	DM_BSY	UN	FLOSS	WBD_BSY	BSY	TXB	RXF
0x02	Class id			—			Tx BP_BSY	Tx_FBP_Sel		LCP	Bundle ID			Link ID		
0x04	Queue Descriptor pointer/Tx BP Busy Buffer Pointer															
0x06																

Figure 37-48. Interrupt Queue Entry

Table 37-37 describes the interrupt queue entry fields.

Table 37-37. PPP Interrupt Queue Entry Fields Descriptions

Offset	Bits	Name	Description
0x00	0	V	Valid interrupt entry 0 This interrupt queue entry is free and can be used by the RISC. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	W	Wrap bit. When set, this is the last interrupt entry in the circular table. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	2	MRU	A fragment/frame was received with MRU violation.The Link ID field specified on which Link it happened. Mask for this interrupt is defined in LINTMSK register in the LPT

Table 37-37. PPP Interrupt Queue Entry Fields Descriptions (continued)

Offset	Bits	Name	Description
	3	Rx_BP_BSY	Buffer Pool Busy. Set when a free buffer pool Busy condition occurs. It means no buffer is available for reception. Important: This is a special event and will generate an interrupt regardless of the condition of the counter reaching the desired threshold.
	4	NIDL	Non idle state. The line is not idle.
	5	IDL	Idle state. This line is idle.
	6	BP_RLI	Buffer Pool RLI. Set when a free buffer pool has reached the level of the RLI threshold. Important: This is a special event and will generate an interrupt regardless of the condition of the counter reaching the desired threshold.
	7	FLOSS_TH	Fragment loss due to threshold reached. See Figure 37-25. A fragment loss was detected by the receiver. The packet was discarded. The Bundle ID field and the Class ID field provide to the user information about the WBD ring it happened to. This interrupt can not be masked.
	8	PRT_BSY	Packet Reconstruction Table Busy condition. The Packet Reconstruction table is busy. Packets were discarded due to this condition. This interrupt can not be masked.
	9	DM_BSY	De-mux Busy condition. The Demux table is busy. Fragments/frames were discarded due to this condition. This interrupt can not be masked. This implies that during the Demux process some sub-frames are lost.
	10	UN	Tx no data. The RISC sets this flag if there is no data available to be sent to the transmitter. The transmitter sends an ABORT indication and then sends idles. The Link ID field indicates on which link it happened.
	11	FLOSS	Fragment loss occurance.There was a fragment loss detected by the receiver.Packet was discarded.The Bundle ID field and the Class ID field provide to the user information about the WBD ring it happened to.This interrupt can not be masked.
	12	WBD_BSY	Busy condition in WBD ring.The WBD ring associated to the class specified in the Class ID field, is busy.Packets were discarded due to this condition. This interrupt can not be masked.
	13	BSY	Busy condition. The RxBD table, associated with the queue specified in the Queue Descriptor field, is busy. Packets were discarded due to this condition. This is an unmaskable interrupt
	14	TXB	TX buffer. A buffer has been prepared for transmission and the corresponding BD is free to get a new Data buffer from the host.
	15	RXF	RX frame. A frame was received in the associated queue. This interrupt can be mask by clearing the INTMSK bit in the Queue Descriptor.
0x02	0-2	ClassID	Class ID. Indicates the Class where events like RxF, TxB, WBD_BSY, FLOSS, PRT_BSY and DM_BSY occurred.
	3–5	—	Reserved
	6	Tx_BP_BSY	Tx Buffer Pool Busy. Set when a Transmitter free buffer pool Busy condition occurs. It means no room is available for the buffer return on transmission. Important: This is a special event and will generate an interrupt regardless of the condition of the counter reaching the desired threshold.
	7–8	Tx_FBP_Sel	Tx_FBP_Sel- Indicates the Buffer Pool on which the busy conditions occurred.
	9	LCP	Indicates LCP frame reception, MRU violation of LCP frame or LCP queue Busy.
	10–12	Bundle ID	Bundle ID. Indicates the Bundle where events like RxF, TxB, WBD_BSY, PRT_BSY, FLOSS, BP_BSY, BP_RLI and DM_BSY occurred.
	13–15	Link ID	Indicates the LinkId where events like TXBD (if occurred on Link), MRU,DM_BSY (if occurred on Link), UN, RXF (if occurred on Link). In a ML/MC event, this field is not valid.

Table 37-37. PPP Interrupt Queue Entry Fields Descriptions (continued)

Offset	Bits	Name	Description
0x04	Word	Queue Descriptor/ Tx BP Busy Buffer Pointer	This field contains the pointer to the Queue Descriptor where the event occurred. In case of Transmit Buffer Pool busy, this entry contains the buffer pointer which has no room in the FBP due to FBP_Busy conditions.

37.20.3 Interrupt Queue Parameter Tables

The interrupt queue parameters are held in parameter tables in the multi-user RAM; PPP_INTBASE in the Global MCC parameter points to the base address of these tables. Each of fourteen interrupt queues has its own parameter table with starting address given by PPP_INTBASE+IntQ_num*32.

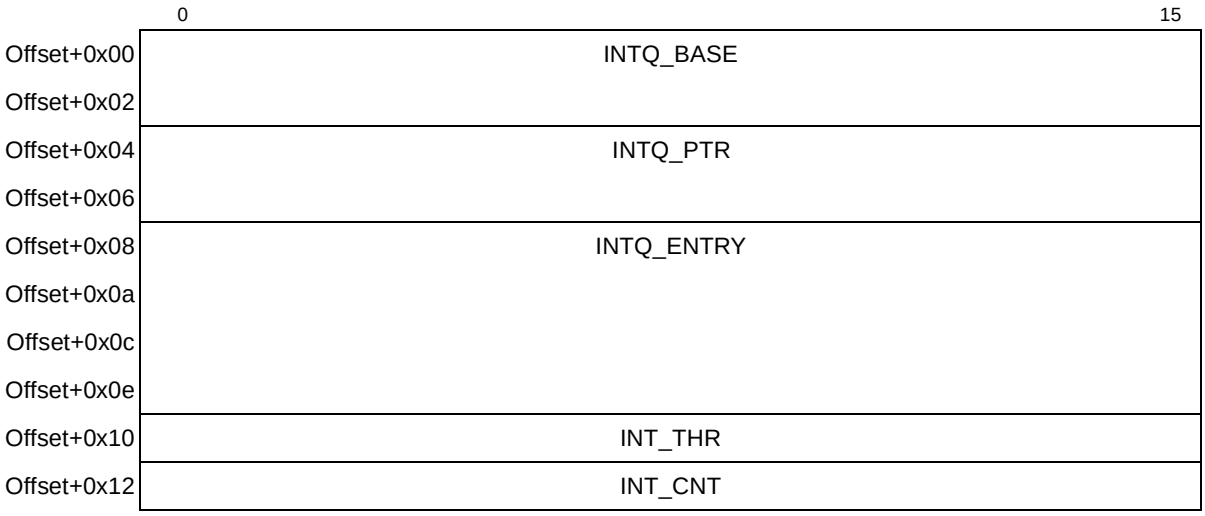

Figure 37-49. Interrupt Queue Parameter Table

Each fields of this table is described in Table 37-38.

Table 37-38. Interrupt Queue Parameter Table Field Descriptions

Offset	Name	Width	Description
0x00	INTQ_BASE	Word	Base address of the interrupt queue. User-defined.
0x04	INTQ_PTR	Word	Pointer to interrupt queue entry. Initialize to INTQ_BASE.
0x08	INTQ_ENTRY	8 bytes	Interrupt queue entry. Must be zero.
0x10	INT_THR	Hword	Interrupt threshold. User-defined global interrupt threshold: the number of interrupts required before the RISC issues a global interrupt (MCCE[INTx]).
0x12	INT_CNT	Hword	Interrupt counter.Initialize with INT_THR, The RISC decrements INT_CNT for each interrupt. When INT_CNT reaches zero, the queue's global interrupt flag MCCE[INTx] is set (and MCCE[8] also).

37.20.4 MCC Event and Mask Registers

Since legacy MCC operation concurrent to the PPP operation is enabled there are two sets of interrupts and interrupts handling. The legacy MCCE is defined to support up to 7 interrupt queues. Each queue could be managed by a different interrupt management since the interrupt entries are different on legacy MCC operation and on PPP operation. It is the user responsibility to use an interrupt queue in a single mode. Trying to use a single queue for MCC and PPP causes erroneous results.

In legacy MCC code, four queues are available for receive operation (queue0-queue 3) and a single queue is available for transmit events per MCC. Processing the interrupts and interrupt queues is described in the MCC global parameter table, see Section 34.2.1, “Global MCC Parameters.”

In PPP mode, numbering the queues still applies but the management is located in the multi-user RAM and pointed to by PPP_INTBASE described in Figure 37-20. An event which is related to a **link** (like MRU violation or reception of plain PPP frame) generates an interrupt if not masked on the MCCE register. The selection of which queue to use is defined in the LMR[RIQN] for the receiver. If there is no legacy MCC code running at the same application, the queues available are 0-3, 6-10 and 13 for the receiver.The transmitter is limited and always uses queue #4 or #11 for link events according to LMR[TI_Low] bit.

An event which is related to **multi-link multi-class** traffic will act the same. The receiver can select a queue using the CMR[RIQN]. If there is no legacy MCC code running at the same application, the queues available are 0-3, 6-10 and 13 for the receiver. The transmitter is limited to using queue #5 or # 12 for multilink multi class events according to CMR[TI_Low] bit.

It is forbidden to mix queues of **link** events and **multi-link multi-class** events that are generated from background tasks. This implies that for multilink multiclass operation there should be for Link events at least one queue for receive, and one for transmit. This is true also for multilink events (background events). This gives a minimum of four queues for a multilink multiclass operation.

The MCCE/MCCM register is described below. For each bit the corresponding bit in the MCCM register enables the interrupt.

Offset:

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Figure 37-50. MCC Event Register (MCCE)/Mask Register (MCCM)

Table 37-39 describes MCCE fields.

Table 37-39. MCCE/MCCM Register Field Descriptions

Bits	Name	Description
0	QOV0	PPP interrupt queue x overflow (QOVx). Set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table number x. Global Interrupt (GINTx). Set when the number of interrupt issued in the interrupt queue x reaches the pre-defined threshold. These four queues are available for receive events on standard MCC operation and for PPP operation for link and class events (for PPP is selected based on CPT[RIQN] or LPT[RIQN]).
1	GINT0	
2	QOV1	
3	GINT1	
4	QOV2	
5	GINT2	
6	QOV3	
7	GINT3	
8	QOV4	PPP interrupt queue 4 overflow. QOV4 is set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table number 4.
9	GINT4	Global Interrupt. Set when the number of interrupt issued in the interrupt queue 4 reaches the pre-defined threshold. This queue is dedicated for transmitter Link events when LPT[TI_Low] is cleared.
10	QOV5	PPP interrupt queue 5 overflow. QOV5 is set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table number 5.
11	GINT5	Global Interrupt. Set when the number of interrupt issued in the interrupt queue 5 reaches the pre-defined threshold. This queue is dedicated for transmitter Class events when CPT[TI_Low] is cleared.
12	QOV6	PPP interrupt queue 6 overflow. QOV6 is set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table number 6.
13	GINT6	Global Interrupt. Set when the number of interrupt issued in the interrupt queue 6 reaches the pre-defined threshold. This queue is dedicated for legacy MCC code transmitter event or for receiver PPP link or class event (for PPP is selected based on CPT[RIQN] or LPT[RIQN]).
14	GUN	Global transmit underrun. This flag indicates whether an underrun occurred inside the MCC's transmit FIFO array. The user must clear this bit.
15	GOV	Global receiver overrun. This flag indicates whether an overrun occurred inside the MCC's receive FIFO array. The user must clear this bit.
16	QOV7	**Note:** Queue 7 OverFlow. Set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table.
17	GINT7	This queue is available for PPP operation and is considered as an extra. This queue is available for PPP operation for link and class events and is selected based on CPT[RIQN] or LPT[RIQN]. **Note:** Global Interrupt (GINTx). Set when the number of interrupt issued in the interrupt queue x reaches the pre-defined threshold.
18	QOV8	Queue 8 OverFlow. Set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table.

Table 37-39. MCCE/MCCM Register Field Descriptions (continued)

Bits	Name	Description
19	GINT8	This queue is available for PPP operation and is considered as an extra. This queue is available for PPP operation for link and class events and is selected based on CPT[RIQN] or LPT[RIQN]. Global Interrupt (GINTx). Set when the number of interrupt issued in the interrupt queue x reaches the pre-defined threshold.
20	QOV9	Queue 9 OverFlow. Set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table.
21	GINT9	This queue is available for PPP operation and is considered as an extra. This queue is available for PPP operation for link and class events and is selected based on CPT[RIQN] or LPT[RIQN]. Global Interrupt (GINTx). Set when the number of interrupt issued in the interrupt queue x reaches the pre-defined threshold.
22	QOV10	Queue 10 OverFlow. Set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table.
23	GINT10	This queue is available for PPP operation and is considered as an extra. This queue is available for PPP operation for link and class events and is selected based on CPT[RIQN] or LPT[RIQN]. Global Interrupt (GINTx). Set when the number of interrupt issued in the interrupt queue x reaches the pre-defined threshold.
24	QOV11	PPP interrupt queue 11 overflow. QOV11 is set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table number 11.
25	GINT11	Global Interrupt. Set when the number of interrupt issued in the interrupt queue 11 reaches the pre-defined threshold. This queue is dedicated for transmitter Link events when LPT[TI_Low] is set.
26	QOV12	PPP interrupt queue 12 overflow. QOV12 is set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table number 12.
27	GINT12	Global Interrupt. Set when the number of interrupt issued in the interrupt queue 12 reaches the pre-defined threshold. This queue is dedicated for transmitter Class events when CPT[TI_Low] is set.
28	QOV13	PPP interrupt queue 13 overflow. QOV13 is set (and an interrupt request generated) by the RISC whenever an overflow occurs in the PPP circular interrupt table number 13.
29	GINT13	This queue is available for PPP operation and is considered as an extra. This queue is available for PPP operation for link and class events and is selected based on CPT[RIQN] or LPT[RIQN]. Global Interrupt. Set when the number of interrupt issued in the interrupt queue 13 reaches the pre-defined threshold.
30	CUN	Channel Transmit Underrun.
31	Res	Reserved

37.20.5 PPP Demux Interrupt Queue Entry

The de-mux process has it's own event register and queue management. The management of the interrupt queue is done in the Demux Management Table (DMT) described at Table 37-30. Masking the interrupts is defined in the queue descriptor of the demux queue by the INTMSK bit. See Figure 37-31.

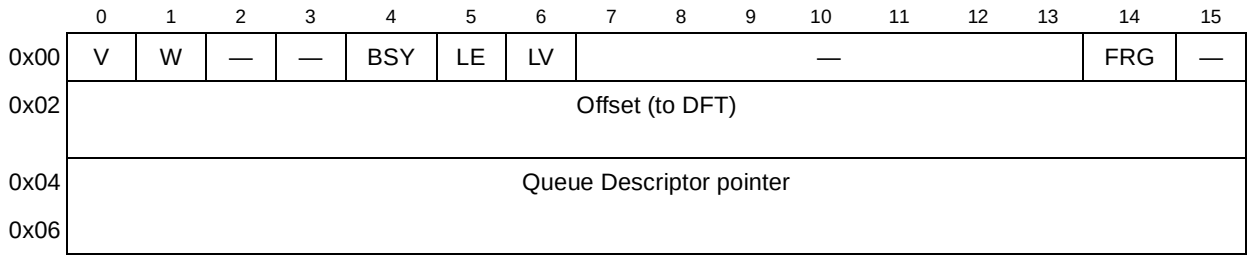

Figure 37-51. Demux Interrupt Queue Entry

Table 37-40 describes PPP DeMux Interrupt Queue Entry fields.

Table 37-40. PPP DeMux Interrupt Queue Entry Field Descriptions

Offset	Bits	Name	Description
0x00	0	V	Valid interrupt entry 0 This interrupt queue entry is free and can be used by the RISC. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	W	Wrap bit. When set, this is the last interrupt entry in the circular table. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	2–3	—	Reserved. Should be cleared.
	4	BSY	Busy condition. The RxBD table associated with this sub-frame is busy. sub-frames were discarded due to this condition.
	5	LE	Length Error. Indicates a Length Error condition on a sub-frame. It happens when a sub-frame length exceeds the length of the whole super-frame.
	6–13	—	Reserved. Should be cleared.
	14	FRG	For Termination mode: Rx PPP mux fragment interrupt. A fragment was received and one or more sub-frame were extracted by the de-mux process. In case of an error two bits are set. .
	15	—	Reserved. Should be cleared.
0x02	Hword	Offset (to DFT)	This field holds the offset to the DeMUX fragment table (DFT) from the DFT base. This directs the host to the fragment on which this sub frame has been received. Once all the sub frames are processed the host has to change the STATE of this DFT entry. The address to the entry is calculated in the following way: DFT pointer+(offset*0x20).
0x04	Word	QD pointer	This field holds the pointer to the queue Descriptor to which the Sub Frames were assigned to.

37.20.6 PPP Mux Interrupt Queue Entry

The mux process share the event register with the demux. The management of the interrupt queue is done in the Mux Management Table described at Table 37-30. Masking the interrupts is defined in the queue descriptor of the mux queue by the INTMSK bit. See Figure 37-32. Figure 37-52 illustrates the interrupt queue entry for mux process.

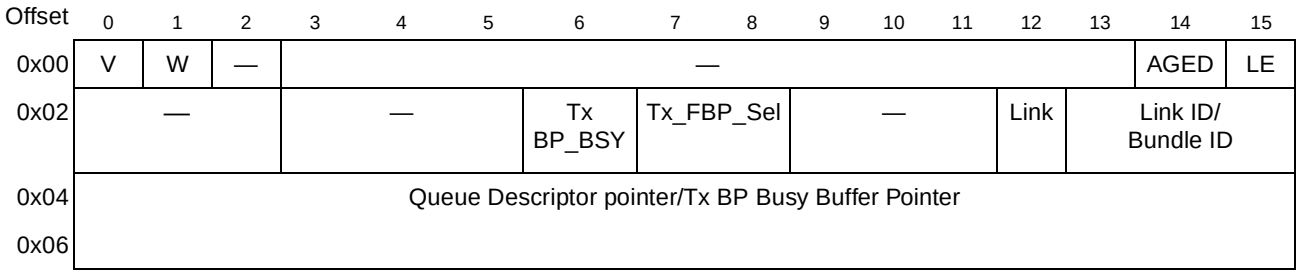

Figure 37-52. Mux Interrupt Queue Entry

Table 37-41 describes PPP Demux Interrupt Queue Entry fields.

Table 37-41. PPP Mux Interrupt Queue Entry Field Descriptions

Offset	Bits	Name	Description
0x00	0	V	Valid interrupt entry 0 This interrupt queue entry is free and can be used by the RISC. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	2	W	Wrap bit. When set, this is the last interrupt entry in the circular table. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	2–13	—	Reserved. Should be cleared.
	14	AGED	A Tx BD was dropped due to aging mechanism if enabled.
	15	LE	Length error indication. The length of the sub frame exceeds the max allowed length of a sub-frame.
	0–5	—	Reserved.
	6	Tx_BP_BSY	Tx Buffer Pool Busy. Set when a Transmitter free buffer pool Busy condition occurs. It means no room is available for the buffer return on transmission. Important: This is a special event and will generate an interrupt regardless of the condition of the counter reaching the desired threshold.
	7–8	Tx_FBP_Sel	Tx_FBP_Sel - Indicates the Buffer Pool on which the busy conditions occurred.
	9–11	—	Reserved.
	12	Link	0-Indicates a ML event. 1-Indicates a link event.
	13–15	Link/ Bundle ID	The link ID on which the event occurred in case this is a link event, or the Bundle ID in ML/MC setup.
0x04	Word	Queue Descriptor/ Tx BP Busy Buffer Pointer	This field contains the pointer to the Queue Descriptor where the sub-frame event occurred. In case of Transmit Buffer Pool busy this entry contains the buffer pointer which has no room in the FBP due to FBP_Busy conditions.

37.20.7 PPP Mux/Demux Event Register

The Mux and Demux processes share the CEVTER event register see Section 20.4.4, “RISC Timer Event Register (CETER)/Mask Register (CETMR).” This register contains the event bit which reports events recognized by the Mux and the Demux tasks. On recognition of an event the task sets its corresponding VTxx bit. The bit is determined by the SNUM of the process which defines it’s VT (Virtual Task) number.

In the event of an Interrupt queue overflow there is an indication in the MMT and in the DMT tables respectively. The bit IQOV is set and indicates the event that there is no space left in the interrupt queue for a new entry. Theses bits are status bits from the QUICC Engine block and should never be cleared by the host. They will be updated by the QUICC Engine block upon every event.

37.21 Bus Selection

Table 37-42 describes the location of the bits which control the bus selection of each external data structure.

Table 37-42. Bus Selectors Location

Structure	Location
Data buffers	BMR[DTB]: Bundle Mode Register, bit 6.
BD’s	BMR[BDB]: Bundle Mode Register, bit 7
WBD ring	BMR[BDB]: Bundle Mode Register, bit 7
TX Free Buffer Pool tables	BMR[BDB]: Bundle Mode Register, bit 7
RX Free Buffer Pool table	BMR[BDB]: Bundle Mode Register, bit 7
Interrupt queues	BMR[BDB]: Bundle Mode Register, bit 7
Queue Descriptors	BMR[BDB]: Bundle Mode Register, bit 7
Fragment Descriptors	BMR[BDB]: Bundle Mode Register, bit 7
Demux Fragment table	DMX_MNG[BIB]: Demux Management Table, offset 0, bit 7
Demux Interrupt Queue	DMX_MNG[BIB]: Demux Management Table, offset 0, bit 7
Mux Interrupt Queue	Mux Management Table, offset 0x02, bit 7 [IB]

37.22 MCC Initialization and Commands for PPP Mode

The following is a general sequence for initializing the MCC and its channels after reset.

- Program the parallel I/O port interface for the TDMs to be used.
- Program the SI’s SIRAM and related registers.
- Initialize all MCC global parameters.
- Initialize MCC channels specific parameters corresponding to each Link Parameter Table (LPT) used. Also configure all relevant data structures.
- Initialize the Super-channel Table.
- Enable Super-channel mode for the MCC transmitter.

- Issue MCC INIT TX according to the number of channels in the setup.
- Issue MCC INIT RX according to the number of channels in the setup.
  — (Could use MCC INIT RX AND TX command as well instead of the two last steps)
- Issue INIT PPP Rx & Tx Link commands for each link (described below.)
- Issue INIT PPP Rx/Tx BACK-END commands as described below if Rx/Tx ML MC or De-MUX processes are enabled.
- If required, issue INIT PPP MUX/De-MUX Processes command as described below.
- Enable the TDM.

37.22.1 PPP Host Commands

When working in ML/MC PPP mode, the following commands must be issued by writing to CECR. This command enables the three tasks working as back-end in the PPP microcode. The commands should be issued before enabling any PPP operation.

All MCC commands are still valid and the new commands should be issued in addition to the PPP specific commands. The reason for this is the fact that the old MCC commands are resetting the MCC channels' FIFOs while the new commands do not effect the FIFO.

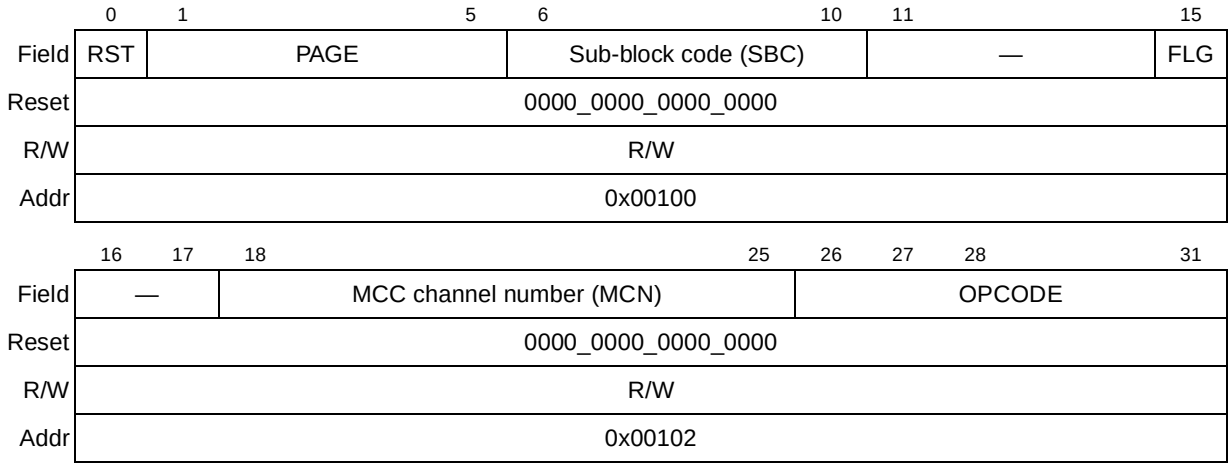

Figure 37-53. QUICC Engine Command Register (CECR)

Table 37-43. CECR Field Descriptions

Bit	Name	Description
0	RST	Software reset command. Set by the core and cleared by the RISC. When this command is executed, RST and FLG bit are cleared within two general system clocks. The QUICC Engine reset routine is approximately 60 clocks long, but the user can begin initialization of the QUICC Engine block immediately after this command is issued. RST is useful when the core wants to reset the registers and parameters for all the channels (UCCs, SPI, MCC) as well as the RISC and RISC timer tables. However, this command does not affect the serial interface (SI) or parallel I/O registers.
1–5	PAGE	Indicates the parameter RAM page number associated with the sub-block being served. See the SBC description for page numbers.

Table 37-43. CECR Field Descriptions (continued)

Bit	Name	Description
6–10	SBC	Sub-block code. Set by the core to specify the sub-block on which the command is to operate. For a listing of the SBC values, see Table 20-3. Set according to OPCODE[28-31]. Refer to Table 37-44.
15	FLG	Command semaphore flag. Set by the core and cleared by the RISC. 0 The RISC is ready to receive a new command. 1 The CECR contains a command that the RISC is currently processing. The RISC clears this bit at the end of command execution or after reset.
16–17	—	Reserved
18–25	MCN	MCC channel number. Specifies the first channel number associated to the link in case of MCC-PPP command.
26–31	OPCODE	Operation code. This field is extended from 4 bits to 6 bits for the PPP protocol. For the PPP operation the following opcodes are valid: INIT PPP Rx link - Opcode= 0b'011011 INIT PPP Tx link - Opcode= 0b'001011 INIT PPP Rx & Tx Link - Opcode= 0b'101011 INIT PPP Rx back-end - Opcode= 0b'011101 INIT PPP Tx back-end - Opcode= 0b'001101 INIT PPP back-end - Opcode= 0b'101101 INIT DE-MUX Process- Opcode= 0b'011110 INIT MUX Encapsulation Process- Opcode=0b'001110 INIT PPP MUX Processes - Opcode=0b'101110

The following table describes the PPP host commands:

Table 37-44. PPP Commands

Command	Description
INIT PPP Rx link	This command initializes the correct state for PPP receiver operation. MCN should be point to the channel which is mapped to the LPT. The host should issue this command for each link in the system. It should be issued AFTER the MCC INIT Rx command.
INIT PPP Tx link	This command initializes the correct state for PPP transmitter operation. MCN should be point to the channel which is mapped to the LPT. The host should issue this command for each link in the system. It should be issued AFTER the MCC INIT Tx command.
INIT PPP Rx & Tx Link	This command combines both previous commands.
INIT PPP Rx back-end	Initializes the Rx back-end tasks of the PPP. This commands initializes the Rx Packet reconstruction task. Should be issued if Rx ML MC is enabled or De-MUX operation is needed.
INIT PPP Tx back-end	Initializes the Tx back-end tasks of the PPP. This commands initializes the Tx fragmentation process. Should be issued if Tx ML MC is enabled.
INIT PPP back-end	Initializes the Tx back-end and the Rx back-end tasks. Combines the both previous commands
INIT DE-MUX Process	Initializes the Rx De-Mux process This command should be issued following the back-end initialization
INIT MUX Encapsulation Process	Initializes the Tx MUX encapsulation process.
INIT PPP MUX Processes	Initializes both, the Tx MUX encapsulation process and the receive de-mux process.

37.22.2 Dynamic Addition and Removal of a Link

The user may want to dynamically add links into a specific bundle, or remove links from a bundle. The user should allocate memory space which can accommodate the maximum number of links expected to be active in the bundle. When initializing the data structures a smaller number can be used, but it enables adding more links if needed. The removal and adding of a link to a bundle is done by the host by setting a few parameters.

37.22.2.1 Removal of Link

For removing a link from a bundle, the host has to execute the next steps:

- Clear the ML bit in the LMR register placed in the Link Parameter Table.
- Clear the Link entry, according to the Link ID, in all the Classes Extension Tables of the bundle as described in Table 37-16.
- Update the BPT[No_Links] parameter, so now it will be equal to the new no. of links in the bundle

NOTE

When removing a link from a bundle, plain PPP traffic is still processed by the RISC if available on the link. For completely removing the traffic one can change the SI RAM using the shadow RAM.

37.22.2.2 Addition of Link

To add a link in a bundle, the user is required to execute the next steps:

- Prepare the LPT structures, by setting the LPT(BNDLPTR) parameter
- Update the BPT[No_Links] parameter, so now it will be equal to the new number of links in the bundle.
- For each of the classes which are active in the bundle do the following:
  - Read the CPT[Rx MaX] value and put this values to CPT[RxCLx_SQ] of the appropriate entry which correspond to the Link ID of the link which is currently added.
  - Set the Valid bit in this entry. See 37.13.4 for description of each entry.
- Set the LMR[ML] bit.

NOTE

Adding a link to a bundle assumes there was a link that was previously removed from the bundle. i.e. the system has allocated memory for the data structures needed for fragmentation process.

37.23 MURAM Usage

37.23.1 Summary

Table 37-45 summarizes the PPP microcode's usage of multi-user RAM.

Table 37-45. RAM Usage Table

Structure	RAM Usage (bytes)	Pointer Location	Remarks
LPT	268	—	Free area for temporary parameters = 64 bytes
BPT	128	—	—
CPT	128	—	—
CPT Extension	32	CPT	—
Link Statistics Table	48	LPT	—
RxIB	32	LPT	Pointed by Rx_IB_ptr
Tx_LWFQ_ptr	64	LPT	—
Int_TxQD	16	LPT	Only if using external Tx QD. Pointed by Int_TxQD_ptr.
LInt_Frg	64	LPT	Pointed by Tx_LInt_Frg_Ptr
Int_RxQD	32	LPT	Only if using external Rx QD or Rx DeMUX. Pointed by Int_RxQD_ptr.
TxFBPT_BASE	16	BPT	Tx Free Buffer Pool parameter table.
RxFBPT_BASE	16	BPT	Rx Free Buffer Pool parameter table.
CLS Convert Table	16	BPT	Pointed by CLS Convert Table ptr.
CWFQ	64	BPT	—
Packets Reconstruction Management	64	MCC global parameter RAM	—
Packets Reconstruction Table	2 *Packet Reconstruction request entries	PRM	—
SB_mngt_tbl	32	BPT	Pointed by ShB_mngt_tbl_Base.
Int_MLQD	16	CPT	Only if using external Tx QD. Pointed by Int_MLQD_ptr.
Status Ring	nibble*(number of WBD entries)	CPT	—
Demux Management Table	64	DeMUX Page	—
Mux Management Table	56 + (16 if using Ext TxQD)	MUX Page	—

Table 37-45. RAM Usage Table (continued)

Structure	RAM Usage (bytes)	Pointer Location	Remarks
Int Queue parameter Table	32* number of interrupt queues	—	—
MUX parameter Table	64* number of Muxed queues	MMT	—

37.23.2 Example

To determine multi-user RAM usage, consider the following example. Assume a system with 2 bundles, 4 links per bundle, External QDs, and 8 classes per Bundle. Also assume that the number of fragments under the WBD ring is 200 (this means that the Status Ring Base allocates 100 bytes per CPT; see Section 37.16.1, "WBD Ring and Status Ring Size"). Also assume external Demux Fragment Table entries.

The usage of the multi-user RAM would then be as follows:

1. 2 (BPT) * 128= 256 bytes (0x100)
2. 4 (LPT) * 256 * 2 (# bundle) = 2048bytes (0x800)
3. 8 (CPT) * 128 * 2 (# bundle) = 2048 bytes (0x800)
4. 8 (CPT Ext) * 32 *2 (# bundle) = 512. (0x200)
5. 8 (LInt_Frg) * 64 = 512 bytes (0x200)
6. 8 (#links) * (Link Statistics Table) 64= 512 (0x200)
7. (SB_mngt_tbl) * 32* 2 (# bundle)= 64 bytes (0x40)
8. 8 (# links) * (LWFQ) * 64 = 512 bytes (0x200)
9. 8 (# links) (Int_TxQD_PTR)* 16= 128 bytes (0x80)
10. 8 (#links) (RxIB)*32= 256 bytes (0x100)
11. 8 (#links) (RxQD_PTR)*32=256 bytes (0x100)
12. 2 (# bundle) (CWFQ) * 64= 128 bytes (0x80)
13. 2 (# bundle) (FBPT_BASE) * 32 = 64 bytes (0x40)
14. 2 (# bundle) (FPTB)*16 = 32 bytes (0x20)
15. 2 (# bundle) (CLS Convert Table) * 16= 32 bytes (0x20)
16. (Packets Reconstruction Table Base) * (32 req entries*2) = 64 bytes (0x40)
17. (Packets Reconstruction Management) = 64bytes (0x40)
18. [8 (# Class) (Status Ring)*100]* 2(# bundle) = 1600 bytes (0x640)
19. [8 (# Class) (Int_MLQD)*16]* 2(# bundle) =256 bytes (0x100)
20. (Demux Management Table) * 64 = 64 bytes (0x40)
21. (Mux Management Table) * 56 = 56 bytes (0x38)
22. 2*7 (#Interrupt queue parameter table)* 16= 224 bytes (0xE0)

Therefore, the sum for total multi-user RAM usage for this example would be ~ 10.1K bytes.

Chapter 38
Serial ATM Microcode

The serial ATM microcode (SAM) complies with the ITU-T I.432 (transmission convergence sublayer) for SDH-based ATM systems. From the perspective of the QUICC Engine block, the SAM operates on ATM cells transferred over the SI through the MCC and UCC. Figure 38-1 shows the structure of the SAM.

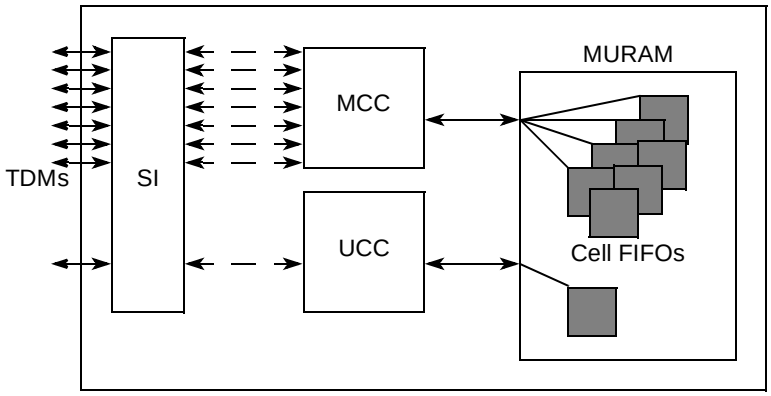

Figure 38-1. Serial ATM Microcode Structure

Each MCC controls 8 TDMs, the MCC can control more TC layers than TDMs, each ATM-based TDM channel has its own cell FIFO ring. Each UCC controls one TDM link and therefore one TC layer. The routing of cells to either an MCC or UCC based TC layer is programmed in the SIRAM.

38.1 Features

The main features of the SAM include the following:

- Operates on both MCC and UCC
- Runs concurrently with MCC SS7, HDLC and Transparent channels
- Eight TDM channels routed by the SI to 64 Microcode TC layer blocks
  - — Protocol-specific overhead bits may be discarded or routed to other controllers by the SI
  - — Performing ATM TC layer functions (according to ITU-T I.432)
  - — Transmit (Tx) SAM features are as follows:
    - – Cell HEC generation
    - – Payload scrambling using self synchronizing scrambler (programmable by the user)
    - – Coset generation (programmable by the user)
    - – Cell rate decoupling by inserting idle cells
    - – Programmable cell FIFO size

— Receive (Rx) SAM features are as follows:
  – Cell delineation using bit by bit HEC checking and programmable ALPHA and DELTA parameters for the delineation state machine
  – Bit and byte synchronous cell delineation modes
  – Payload descrambling using self synchronizing scrambler (programmable by the user)
  – Coset removing (programmable by the user)
  – Filtering idle/unassigned cells (programmable by the user)
  – Performing HEC error detection and single bit error correction (programmable by the user)
  – Generating loss of cell delineation status/interrupt (LOC / LCD)
  – Programmable cell FIFO size
- Supports the TC layer and PMD (physical medium dependent) WIRE interface (according to the ATM-Forum af-phy-0063.000)
- Statistical data per TC layer via cell counters

38.2 Microcode TC Layer (MTC)

The channels present within TDM frame are connected to an MTC, the MTC is the entity responsible for performing the ITU-T I.432 specific tasks. It is also responsible for interfacing to the SI through the MCC and/or the UCC and provides the bridge from the ATM/IMA microcodes to the physical transmission medium. The MTC relationship to other QUICC Engine module resources is depicted in Figure 38-2.

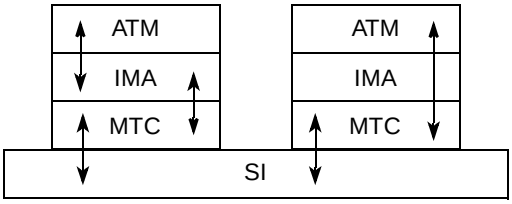

Figure 38-2. QUICC Engine ATM Stack with MTC

On a per-MTC basis, the MTC can be configured to pass cells to/from the IMA microcode or directly to/from the ATM controller of the QUICC Engine block.

38.2.1 Transmit MTC

The transmit MTC architecture is illustrated in Figure 38-3.

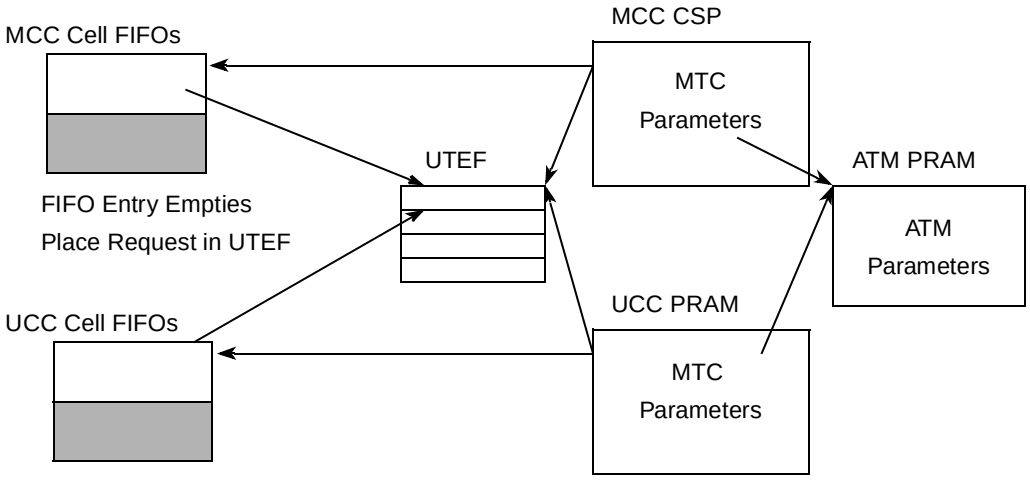

Figure 38-3. MTC Transmit Architecture

Each MURAM-based cell FIFO ring is unique to the MTC controlling the ring. The size of the Tx cell FIFO ring is programmable. Regardless of the QUICC Engine peripheral controlling an MTC, the programming model is compatible. The MTC is independent of the QUICC Engine peripheral on which the cells are generated.

When a cell FIFO entry is emptied, a request is made to the ATM controller for a cell to be transferred to the FIFO, and the UCC or MCC moves to the next cell FIFO entry in the ring to begin transmitting the next cell. The request is placed into the UTOPIA emulation FIFO (UTEF). The ATM microcode polls the UTEF, and when an entry is added this triggers the ATM/IMA controllers in the QUICC Engine block to deliver a cell to the emptied FIFO entry. As Figure 38-3 illustrates, more than one MTC can be directed to the same UTEF. This configuration is analogous to a multi-PHY configuration of the UTOPIA bus. Multiple MTCs place requests into the same UTEF, and each MTC routes the received cells to the ATM layer through the same ATM Parameter RAM. Each MTC has its own PHY identifier that the ATM controller interprets as a UTOPIA PHY address. Requests from different MTCs to a shared UTEF are handled in the order in which they are added to the UTEF. This emulates UTOPIA polling. A faster PHY has more requests added to the UTEF, which is analogous to more Clav assertions.

The ATM parameter RAM (and hence the ATM controller) must be that of UCC1-8.

38.2.1.1 MCC Transmitter

When an MCC channel is ATM-based, the MCC Tx channel must be programmed as a super channel. The MCC HDLC, SS7, PPP and transparent channels can coexist alongside ATM-based MCC channels. Also, the super channel table must be configured in the MURAM.

When the MCC controls an MTC, the MTC parameters reside in the channel-specific parameters (CSP) for the MCC super channel configured to operate as an MTC layer. The MCC transmit super channel number used for any MTC after subtracting 2 must be divisible by 4. 16-bit super channels should be used

for SAM-based MCC channels, which yields the best overall performance for the SAM when the MCC is used.

The MCC begins transmitting the cell by accessing the current entry in the cell FIFO. It transmits one byte at a time, and the MTC passes it four bytes of the cell payload from the current cell FIFO entry—except when the HEC byte is passed to the MCC and the MTC passes only one byte to the MCC. After the MTC passes all the cell payload to the MCC for transmission, the current cell FIFO entry is emptied and the cell FIFO extract pointer (MTC_TX_CF_XP) is incremented. The MTC then starts to pass the cell to the MCC from the entry to which the incremented MTC_TX_CF_XP to the MCC is pointing. Meanwhile, the MTC requests that a cell be delivered from the ATM or IMA microcode to the emptied cell FIFO entry. This cell is delivered before the MCC transmitts the cell present at the incremented MTC_TX_CF_XP. Otherwise, an underrun condition occurs.

38.2.1.2 UCC Transmitter

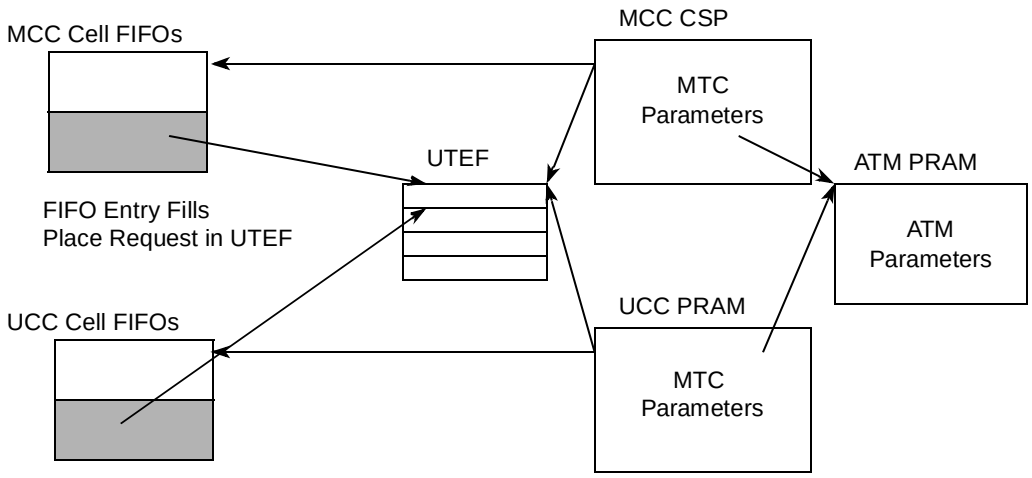
When a UCC controls an MTC, the UCC Parameter RAM should be used to hold the MTC parameters. The UCC transmitter scheme is similar to that of the MCC, except that the UCC transmits four bytes at a time save the HEC byte. The MTC behaves in exactly the same way as the MCC, passing four bytes of the cell payload from the current cell FIFO entry until all of the cell is transmitted.

The UCC that runs the SAM microcode must be programmed to operate as a slow communications controller and must be programmed for QMC mode in the GUMR_L.

38.2.2 Receive MTC

The receive MTC architecture is illustrated in Figure 38-4.

Figure 38-4. MTC Receive Architecture



The MTC receive architecture is similar to that of the transmitter. Each MTC has its own programmable cell FIFO receive ring. The ATM microcode polls the receiver UTEF. When a cell is received into the cell FIFO, a request placed into the UTEF, triggers the CPM ATM controller to remove the cell from the FIFO and pass the cell to the ATM or IMA layers. Multiple receive MTCs can use the same UTEF so that multiple MTCs can be behave like a multi-PHY configuration on the UTOPIA bus. One ATM controller

processes cells received from multiple TC layers through a single ATM controller's PRAM. Of course, each MTC can have its own unique non-shared PRAM and therefore its own UTEF.

The ATM PRAM must be that of UCC1-8, so the SNUM used for the ATM controller must be UCC1-8.

38.2.2.1 MCC Receiver

When the MCC controls the MTC, the CSP contains the MTC parameters. For the receiver, no super channel should be enabled for any ATM-based MCC channels. The SIRAM entries corresponding to the ATM-based MCC channels must have the SUPER bit cleared. MCC HDLC, SS7, PPP and transparent channels can coexist alongside ATM-based MCC channels.

Each MCC channel works on 2 bytes at a time, and after 4 bytes are received they are passed to the MTC. The MTC performs the ITU-T I.432 cell delineation on the 4 bytes by checking whether a valid HEC is found. When the receiver is synchronized, the MTC uses the first 4 bytes of the cell after SYNC state is reached to start building a cell in the first cell FIFO entry. The cell is then built 4 bytes at a time. When a full cell is received, MTC_RX_CF_FP is incremented and a request is placed in the UTEF. The next 4 bytes passed to the MTC from the MCC are used to start building a new cell in the FIFO ring. The ATM microcode processes the fully received cell, and when cell processing is complete it releases this cell FIFO entry by incrementing MTC_RX_CF_XP. The cell processing must complete before the MCC receives another cell in entirety or an overrun condition occurs.

38.2.2.2 UCC Receiver

When a UCC controls an MTC, the UCC PRAM should be used to hold the MTC parameters. The UCC transmitter scheme is similar to that of the MCC, except that the UCC receives works on four bytes at a time and passes this directly to the MTC. The MTC behaves in exactly the same way as the MCC, passing 4 bytes of the cell payload to the current cell FIFO entry until all of the cell is received.

The UCC that runs the SAM microcode must be programmed to operate as a slow communications controller and must be programmed for QMC mode in the GUMR_L.

38.2.3 SAM With The Serial Interface

The serial interface defines which timeslots on each of the TDMs are passed to which QUICC Engine peripheral and, for the MCC, which MCC channel. It offers a very flexible TDM mapping scheme for ATM data. It is possible to achieve the following with the SAM:

- More than 1 ATM stream on any given TDM
- More TC layers than TDMs

Figure 38-5 illustrates how to use the TDM to achieve both of these goals:

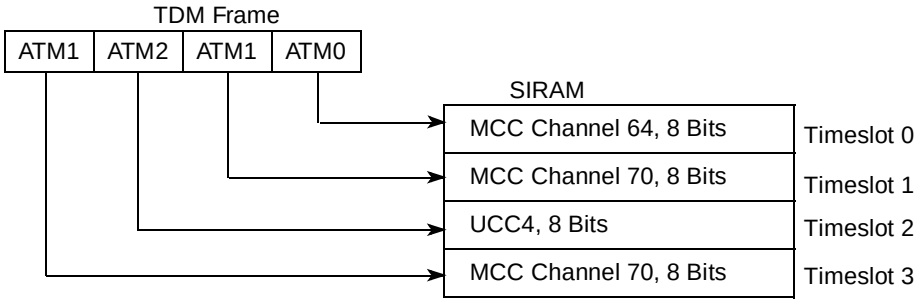


Figure 38-5. SIRAM Flexibility with SAM

The timeslots of one TDM frame can be routed to multiple MCC channels and/or UCCs. Figure 38-5 depicts a TDM stream with four timeslots and three ATM streams. ATM stream 0 in timeslot 0 is routed to MCC channel 64, which is programmed to be an ATM channel (MTC). Similarly, ATM stream 1 in timeslots 1 and 3 is routed to MCC channel 70, which is also an ATM-based MCC channel. Finally, ATM stream 2 on timeslot 2 is routed to UCC4, which is programmed to operate as an MTC.

To have more TC layers than TDMs, each MCC channel active in the SIRAM can be configured as an ATM channel in the CSP for that channel. Up to 64 MTCs can be supported, each requiring 256 bytes of MURAM, which is equivalent to 4 CSP [4*64] worth of MURAM. For example, for an application that requires 16 TC layers running at E1 rates with only 8 TDMs available in the system, the solution is to overclock each TDM at 2*E1 rate and pass 2 ATM streams on each of the 8 TDMs. Use the SIRAM to route each ATM stream to a unique MCC channel programmed to operate as an MTC.

38.2.4 I.432 Functionality

During transmission of a cell, the MTC performs cell header HEC generation, a coset on HEC through a programmable coset field, and scrambling using generator polynomial $x^{43} + 1$. The HEC is generated using the polynomial $x^8 + x^2 + x + 1$. The coset polynomial $x^6 + x^4 + x^2 + 1$ is added (modulo 2) (programmable by the user) to the calculated HEC octet. When the transmit FIFO is empty, the MTC inserts idle cells (counted in ICC) and optionally generates an underrun interrupt to the core. The MTC transmit function also includes a transmit cell counter (TCC).

The MTC receive functions include cell delineation, cell payload descrambling, HEC verification, and correction and idle/unassigned cell filtering. For cell delineation the MTC searches the incoming bit stream in two modes, bit synchronous or byte synchronous. In bit synchronous mode the MTC looks at every 33rd bit received and checks for a valid HEC. In byte synchronous mode the MTC checks every byte for a valid HEC. While searching for the cell boundary, the cell delineation state machine is in HUNT state. When a correct HEC is found, the MTC locks on the particular cell boundary and enters the PRESYNC state, which indicates that the previously detected HEC pattern is not a false indication. If a correct HEC pattern is false, an incorrect HEC is received within the next DELTA cells. If an incorrect cell is detected, then a transition to the HUNT state is made. If an incorrect HEC is not detected in the PRESYNC state, a transition to the SYNC state is made after DELTA cells. In the SYNC state, the MTC is assumed to be synchronized so that other functions can be applied to the received cell. A transition back to the HUNT state is made only after ALPHA consecutive incorrect HEC patterns are detected. When the cell delineation enters or leaves the SYNC state an interrupt can optionally be generated to the core.

The cell delineation state machine is shown in Figure 38-6. The ALPHA and DELTA parameters determine the robustness of the delineation method. ALPHA determines the robustness against false alignment due to bit errors. DELTA determines the robustness against false delineation in the synchronization. Both parameters are programmable for each TC block and are provided to help tune the system according to the line error characteristics of a specific application.

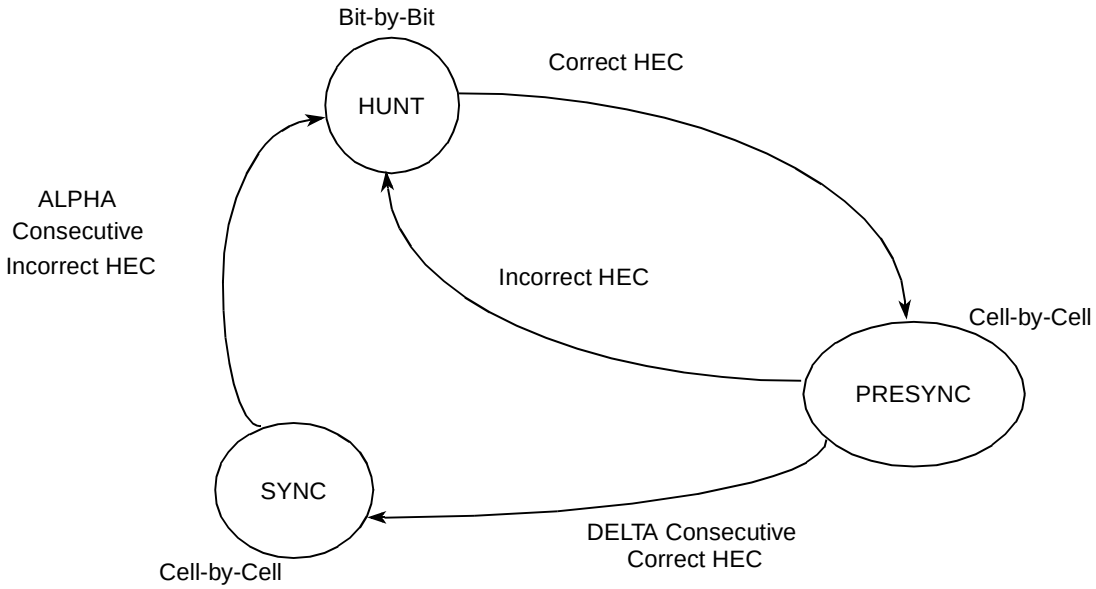

Figure 38-6. TC Cell Delineation State Machine

The MTC descrambles (programmable) the cell payload using the self-synchronizing descrambler with a polynomial of $x^{43} + 1$.

The HEC calculation is a CRC-8 calculation over the first four octets of the ATM cell header. The MTC verifies the received HEC using the accumulation polynomial, $x^8 + x^2 + x + 1$. The coset polynomial $x^6 + x^4 + x^2 + 1$ is added (modulo 2) to the received HEC octet before comparison with the calculated result (programmable).

The MTC can perform single bit error correction on the header. If multiple bit errors are found in the HEC, the cell is discarded. If the single bit error correction mode is not enabled (MTC_MODE[SBC] = 1), the cell is also discarded when a single bit error is found in the header. The MTC references a correction table in the multi-user RAM (MURAM) in order to determine if correction is possible.

When the cell delineation state machine is in the SYNC state, the HEC verification state machine (see Figure 38-7) implements the correction algorithm. This state machine ensures that a single cell header is corrected at a time. If consecutive cells are detected with single bit errors in their headers, only the first cell error is corrected and the rest are discarded. This state machine reduces the probability of the delivery of cells with erroneous headers under bursty error conditions.

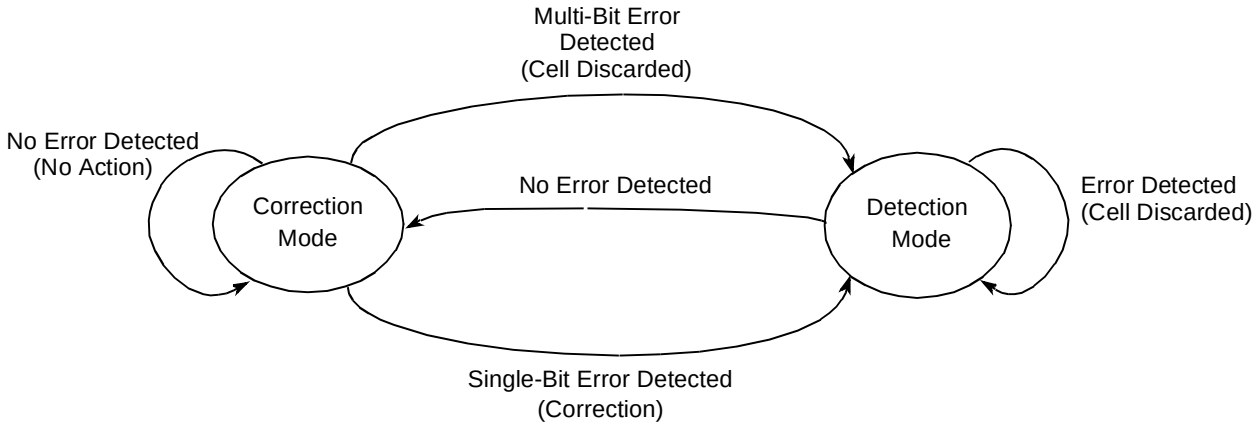

Figure 38-7. HEC: Receiver Modes of Operation

The MTC can also perform idle/unassigned cell filtering. Both features are programmable (MTC_MODE[CF]). Cells that are detected to be idle/unassigned are discarded, that is, not forwarded to the ATM controller in the QUICC Engine module. The MTC receive function also includes cell statistics and maintains counters for received cells (RCC), corrected cells (CCC), filtered cells (FCC) and erroneous cells (ECC). The counters are active when the cell delineation is in the SYNC state, each counter is 16 bits wide and when a counter overflows an interrupt can optionally be generated to the core.

38.3 SAM Programming Model

The MTC parameters are stored in the multi-user RAM (MURAM), Figure 38-8 shows the relationship between internal and external parameters controlled by an MTC:

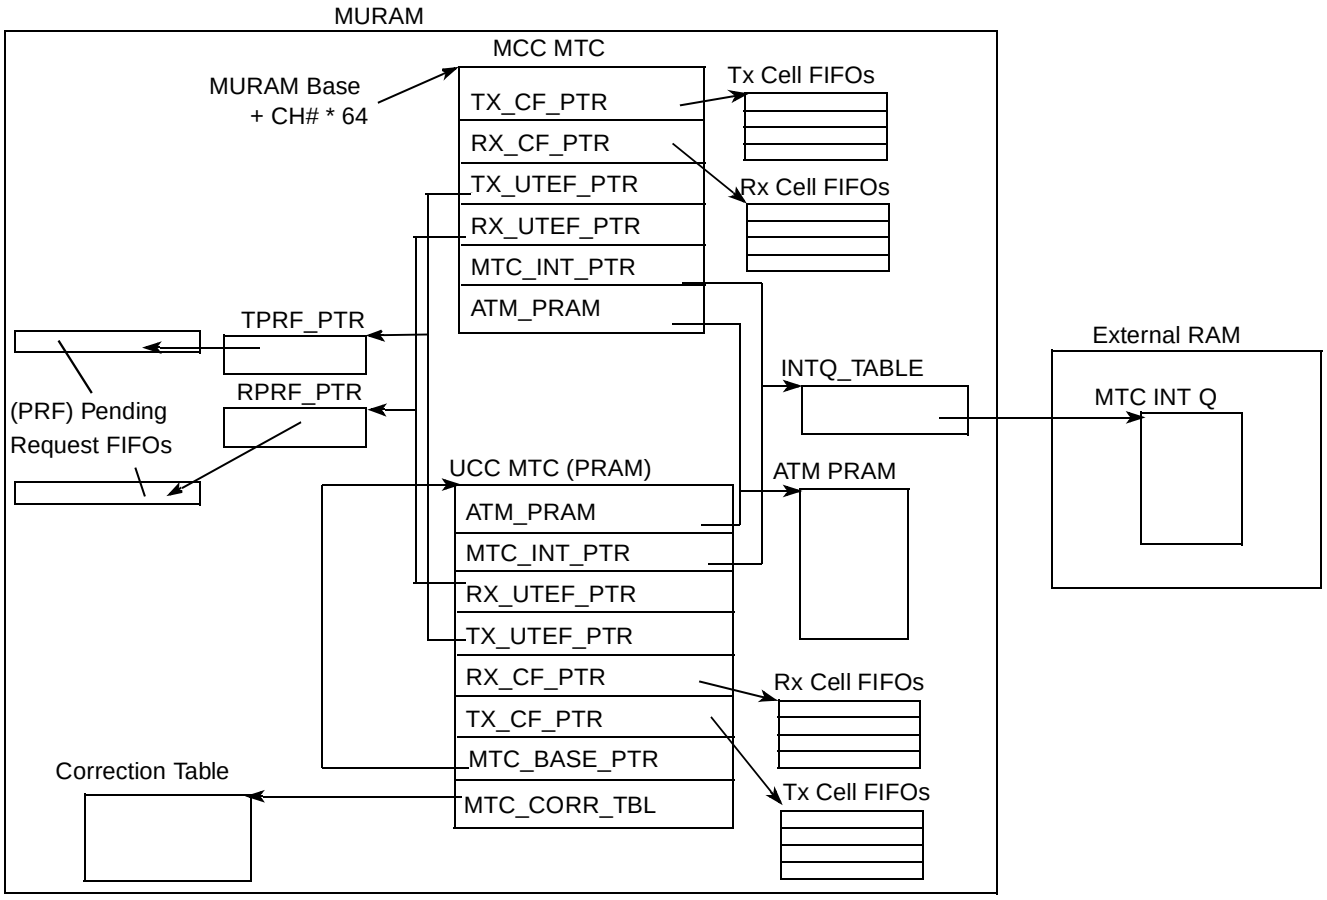

Figure 38-8. MTC Parameters

Each MTC PRAM requires 256 bytes of MURAM, in addition the MTC PRAM must be 256 bytes aligned, when using an MCC channel to hold the MTC Parameters the channel number after subtracting 2 must be a multiple of 4. The base of an MTC PRAM for the MCC is found by using the MCC channel number multiplied by 64 and adding to the MURAM base. The programming model is almost identical when using an UCC or an MCC, the UCC contains an extra parameter, MTC_UCC_BASE_PTR, located in the UCC PRAM. The MTC_UCC_BASE_PTR points to the base of the MTC PRAM for this UCC-controlled MTC. It is recommended but not mandatory that this pointer point to the base of the UCC PRAM for the UCC in serial ATM mode.

Figure 38-8 shows all parameters that consume MURAM bytes with the MTC PRAM. These include cell FIFOs, correction table, the UTEF and its associated pending request FIFO (PRF), the interrupt queue table, and the ATM PRAM. Each MTC PRAM controls both a transmitter and a receiver for one TC layer. Each MTC has both an Rx and a Tx cell FIFO ring of programmable depth. These cell FIFOs cannot be shared with another MTC. There is a pointer in the MTC PRAM to a transmit UTEF and a receive UTEF can be shared with other MTCs transmitters and receivers, respectively. Configure the TX_UTEF_PTR or RX_UTEF_PTR to reference the same UTEF. Tthe transmit UTEF and Rx UTEF are separate structures and cannot be shared between Tx and Rx. Each UTEF table contains pointers to either an RxPRF or a TxPRF.

Each MTC PRAM has a pointer, MTC_INT_PTR, that points to the interrupt queue table pointers. Multiple MTCs can use the same interrupt queue in external memory. Each MTC can have its own interrupt queue or its interrupts can be directed to a shared queue, which allows the application to prioritize interrupts accordingly. Note that the interrupt queue for an MTC must reside in external memory.

With respect to the ATM controller, each MTC is essentially a PHY, and therefore an MTC has an associated ATM PRAM that can be shared between MTCs or unique to an MTC. There is a direct relationship between the ATM PRAM and an UTEF. MTCs cannot use a common UTEF to reference different ATM PRAM peripherals. If MTCs are configured to use the same UTEF, they must reference the same ATM PRAM.

If correction is enabled (MTC_MODE[SBC] = 0), a pointer, MTC_CORR_TBL, is required for the correction table. All MTCs that require correction should configure MTC_CORR_TBL to the same value.

38.3.1 MTC PRAM

Table 38-1 shows the MTC PRAM.

Table 38-1. MTC Parameter RAM Map

Offset[1]	Name	Width	Description
0x00	MTC_MODE	Hword	MTC Mode. See Section 38.3.1.1, “MTC Mode Register MTC_MODE.”
0x02—0x05	—	—	Reserved. Initialize to 0
0x06	MTC_RCC	Hword	MTC Received Cells Counter. Counts the number of received cells that are neither filtered, corrected or have any errors. This counter is only active when the cell delineation is in the SYNC state.
0x08	MTC_INT_MASK	Hword	MTC Interrupt Mask. This interrupt mask has the same bit definitions as an MTC Interrupt Queue Entry Event field. See Section 38.3.1.5, “MTC Interrupt Table And Queues,” for more details.
0x0A	MTC_FCC	Hword	MTC Filtered Cells Counter. Counts the number of filtered cells that are received by this TC layer. If MTC_MODE[CF] allows the cell to pass through without filtering then the cell is counted in MTC_RCC. This counter is only active when the cell delineation is in the SYNC state.
0x0C	MTC_CCC	Hword	MTC Corrected Cells Counter. Counts the number of corrected cells received by this TC layer. If MTC_MODE[SBC] = 1 then no cells are corrected and the MTC_ECC is used to count these cells. This counter is only active when the cell delineation is in the SYNC state and the ITU-T I.432 specification correction mode.
0x0E	MTC_ICC	Hword	MTC Idle Cells Counter. Counts the number of idle cells generated by the TC layer transmitter when the Tx Cell FIFO ring is empty. Idle cells generated by the ATM layer are counted here as well as those generated during underrun condition.
0x10	MTC_TCC	Hword	MTC Transmitted Cells Counter. Counts the number of data cells transmitted by this TC layer.
0x12	MTC_ECC	Hword	MTC Errored Cells Counter. Counts the number of cells with multiple bit HEC errors or single bit errors that can’t be corrected. This counter is only active when the cell delineation is in the SYNC state.

Table 38-1. MTC Parameter RAM Map (continued)

Offset[1]	Name	Width	Description
0x14	MTC_STATE_TX	Hword	MTC State Transmit. Initialize to 0x8800. See Section 38.3.1.2, "MTC_STATE_TX Register."
0x16	MTC_STATE_RX	Hword	MTC State Receive. Initialize to 0x0000. See Section 38.3.1.3, "MTC_STATE_RX Register."
0x18-0x1B	—	—	Reserved. Initialize to 0.
0x1C	MTC_UCC_BASE_PTR	Word	MTC UCC Parameters Base Pointer. Offset in the MURAM where the MTC PRAM begins. This parameter must point to a 256 byte aligned address and is valid only when the UCC controls an MTC. This parameter is offset from the UCC parameter base. The recommended value is the PRAM base for the UCC controlling the MTC.
0x20	MTC_INT_PTR	Word	MTC Layer Interrupt Table Pointer. Pointer to a MURAM offset where the MTC Interrupt Tables reside. It is recommended that all MTCs program MTC_INT_PTR to the same value. This parameter must be 16 byte aligned. See Section 38.3.1.5, "MTC Interrupt Table And Queues."
0x24	MTC_SCTL	Byte	MTC SDMA Control. Controls the SDMA options for interrupts written to the interrupt queue. See Section 38.3.1.7, "MTC Interrupt Queue SDMA Control."
0x25	MTC_INT_NUM	Byte	MTC Interrupt Number. Required for identifying entries written to the interrupt queue, identifies the source MTC of an interrupt entry in the interrupt queue. See Section 38.3.1.5, "MTC Interrupt Table And Queues."
0x26	MTC_INT_TOF	Byte	MTC Interrupt Transmit Table Offset. Defines which Interrupt Table this MTC uses for the transmitter. The Interrupt Queue Table use by this MTC is found by MTC_INT_PTR + MTC_INT_TOF * 16. It is therefore possible for each MTC to have a separate interrupt queue by programming MTC_INT_TOF to differing values, or to share an interrupt queue setting MTC_INT_TOF to the same value in the MTCs' PRAM. The MTC_INT_TOF must be use a different table than that used by MTC_INT_ROF. It is not possible for any MTC receiver to access the interrupt queue used by any MTC transmitter. See Section 38.3.1.5, "MTC Interrupt Table And Queues."
0x27	MTC_INT_ROF	Byte	MTC Interrupt Receive Table Offset. Defines which Interrupt Table this MTC uses for the receiver. The Interrupt Queue Table use by this MTC is found by MTC_INT_PTR + MTC_INT_ROF * 16. It is therefore possible for each MTC to have a separate interrupt queue by programming MTC_INT_ROF to differing values, or to share an interrupt queue setting MTC_INT_ROF to the same value in the MTCs' PRAM. The MTC_INT_ROF must be use a different table than that used by MTC_INT_TOF. No MTC transmitter can access the interrupt queue used by any MTC receiver. See Section 38.3.1.5, "MTC Interrupt Table And Queues."
0x28-0x3F	—	—	Reserved. Initialize to 0
0x40	MTC_TX_SCRAM_HI	Word	MTC Transmit Scrambler State High Word. Microcode managed parameter initialize to 0.
0x44	MTC_TX_SCRAM_LO	Word	MTC Transmit Scrambler State Low Word. Microcode managed parameter initialize to 0.

Table 38-1. MTC Parameter RAM Map (continued)

Offset[1]	Name	Width	Description
0x48	MTC_TX_ATM_PRAM	Hword	Transmitter ATM PRAM. Identifies which available thread is used to serve as the ATM Parameter RAM. MTC_RX_ATM_PRAM should be programmed to access the same PRAM area as MTC_TX_ATM_PRAM. See Section 38.3.1.8, "MTC Transmit ATM PRAM—MTC_TX_ATM_PRAM."
0x4A	MTC_TX_COSET	Byte	MTC Transmit Coset. XORed with cell HEC before transmission when MTC_MODE[TC] = 0. The recommended value is 0x55. The least significant bit of MTC_TX_COSET is XORed with the least significant bit of the cell HEC. Similarly, the most significant bit is XORed with the HEC msb.
0x4B-0x4F	—	—	Reserved. Initialize to 0
0x50	MTC_TX_CF_BP	Hword	MTC Transmit Cell FIFO Ring Base Pointer. Pointer to MURAM address that is the start of the address of this cell FIFO ring. Must point to a 64 byte aligned address. See Section 38.3.1.9, "Transmit Cell FIFO Ring."
0x52	MTC_TX_CF_EP	Hword	MTC Transmit Cell FIFO Ring End Pointer. Pointer to MURAM address that is the end address of this MTC cell FIFO ring. No entry exists at this address. Must point to a 64 byte-aligned address within the MURAM.
0x54	MTC_TX_CF_FP	Hword	MTC Transmit Cell FIFO Ring Fill Pointer. Updated by the MTC when the ATM controller delivers a cell to the FIFO ring. Microcode managed parameter; initialize to MTC_TX_CF_BP.
0x56	MTC_TX_CF_XP	Hword	MTC Transmit Cell FIFO Ring Extract Pointer. Updated by the MTC whenever a cell is fully transmitted via the SI. Microcode managed parameter; initialize to MTC_TX_CF_BP.
0x58	MTC_TX_PAGE	Word	MTC Transmit Page. Must be programmed to the page base of the ATM controller that this MTC accesses. For example, if this MTC uses UCC2 Tx as the ATM controller SNUM and the default page has not been changed for UCC2 through the Assign Page Host Command, program MTC_TX_PAGE to 0x00008500.
0x5C-0x63	—	—	Reserved. Initialize to 0
0x64	MTC_TX_MPHY_ADD	Word	MTC Transmit Multi Phy Address. Required in order to assign an APC table to this MTC. See Section 38.3.1.10, "MTC Transmit Multi PHY Address—MTC_TX_MPHY_ADD."
0x68	MTC_TX_PLD_PTR	Word	MTC Transmit Payload Pointer. Microcode managed parameter ; initialize to 0.
0x6C-0x6E	—	—	Reserved. Initialize to 0
0x6F	MTC_TX_PLD_CTR	Byte	MTC Transmit Payload Counter. Microcode managed parameter; initialize to 0.
0x70	MTC_TX_UTEF_PTR	Word	MTC Transmit Utopia Emulation Pointer. Pointer to a MURAM address that contains the Utopia emulation FIFO table for this MTC. This parameter must be programmed to a 16-byte aligned address. See Section 38.3.1.11, "MTC Transmit Utopia Emulation FIFO."
0x74	MTC_TX_HEC	Byte	MTC Transmit HEC. Microcode managed parameter initialize to 0.
0x75-0x7F	—	—	Reserved. Initialize to 0.

Table 38-1. MTC Parameter RAM Map (continued)

Offset[1]	Name	Width	Description
0x80	MTC_TSTATE	Word	MTC Transmit State. When using the MCC to control any MTC the MCC channel number associated with an MTC must be aligned to the MTC PRAM base + 128 bytes. For example if the MTC PRAM begins at the offset for MCC channel number 4 (0x100) then MTC_TSTATE must reside at 0x180. Because the MCC expects this parameter to reside at 0x180 and not 0x100, the MCC channel number programmed in the SIRAM should be 6 and not 4. This is true for both the transmitter and receiver. Microcode managed parameter ; Initialize to 0x00800000 regardless of the peripheral used for this MTC (MCC or UCC).
0x84	MTC_ZISTATE	Word	MTC zero-insertion machine state. Microcode managed parameter Initialize to 0x10000207.
0x88	MTC_ZIDATA0	Word	MTC zero insertion high word data buffer. Microcode managed parameter Initialize to 0xFFFFFFFF.
0x8C	MTC_ZIDATA1	Word	MTC zero insertion low word data buffer. Microcode managed parameter Initialize to 0xFFFFFFFF.
0x90-0x99	—	—	Reserved. Initialize to 0.
0x9A	MTC_CHAMR	Hword	MTC Channel Mode Register. This parameter is only valid when the MTC is controlled via an MCC channel, it controls the MCC channel mode of operation. When using the UCC this parameter is reserved and should be set to 0. See Section 38.3.1.4, “MTC Channel Mode Register MTC_CHAMR.”
0x9C-0x9F	—	—	Reserved. Initialize to 0.
0xA0	MTC_RX_SCRAM_HI	Word	MTC Receive Scrambler State High Word. Microcode managed parameter; initialize to 0.
0xA4	MTC_RX_SCRAM_LO	Word	MTC Receive Scrambler State Low Word. Microcode managed parameter; initialize to 0.
0xA8	MTC_RX_ATM_PRAM	Hword	Receiver ATM PRAM. Identifies which available thread is used to serve as the ATM Parameter RAM. It is recommended that MTC_TX_ATM_PRAM is programmed to access the same PRAM area as MTC_RX_ATM_PRAM. See Section 38.3.1.12, “MTC Receive ATM PRAM—MTC_RX_ATM_PRAM.”
0xAA	MTC_RX_COSET	Byte	MTC Receive Coset. XORed with cell HEC before HEC validation when MTC_MODE[RC] = 0. Recommended value is 0x55, the least significant bit of MTC_RX_COSET is XORed with the least significant bit of the Rx cell HEC, similarly the most significant bit is XORed with the HEC msb.
0xAB	MTC_RX_CTR	Byte	MTC Receive Counter. Used when the receiver is the MCC. Microcode managed parameter initialize to 0.
0xAC	MTC_RX_PLD	Hword	MTC Receive Payload. Cell data temporary storage. Microcode managed parameter ; initialize to 0.
0xAE	MTC_SHIFT_CTR_LFT	Byte	MTC Shift Counter Left. Required for cell delineation. Microcode managed parameter ; initialize to 0.
0xAF	MTC_SHIFT_CTR_RGT	Byte	MTC Shift Counter Right. Required for cell delineation. Microcode managed parameter ; initialize to 0.

Table 38-1. MTC Parameter RAM Map (continued)

Offset[1]	Name	Width	Description
0xB0	MTC_RX_CF_BP	Hword	MTC Receive Cell FIFO Ring Base Pointer. Pointer to MURAM address that is the start of the address of this cell FIFO ring. Must point to a 64-byte aligned address. See Section 38.3.1.13, "Receive Cell FIFO Ring," for more details.
0xB2	MTC_RX_CF_EP	Hword	MTC Receive Cell FIFO Ring End Pointer. Pointer to MURAM address that is the end address of this MTC cell FIFO ring. No entry exists at this address. Must point to a 64 byte-aligned address within the MURAM.
0xB4	MTC_RX_CF_FP	Hword	MTC Receive Cell FIFO Ring Fill Pointer. Updated by the MTC when the MTC controller delivers a full cell to the FIFO ring. Microcode managed parameter; initialize to MTC_RX_CF_BP.
0xB6	MTC_RX_CF_XP	Hword	MTC Receive Cell FIFO Ring Extract Pointer. Updated by the ATM Controller whenever a cell is passed to the ATM layer. Microcode managed parameter; initialize to MTC_RX_CF_BP.
0xB8	MTC_RX_HEC	Byte	MTC Receive HEC. Microcode managed parameter ; initialize to 0.
0xB9-0xBB	—	—	Reserved. Initialize to 0
0xBC-0xBF	MTC_RX_PAGE	Word	MTC Receive Page. Must be programmed to the page base of the ATM controller that this MTC accesses. For example, if this MTC uses UCC3 Rx as the ATM controller SNUM and the default page has not been changed for UCC3 through the Assign Page Host Command, program MTC_RX_PAGE to 0x00008600.
0xC0	MTC_RX_MPHY_ADD	Word	MTC Receive Multi Phy Address. Required to perform address compression correctly for this MTC. See Section 38.3.1.14, "MTC Receive Multi PHY Address—MTC_RX_MPHY_ADD and MTC_RX_MPHY_ADD_EXT."
0xC4	MTC_RX_MPHY_ADD_EXT	Word	MTC Receive Multi Phy Address Extension. Required in order to correctly perform address compression for this MTC. See Section 38.3.1.14, "MTC Receive Multi PHY Address—MTC_RX_MPHY_ADD and MTC_RX_MPHY_ADD_EXT."
0xC8	MTC_RX_PLD_PTR	Word	MTC Receive Payload Pointer. Microcode managed parameter; initialize to 0.
0xCC-0xCE	—	—	Reserved. Initialize to 0.
0xCF	MTC_RX_PLD_CTR	Byte	MTC Receive Payload Counter. Microcode managed parameter; initialize to 0.
0xD0	MTC_RX_UTEF_PTR	Word	MTC Receive Utopia Emulation Pointer. Pointer to a MURAM address that contains the Utopia Emulation FIFO Table for this MTC. This parameter must be programmed to a 16 byte-aligned address. See Section 38.3.1.15, "MTC Receive Utopia Emulation FIFO."
0xD4	MTC_RX_CD_PLD	Word	MTC Receiver Cell Delineation Payload. Remainder after cell delineation. Microcode managed parameter initialize to 0.
0xD8	MTC_CD_CTR	Byte	MTC Cell Delineation Counter. Microcode managed parameter; initialize to 0.
0xD9	MTC_ALPHA	Byte	MTC Alpha. ITU-T I.432 Alpha; recommended value is 7.
0xDA	MTC_ALPHA_CTR	Byte	MTC Alpha Counter. Up counter for ALPHA; initialize to 0.

Table 38-1. MTC Parameter RAM Map (continued)

Offset[1]	Name	Width	Description
0xDB	MTC_DELTA	Byte	MTC Delta. ITU-T I.432 Delta; recommended value is 6.
0xDC	MTC_DELTA_CTR	Byte	MTC Delta Counter. Up counter for DELTA; initialize to 0.
0xDD-0xDF	—	—	Reserved. Initialize to 0.
0xE0	MTC_CORR_TBL	Word	MTC Correction Table. Pointer to the correction table that is valid only when MTC_MODE[SBC] = 1. Must point to a 256 byte-aligned address. See Section 38.3.1.16, “MTC Correction Table—MTC_CORR_TBL.”
0xE4-0xFF	—	—	Reserved. Initialize to 0.

1 Offset from MCC base + (MCC channel number * 64) + 128 when using MCC. Offset from UCCx PRAM when using UCC and MTC_BASE_PTR = UCCx PRAM Base.

38.3.1.1 MTC Mode Register MTC_MODE

Each MTC layer block is configured using a TC layer mode register MTC_MODE, as shown in Figure 38-9.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	RXEN	TXEN	RPS	TPS	RC	TC	SBC	CF		BBS	—			IMA	RAD	THD
Offset	0x00															

Figure 38-9. MTC Mode Register MTC_MODE

Table 38-2 describes the MTC_MODE fields.

Table 38-2. MTC_MODE Field Descriptions

Bits	Name	Description
0	RXEN	MTC Layer Rx enable bit. Enables the MTC receiver: 0 MTC Layer Rx operation is disabled. 1 MTC Layer Rx operation is enabled.
1	TXEN	MTC Tx enable bit. Enables the MTC transmitter: 0 MTC Tx operation is disabled. 1 MTC Tx operation is enabled.
2	RPS	Rx Payload DeScrambling 0 Payload descrambling is performed on received payload data. 1 No payload descrambling is performed on received payload data.
3	TPS	Tx Payload Scrambling 0 Payload scrambling is performed on transmitted payload data. 1 No payload scrambling is performed on transmitted payload data.
4	RC	Rx Coset Enable 0 XOR with RX_COSET is done on received HEC. 1 No XOR with RX_COSET is done on received HEC.
5	TC	Tx Coset Enable 0 XOR with TX_COSET is done on transmitted HEC. 1 No XOR with TX_COSET is done on transmitted HEC.

Table 38-2. MTC_MODE Field Descriptions (continued)

Bits	Name	Description
6	SBC	Header Single-Bit error Correction 0 Perform single-bit error correction on the header according to HEC while in SYNC state. 1 Do not perform single-bit error correction on the header. When this bit is cleared, the correction table referenced by MTC_CORR_TBL must be initialized.
7–8	CF	Rx Idle/Unassigned Cells Filtering 00 No cell filtering on Rx cells. 01 Idle cell filtering—idle cells are discarded. 10 Unassigned cell filtering—unassigned cells are discarded. 11 Idle and unassigned cell filtering—both idle and unassigned cells are discarded. The Header of idle cell (ITU-T I.361): b00000000_00000000_00000000_00000001 The Header of unassigned cell (ITU-T I.361): b00000000_00000000_00000000_0000xxx0 Note that physical layer cells bypass the TC layer; they are not filtered. Also note that the filter works on the header only and ignores the HEC.
9	BBS	Bit/Byte Synchronous mode for cell delineation. 0 Bit synchronous. The ATM cells starts at an arbitrary offset within the TDM frame. 1 Byte synchronous. The ATM cell is byte aligned within the TDM frame.
10–12	—	Reserved. Initialize to 0.
13	IMA	IMA mode 0 Rx is not in IMA. 1 Rx is in IMA mode.
14	RAD	Receive ATM Disable 0 Pass cells, except filtered cells, to the ATM or IMA microcode. 1 No cells are passed to the ATM or IMA microcode. The MTC will maintain the cell delineation algorithm and counters will be updated.
15	THD	Transmit HEC disable. 0 Transmit HEC 1 HEC transmission disabled.

38.3.1.2 MTC_STATE_TX Register

MTC_STATE_TX, shown in Figure 38-10, holds the current state of the MTC transmitter. It is required for transmit state fields that require coherency in a multi-RISC environment.

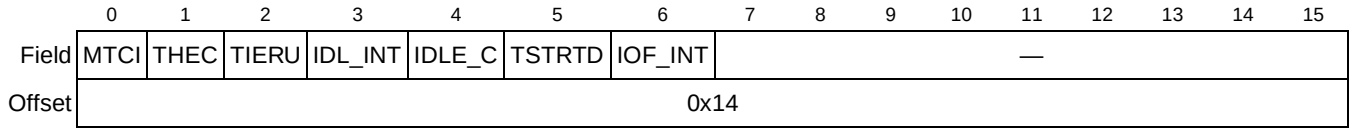

Figure 38-10. MTC_STATE_TX Register

Table 38-3 describes the MTC_STATE_TX fields.

Table 38-3. MTC_STATE_TX Field Descriptions

Bits	Name	Description
0	MTCI	MTC Transmit Idle. Reserved for internal use. Initialize to 1.

Table 38-3. MTC_STATE_TX Field Descriptions (continued)

Bits	Name	Description
1	THEC	Transmit HEC. Reserved for internal use. Initialize to 0.
2	TIERU	Transmit Interrupt Event Register Update. Reserved for internal use. Initialize to 0.
3	IDL_INT	Idle Interrupt. Reserved for internal use. Initialize to 0.
4	IDLE_C	Idle Check. Reserved for internal use. Initialize to 1.
5	TSTRTD	Transmit Started. Reserved for internal use. Initialize to 0.
6	IOF_INT	IOF Interrupt generation. Reserved for internal use. Initialize to 0.
7–15	—	Reserved. Initialize to 0.

38.3.1.3 MTC_STATE_RX Register

MTC_STATE_RX, shown in Figure 38-11, holds the current state of the MTC receiver. It is used to hold receive state fields that require coherency in a multi-RISC environment.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	CFOV	RHEC	WAIT	CM	CDS		RIERU	CFOV_C	—			RCC				—
Offset	0x16															

Figure 38-11. MTC_STATE_RX Register

Table 38-4 describes the MTC_STATE_RX fields.

Table 38-4. MTC_STATE_RX Field Descriptions

Bits	Name	Description
0	CFOV	Cell FIFO Overflow. Reserved for internal use. Initialize to 0.
1	RHEC	Receive HEC. Reserved for internal use. Initialize to 0.
2	WAIT	Cell Delineation Wait. Reserved for internal use. Initialize to 0.
3	CM	Correction Mode. 0 Detection mode. 1 Correction mode. Reserved for internal use. Initialize to 0.
4–5	CDS	Cell Delineation State. 00 HUNT state. 01 PRESYNC state. 10 Reserved. 11 SYNC state. Reserved for internal use. Initialize to 0.
6	RIERU	Receive Interrupt Event Register Update. Reserved for internal use. Initialize to 0.
7	CFOV_C	Cell FIFO Overflow Check. Reserved for internal use. Initialize to 0.
8–10	—	Reserved. Initialize to 0.

Table 38-4. MTC_STATE_RX Field Descriptions (continued)

Bits	Name	Description
11–14	RCC	Receive Counter Code. 0000 Reserved. 0001 Reserved. 0010 Reserved. 0011 MTC_RCC. 0100 Reserved. 0101 MTC_FCC. 0110 MTC_CCC. 0111 Reserved. 1000 Reserved. 1001 MTC_ECC. 1010 Reserved. 1011 Reserved. 1100 Reserved. 1101 Reserved. 1110 Reserved. 1111 Reserved. Reserved for internal use. Initialize to 0.
15	—	Reserved. Initialize to 0.

38.3.1.4 MTC Channel Mode Register MTC_CHAMR

When an MTC is controlled by an MCC channel, the MTC_CHAMR, shown in Figure 38-12, is used to determine whether the channel is an ATM-based channel or HDLC, transparent or SS7 channel.

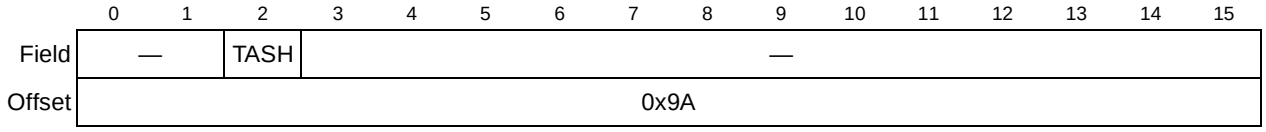

Figure 38-12. MTC Channel Mode Register MTC_CHAMR

Table 38-5 describes MTC_CHAMR fields.

Table 38-5. MTC_CHAMR Field Descriptions

Bits	Name	Description
0–1	—	When MTC_CHAMR[TASH] = 1, these bits are configured according to the description of the MCC controller CHAMR. When MTC_CHAMR[TASH] = 0 initialize theses bits to 0.
2	TASH	Transparent ATM SS7 or HDLC mode. 0 This channel is ATM-based. 1 This channel is not ATM-based. This channel is either an HDLC, Transparent, or SS7 MCC channel.
3–15	—	When MTC_CHAMR[TASH] = 1, these bits are configured according to the description of the MCC controller CHAMR. When MTC_CHAMR[TASH] = 0 initialize these bits to 0.

38.3.1.5 MTC Interrupt Table And Queues

Each MTC interrupt queue holds the interrupt entries for one or more MTCs. Each interrupt queue is controlled through an interrupt table in the MURAM. The interrupt tables must be 16 bytes aligned. Table 38-6 defines the MTC interrupt table parameters. For the application to prioritize interrupts, the SAM supports up to 256 MTC interrupt tables controlled by the MTC_INT_TOF and MTC_INT_ROF in the MTC PRAM. A transmit and receive MTC cannot reference the same MTC interrupt table. Also, two transmit (or receive) MTCs on differing QUICC Engine peripherals cannot access the same MTC interrupt table, For example, a transmit MTC on MCC1 cannot be programmed to use the same MTC interrupt table as a transmit MTC on any UCC. However, multiple transmit MTCs on the same MCC can access the same transmit interrupt table or multiple receivers on the same MCC can access the same receive interrupt table.

Table 38-6. MTC Interrupt Table

Offset[1]	Name	Width	Description
0x00	MTC_INTQ_BASE	Word	MTC or MTCs Interrupt Queue Base. Pointer to external memory to the interrupt queue base for this MTC. This address must be 4 bytes aligned.
0x04	MTC_INTQ_PTR	Word	MTC Interrupt Queue Pointer. Current interrupt queue entry offset. Microcode managed parameter initialize to MTC_INTQ_BASE.
0x08	MTC_INTQ_ENT	Word	MTC Interrupt Queue Entry. Holds the interrupt queue entry. Microcode managed parameter, initialize to 0.
0x0C	MTC_INTE_CTL	Byte	MTC Interrupt Event Control. Used to identify which interrupt bit in the UCCE or MCCE this MTC Interrupt Table Uses. See Section 38.3.1.6, “Event Registers” for more details.
0x0D-0x0F	—	—	Reserved. Initialize to 0.

1 Offset from MTC_INT_PTR + MTC_INT_TOF * 16. Must be 16 bytes aligned in the MURAM.

Figure 38-13 shows the format of an interrupt entry written to the MTC Interrupt Queue.

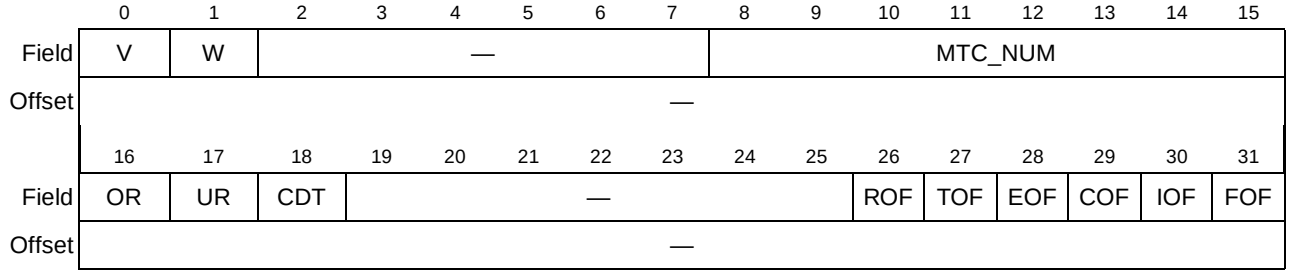

Figure 38-13. MTC Interrupt Queue Entry

Table 38-7 shows the MTC interrupt queue entry field definitions. More than one interrupt bit can be set in the same entry in the interrupt queue.

Table 38-7. MTC Interrupt Queue Field Descriptions

Bits	Name	Description
0	V	Valid. 0 This interrupt entry is not valid; no interrupt entry is present. The host should initialize each entry's V bit to 0. 1 This interrupt entry is valid and the host can process this interrupt entry. The host should clear this field after reading this interrupt entry.
1	W	Wrap. 0 This is not the last entry in the interrupt queue. 1 This is the last entry in the interrupt queue, wraps back MTC_INTQ_BASE after an interrupt is written to the entry with W = 1. The host should initialize this field.
2–7	—	Reserved. Initialize to 0.
8–15	MTC_NUM	MTC Number. This field is copied to the interrupt entry from the MTC_INT_NUM parameter of the MTC PRAM. This field is used to identify which MTC this interrupt entry originates from.
16	OR	Overrun. Rx FIFO OverFlow. Set when Rx FIFO is full and another cell is received. The cell is discarded.
17	UR	Underrun. No ATM cell to transmit. Set when the Tx FIFO is empty and the transmission of a cell is completed. An idle cell is sent. The idle cell header is: 0x00000001 (I.432), whose HEC is: 0x52. The idle cell payload is:0x6A (I.432).
18	CDT	Cell delineation toggled. Set when the cell delineation transitions to or from the SYNC state.
19–25	—	Reserved. Initialize to 0.
26	ROF	Received cell counter overflow Set when the received cells counter passes its maximum value.
27	TOF	Transmitted cell counter overflow Set when the transmitted cells counter passes its maximum value.
28	EOF	Errored cells counter overflow Set when the errored cells counter passes its maximum value.
29	COF	Corrected cells counter overflow. Set when the corrected cells counter passes its maximum value.
30	IOF	Tx Idle cells counter overflow. Set when the Tx idle cells counter passes its maximum value.
31	FOF	Filtered cells counter overflow. Set when the filtered cells counter passes its maximum value.

38.3.1.6 Event Registers

The MCC Event and Mask Register is shown below in Figure 38-14. The MTC_INTE_CTL is used to determine which bit in the event register is set. The corresponding MCCM bit must also be set if the interrupt is to be issued to the core.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	TQOV	TINT	GUN	GOV
MTC_INTE_CTL	0x0	0x0	0x1	0x1	0x2	0x2	0x3	0x3	0x4	0x4	0x5	0x5	—	—	—	—

	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
Field	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE
MTC_INTE_CTL	0x8	0x8	0x9	0x9	0xA	0xA	0xB	0xB	0xC	0xC	0xD	0xD	0xE	0xE	0xF	0xF

Figure 38-14. MCC Event/Mask Register

Table 38-8 details the MTC event register interrupt bits.

Table 38-8. MTC Event Register For MCC

Bits	Name	Description
0, 2, 4, 6, 8, 10, 14, 16, 18, 20, 22, 24, 26, 28, 30	QOV	Queue Overflow. When this bit is set the interrupt queue corresponding to the MTC_INTE_CTL setting has experienced an overflow.
1, 3, 5, 7, 9, 11, 15, 17, 19, 21, 23, 25, 27, 29, 31	MTCE	MTC Event. The interrupt queue corresponding to the MTC_INTE_CTL has experienced an interrupt event.
12	TQOV	Transmit Queue Overflow. TQOV is set (and an interrupt request is generated) by the QUICC Engine module whenever an overflow occurs in the transmit circular interrupt table. This condition occurs if the QUICC Engine module attempts to write a new interrupt entry into an entry that was not handled by the user. Such an entry is identified by V = 1.
13	TINT	Transmit interrupt. When TINT = 1, at least one new entry in the transmit interrupt circular table was generated by MCC. After clearing it, the user reads the next entry from the transmit interrupt circular table and starts processing a specific channel's exception. The user returns from the interrupt handler when it reaches a table entry with V = 0.[1]
14	GUN	Global Underrun. The MCC Transmit FIFO has experienced an underrun. The MCC should be disabled via the SIMxR and reinitialized.
15	GOV	Global Overrun. The MCC Receive FIFO has experienced an overrun. The MCC should be disabled via the SIMxR and reinitialized.

[1] When an MCC channel is ATM based the CUN, the MCC generates the CUN interrupt in the external MCC interrupt queue for the transmitter. Therefore, the Global MCC Parameters, TINTBASE, TINTPTR and TINTTMP must be initialized when the SAM is in use.

For MCC SS7, HDLC and Transparent channels, the interrupt queue or queues for these channels should not correspond to an MTC_INTE_CTL setting. For example, if these MCC channels are using interrupt queue 0, MTC_INTE_CTL should not be cleared.

Because the UCC must be configured as a slow communications controller for SAM, its event register is 16 bits. The corresponding UCCM bit must be set if the interrupt is to be issued to the core. Figure 38-15 shows the UCC event and mask register.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	QOV	MTCE	GUN	GOV
MTC_INTE_CTL	0x0	0x0	0x1	0x1	0x2	0x2	0x3	0x3	0x4	0x4	0x5	0x5	0x6	0x6	—	—

Figure 38-15. UCC Event/Mask Register

Table 38-9 describes the MTC event register interrupt bits.

Table 38-9. MTC Event Register For UCC

Bits	Name	Description
0, 2, 4, 6, 8, 10, 12	QOV	Queue Overflow. When this bit is set the interrupt queue corresponding to the MTC_INTE_CTL setting has experienced an overflow.
1, 3, 5, 7, 9, 11, 13	MTCE	MTC Event. The interrupt queue corresponding to the MTC_INTE_CTL has experienced an interrupt event.
14	GUN	Global Underrun. The UCC Transmit FIFO has experienced an underrun. The UCC should be disabled via the SIMxR and reinitialized.
15	GOV	Global Overrun. The UCC Receive FIFO has experienced an overrun. The UCC should be disabled via the SIMxR and reinitialized.

NOTE

If there is a QOV interrupt, an interrupt entry in the interrupt queue has been lost. This interrupt may be an OR event. This event effectively disables the MTC receiver. Therefore, after a QOV interrupt the MTC_STATE[CFOV] should be checked to determine whether the MTC receiver should be reinitialized and to determine whether the lost interrupt was a receive cell FIFO overrun.

38.3.1.7 MTC Interrupt Queue SDMA Control

Figure 38-16 shows configuration information for the MTC_SCTL.

	0	1	2	3	4	5	6	7
Field	—		GBL	BO		—		BIB
Offset	0x24							

Figure 38-16. MTC_SCTL—MTC Interrupt Queue SDMA Control Register

Table 38-10 describes the MTC_SCTL bit fields.

Table 38-10. MTC_SCTL Field Descriptions

Bits	Name	Description
0–1	—	Reserved, should be cleared.
2	GBL	Global. Asserting GBL enables snooping of the MTC Interrupt Queue. To use Global mode, SDMR[GBL_1_MSK] must also be set.
3–4	BO	Byte ordering. 00, 01, 11 Reserved 10 Big endian
5–6	—	Reserved, should be cleared.
7	BIB	MTC Interrupt Queue Bus: 0 Resides on the CBS bus. 1 Resides on the secondary bus.

38.3.1.8 MTC Transmit ATM PRAM—MTC_TX_ATM_PRAM

Each MTC has an associated ATM controller. The ATM controller PRAM area used by the MTC can be controlled by any unused UCC transmit SNUM. Figure 38-17 shows the ATM_TX_ATM_PRAM parameter.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	UT_SNUM															
Offset	0x48															

Figure 38-17. MTC_TX_ATM_PRAM

Table 38-11 describes the fields of the MTC_TX_ATM_PRAM.

Table 38-11. MTC_TX_ATM_PRAM Field Descriptions

Bits	Name	Description
0–15	UT_SNUM[1]	Unused UCC Transmit SNUM. Used to identify the SNUM of the UCC that serves as the ATM PRAM for this MTC 0x0000 UCC1, MTC_RX_ATM_PRAM[UR_SNUM] must be programmed to 0x0001 0x0010 UCC2, MTC_RX_ATM_PRAM[UR_SNUM] must be programmed to 0x0011 0x0020 UCC3, MTC_RX_ATM_PRAM[UR_SNUM] must be programmed to 0x0021 0x0030 UCC4, MTC_RX_ATM_PRAM[UR_SNUM] must be programmed to 0x0031 0x0040 UCC5, MTC_RX_ATM_PRAM[UR_SNUM] must be programmed to 0x0041 0x0050 UCC6, MTC_RX_ATM_PRAM[UR_SNUM] must be programmed to 0x0051 0x0060 UCC7, MTC_RX_ATM_PRAM[UR_SNUM] must be programmed to 0x0061 0x0070 UCC8, MTC_RX_ATM_PRAM[UR_SNUM] must be programmed to 0x0071

[1] The UCC SNUM used must not be that of an enabled UCC. The GUMR_L[ENT, ENR] must both be programmed to 0 for any UCC used as the ATM PRAM for SAM based TC layers.

38.3.1.9 Transmit Cell FIFO Ring

A transmit cell FIFO ring is unique to one MTC. The transmit cell FIFO ring configuration is shown in Figure 38-18.

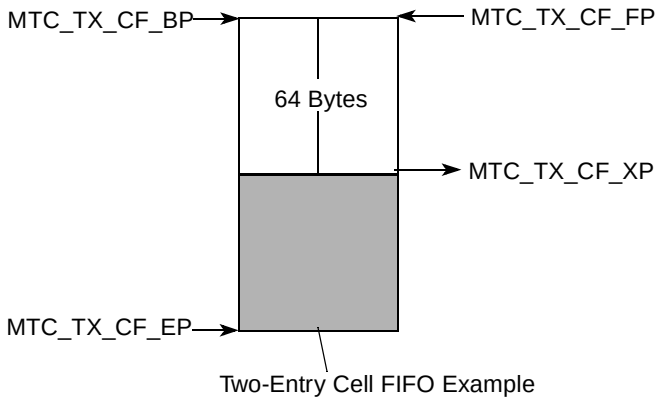

Figure 38-18. MTC Transmit Cell FIFO Ring

Each FIFO entry is 64 bytes. The example shows the configuration required to initialize a two-cell FIFO. The MTC_TX_CF_EP points to the end of the table; it does not point to the beginning of the last entry. The MTC_TX_CF_BP must point to a 64-byte aligned address, as is also true for the MTC_TX_CF_EP. The transmit cell FIFO ring should be two entries long.

38.3.1.10 MTC Transmit Multi PHY Address—MTC_TX_MPHY_ADD

MTC_TX_MPHY_ADD is required in order to assign an APC table to this MTC. The MPHY address programmed in MTC_TX_MPHY_ADD must be unique to the ATM PRAM used by this MTC. Thus, if more than one MTC uses the same ATM PRAM, they must have different multi-PHY addresses. If these MTCs use their own or different ATM PRAM, they can use the same PHY address. An MTC using its own unique ATM PRAM is analogous to a single PHY configuration on the UTOPIA bus. Furthermore, a group of MTCs sharing the same ATM PRAM is similar to a multi-PHY configuration on the UTOPIA bus. Each ATM PRAM used has an associated PHY or group of PHYs, in essence TC layers, that it views as UTOPIA PHYs—even though no UTOPIA bus exists. Figure 38-19 shows the fields of the MTC_TX_MPHY_ADD.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	—	IMART	—					1	0	DC		TX_MPHY[4:0]				
Offset	0x64															
	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
Field	—		1	—			MPHY_EN	—								
Offset	0x66															

Figure 38-19. MTC_TX_MPHY_ADD Register

Table 38-12 describes the MTC_TX_MPHY_ADD fields.

Table 38-12. MTC_TX_MPHY_ADD Field Descriptions

Bits	Name	Description
0	—	Reserved, initialize to 0.
1	IMART	IMA Return 0 If transmitter operates in IMA mode, clear IMART. 1 If transmitter does not operate in IMA mode, set IMART.
2–6	—	Reserved, initialize to 0.
7	—	Must be initialized to 1.
8	—	Must be initialized to 0.
9–10	DC	Device Code. The two most significant bits of the TX_MPH. These bits identify the device on the UTOPIA bus to which this MTCs PHY number belongs. Required in order to identify the APC table for this MTC (PHY).
11–15	TX_MPHY[4:0]	Transmit Multi-PHY Address. Initialize to the PHY address for this MTC.
16-17	—	Reserved, initialize to 0.
18	—	Must be initialized to 1.
19–21	—	Reserved, initialize to 0.
22	MPHY_EN	Multi-PHY Enable. 0 Single-PHY mode. 1 Multi-PHY mode. This bit must be set when MTC_MODE[IMA] = 1. Use single PHY mode when the ATM PRAM associated with this MTC has no other connected MTCs.
23–31	—	Reserved, initialize to 0.

38.3.1.11 MTC Transmit Utopia Emulation FIFO

Each MTC transmit UTOPIA emulation FIFO is composed of two distinct parts, a UTEF table and a pending request FIFO (PRF). The UTEF table contains pointers that define the size of the PRF. The PRF holds requests from the MTCs that use this UTEF. Both the UTEF Table and the PRF are in the MURAM. More than one MTC can access the same UTEF.

Table 38-13. UTEF Table

Offset[1]	Name	Width	Description
0x00	MTC_TPRF_BP	Word	MTC Transmit Pending Request FIFO Base Pointer. Base address of the PRF. Each entry in the PRF is 4 bytes. This address must be 4 bytes aligned.
0x04	MTC_TPRF_EP	Word	MTC Transmit Pending Request FIFO End Pointer. End address of the PRF. The size of the PRF should be 1 greater than the number of associated MTCs Transmit Cell FIFO entries. For example, if t 2 MTCs use this UTEF and each of these MTCs Transmit Cell FIFO rings are 4 entries long, then the size of the table should be 9 entries, 36 bytes. This address must be 4 byte aligned and point to the end of the last entry in the PRF.
0x08	MTC_TPRF_FP	Word	MTC Transmit Pending Request FIFO Fill Pointer. Microcode managed parameter initialize to MTC_TPRF_BP.
0x0C	MTC_TPRF_XP	Word	MTC Transmit Pending Request FIFO Extract Pointer. Microcode managed parameter initialize to MTC_TPRF_BP.

1 Offset from MTC_TX_UTEF_PTR. Must be 16 bytes aligned in the MURAM.

The user must clear the PRF during initialization.

38.3.1.12 MTC Receive ATM PRAM—MTC_RX_ATM_PRAM

Each MTC has an associated ATM controller. The ATM controller PRAM area used by the MTC can be any unused UCC SNUM. Figure 38-20 shows the fields of the MTC_RX_ATM_PRAM.

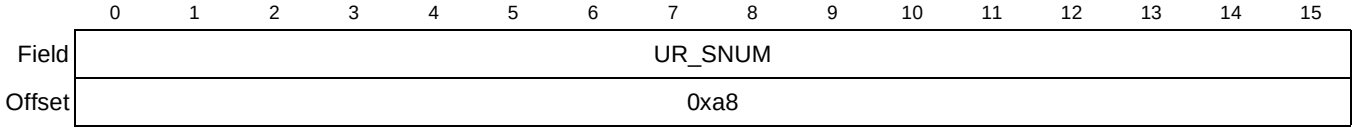

Figure 38-20. MTC_RX_ATM_PRAM

Table 38-14 describes the MTC_RX_ATM_PRAM fields.

Table 38-14. MTC_RX_ATM_PRAM Field Descriptions

Bits	Name	Description
0–15	UR_SNUM[1]	Unused UCC Receive SNUM. Used to identify the SNUM of the UCC that serves as the ATM PRAM for this MTC 0x0001 UCC1, MTC_TX_ATM_PRAM[UT_SNUM] must be programmed to 0x0000 0x0011 UCC2, MTC_TX_ATM_PRAM[UT_SNUM] must be programmed to 0x0010 0x0021 UCC3, MTC_TX_ATM_PRAM[UT_SNUM] must be programmed to 0x0020 0x0031 UCC4, MTC_TX_ATM_PRAM[UT_SNUM] must be programmed to 0x0030 0x0041 UCC5, MTC_TX_ATM_PRAM[UT_SNUM] must be programmed to 0x0040 0x0051 UCC6, MTC_TX_ATM_PRAM[UT_SNUM] must be programmed to 0x0050 0x0061 UCC7, MTC_TX_ATM_PRAM[UT_SNUM] must be programmed to 0x0060 0x0071 UCC8, MTC_TX_ATM_PRAM[UT_SNUM] must be programmed to 0x0070

1 The UCC SNUM used must not be that of an enabled UCC. The GUMR_L[ENT, ENR] must both be programmed to 0 for any UCC used as the ATM PRAM for SAM-based TC layers.

38.3.1.13 Receive Cell FIFO Ring

A receive cell FIFO ring is unique to an MTC. The receive cell FIFO ring configuration is shown in Figure 38-21.

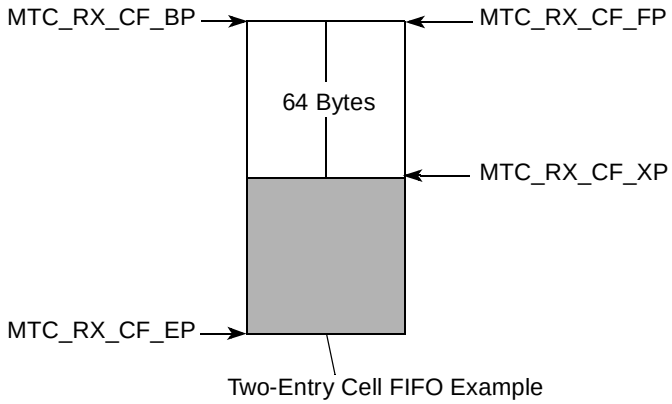

Figure 38-21. MTC Receive Cell FIFO Ring

Each FIFO entry is 64 bytes. The example shows the configuration required to initialize a two-cell FIFO. The MTC_RX_CF_EP points to the end of the table; it does not point to the beginning of the last entry. The MTC_RX_CF_BP must point to a 64-byte aligned address, as is also true for the MTC_RX_CF_EP. The receive cell FIFO ring should be two entries long.

38.3.1.14 MTC Receive Multi PHY Address—MTC_RX_MPHY_ADD and MTC_RX_MPHY_ADD_EXT

MTC_RX_MPHY_ADD, shown in Figure 38-22 is required to perform the address compression correctly for cells received by this MTC. The MPHY address programmed in MRX_RX_MPHY_ADD must be unique to the ATM PRAM used by this MTC. Thus, if more than one MTC uses the same ATM PRAM, they must have different multi-PHY addresses. If these MTCs use their own or different ATM PRAM, the same PHY address can be used for these MTCs.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Figure 38-23. MTC_RX_MPHY_ADD_EXT Register

Table 38-16 describes the MTC_RX_MPHY_ADD_EXT fields.

Table 38-16. MTC_RX_MPHY_ADD_EXT Field Descriptions

Bits	Name	Description
0	—	Reserved, initialize to 0.
1	IMART	IMA Return 0 If MTC_MODE[IMA] = 1 set IMART to 0. 1 If MTC_MODE[IMA] = 0 set IMART to 1.
2–6	—	Reserved, Initialize to 0.
7	MPHY_EN	Multi-PHY Enable. 0 Single PHY mode. 1 Multi PHY mode. This bit must be set when MTC_MODE[IMA] = 1. Use single PHY mode when the ATM PRAM associated with this MTC has no other connected MTCs.
8	—	Reserved, initialize to 0.
9	—	Must be initialized to 1.
10–16	—	Reserved, initialize to 0.
17–18	DC	Device Code. Essentially the 2 most significant bits of the TX_MPHY, these bits identify which device on the UTOPIA bus this MTCs PHY number belongs to. Required for address compression.
19	RX_MPHY[4]	Receive Multi PHY Address 4. Most significant bit of the of the UTOPIA emulation PHY address for this MTC.
20–31	—	Reserved, initialize to 0x2f.

38.3.1.15 MTC Receive Utopia Emulation FIFO

Each MTC receive UTOPIA emulation FIFO is composed of two distinct parts, a UTEF table and a pending request FIFO (PRF). The UTEF table contains pointers that define the size of the PRF. The PRF holds requests from the MTCs that use this UTEF. Both the UTEF table and the PRF are in the MURAM. More than one MTC can access the same UTEF. The user must clear the PRF during initialization.

Table 38-17. UTEF Table

Offset[1]	Name	Width	Description
0x00	MTC_RPRF_BP	Word	MTC Receive Pending Request FIFO Base Pointer. Base address of the PRF. Each entry in the PRF is 4 bytes. This address must be 4 bytes aligned.
0x04	MTC_RPRF_EP	Word	MTC Receive Pending Request FIFO End Pointer. End address of the PRF. The size of the PRF should be 1 greater than the number of associated MTCs Receive Cell FIFO entries. For example, if there are 2 MTCs that use this UTEF and each of these MTCs Receive Cell FIFO rings are 4 entries long then the size of the table should be 9 entries, 36 bytes. This address must be 4 bytes aligned and point to the end of the last entry in the PRF.
0x08	MTC_RPRF_FP	Word	MTC Receive Pending Request FIFO Fill Pointer. Microcode managed parameter initialize to MTC_RPRF_BP.
0x0C	MTC_RPRF_XP	Word	MTC Receive Pending Request FIFO Extract Pointer. Microcode managed parameter initialize to MTC_RPRF_BP.

1 Offset from MTC_RX_UTEF_PTR. Must be 16 bytes aligned in the MURAM.

38.3.1.16 MTC Correction Table—MTC_CORR_TBL

The MTC correction table occupies 256 bytes of MURAM. Each entry in the table is one byte. The correction table allows the MTC to determine whether a cell has a HEC error and whether the error can be corrected. Correction occurs only for single bit errors. The correction table should be initialized only when the MTC_MODE[SBC] = 0. Table 38-18 shows the configuration requirements for the correction table.

Table 38-18. MTC Correction Table

Offset[1]	0	1	2	3	4	5	6	7	8	9	A	B	C	D	E	F

0xE0	13	255	255	255	255	255	255	255	255	255	255	255	255	255	255	255
0xF0	255	255	255	255	255	255	255	255	255	255	255	255	255	255	255	255

1 Offset from MTC_CORR_TBL. Must be 256 bytes aligned in the MURAM.

The correction table must be initialized to the values shown so that the MTC can use it to determine the location of any single-bit errors in the cell header and correct accordingly.

38.4 IMA Root Table SAM Programming

When the SAM is in use, the MTC ATM PRAM must configure the IMA root table IMACNTL parameter. This configuration is mandatory regardless of the setting of the value of MTC_MODE[IMA]. If MTC_MODE[IMA] = 0, only the IMACNTL[SAME] must be configured. However, as the ATM PRAM IMAROOT is initialized, the full IMA root table (128 bytes) must be assigned and is therefore unavailable in the MURAM for other QUICC Engine peripherals. Figure 38-24 shows the IMACNTL.

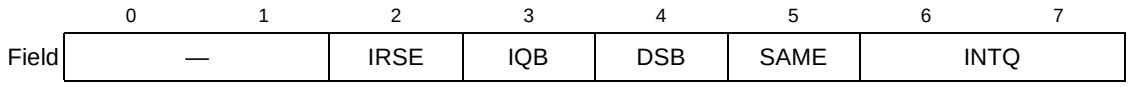

Figure 38-24. IMA Control (IMACNTL)

Table 38-19 describes the IMACNTL bit fields.

Table 38-19. IMACNTL Field Descriptions

Bits	Name	Description
0–1	—	Reserved
2	IRSE	IMA link receive statistics enable. If link receive statistics gathering is disabled, there is no need to initialize IRLINKSTAT or reserve space for the receive statistics table. 0 Link receive statistics gathering is disabled. 1 Link receive statistics gathering is enabled.
3	IQB	Interrupt queue bus. Defines on which bus the IMA interrupt queue is located. 0 On the CSB bus. 1 On the secondary bus.
4	DSB	Data structure bus. Defines on which bus the IMA external structure memory area is located. 0 On the CSB bus. 1 On the secondary bus.

Table 38-19. IMACNTL Field Descriptions (continued)

Bits	Name	Description
5	SAME	Serial ATM Enable. 0 The TC layer is not SAM based 1 The TC layer is SAM based, i.e. a MTC.
6–7	INTQ	Number of the ATM interrupt queue dedicated to IMA events. Note that these do not include ICP cell reception events; the handling of ICP cell reception events is programmed in the RCT of the ICP channel defined by RICPCH.

38.5 ATM Controller UCC_Modes Initialization

Any SNUM of a UCC used by an MTC as the ATM controller must have the following bits in the UCC_Mode set accordingly:

- Non Pipelined UCC_Modes[NPL] = 1
- No multi-thread support UCC_Modes[Multi_Thread_En] = 0

Because the SAM requires any UCC SNUM used to serve as the ATM PRAM is not enabled (GUMR_L[ENT, ENR] = 0), there is no requirement to issue the ATM Transmit Command for this UCC. However, this command should be issued as part of the initialization to configure the UCC_Modes[UID] correctly. This command can be skipped only if the UCC_Modes[UID] is not required for ATM address compression.

38.6 MCC Initialization

If no MCC SS7, HDLC or transparent channels are used in the MCC, the CUN interrupt can still occur. Software must configure the MCC transmit interrupt queue parameters in the Global MCC PRAM.

To configure an MCC channel to act as a MTC the following initialization, perform the following steps:

1. Configure Parallel I/O for the TDM interface required.
2. Initialize the SIU interrupt controller to mask or enable MCCE interrupts as appropriate.
3. Initialize the MCC registers, MCCFx.
4. Initialize the SIRAM and SIRAM registers except SIxGMR.
5. Initialize the MCC global parameters. If no SS7, HDLC, PPP or transparent channels are active in the QUICC Engine block, then the SCTPBASE and associated super channel table should be initialized. Also, the TINTBASE, TINTPTR and TINTTMP should be initialized for the CUN interrupt. For better overall performance, use 16-bit super channels for ATM-based MCC channels that are part of a super channel. On the receiver, only one MCC channel is required per MTC; each SIRAM Rx entry should contain this channel number.
6. Initialize MTC PRAM.
7. Issue the MCC Init Host Command for all channels that are part of the MTC, including any channels programmed in the SIRAM to be part of a super channel connected to the SAM MCC channel.
8. Enable TDM in the SIxGMR.

38.6.1 Disabling the MTC

To disable the MTC transmitter, clear MTC_MODE[TXEN]. Similarly, to disable the receiver, clear MTC_MODE[RXEN]. After these bits are cleared, the MTC PRAM can safely be updated to its default state and the channel re-enabled only after the following conditions are true:

- If MTC TX is to be disabled, software must wait for MTC_STATE_TX[MTCI, IDLE_C] = 0 then wait for MTC_TX_CF_FP = MTC_TX_CF_XP.
- If MTC_RX is to be disabled, software must wait for MTC_STATE_RX[CFOV_C] = 0 and then verify that MTC_RX_CF_XP = MTC_RX_CF_FP.

To re-enable the MTC after the MTC PRAM is updated, set MTC_MODE[TXEN] and/or MTC_MODE[RXEN].

NOTE

It is possible to disable only the transmitter or the receiver and leave the other active. Clear MTC_MODE[TXEN] or MTC_MODE[RXEN], then update only the transmit or receive MTC parameters. The MTC_TSTATE, MTC_ZISTATE, MTC_ZIDADTA0 and MTC_ZIDADTA1 are part of MTC, but for the MCC, these should not be updated if the TDM is still enabled in the SIxGMR.

If the MTC and therefore an associated TDM is to be completely disabled, perform the following steps:

1. Clear MTC_MODE[TXEN] and MTC_MODE[RXEN].
2. Software must wait for MTC_STATE_TX[MTCI, IDLE_C] = 0 and then wait for MTC_TX_CF_FP = MTC_TX_CF_XP.
3. Software must wait for MTC_STATE_RX[CFOV_C] = 0 and then check that MTC_RX_CF_XP = MTC_RX_CF_FP.
4. Disable TDM through the SIxGMR. If there is more than 1 ATM stream on the TDM and only 1 ATM stream is to be disabled, do not disable the TDM here. Issue the MCCTSTOP command for the MCC Tx super channel used for this MTC. If this channel is to be assigned to another MCC protocol, MTC_CHAMR[TASH] should remain clear until all CSP for this channel are updated except MTSTATE and MRSTATE. Then MTC_CHAMR[TASH] should be set and MTSTATE and MRSTATE should be updated to their default values for the protocol chosen.

After these steps, the MTC is completely disabled and its PRAM area can be updated or reassigned as required. The MCC channel can also be assigned to another protocol, such as HDLC.

38.6.2 Response to GUN or GOV

A GOV or GUN is a non-recoverable event for the MCC; after this event the following procedure should be performed:

1. Clear MTC_MODE[TXEN] and MTC_MODE[RXEN].
2. Disable all TDMs connected to the MCC that experienced GOV or GUN through the SIxGMR
3. Software must wait for MTC_STATE_TX[MTCI, IDLE_C] = 0 and then wait for MTC_TX_CF_FP = MTC_TX_CF_XP for all ATM-based MCC channels

4. Software must wait for MTC_STATE_RX[CFOV_C] = 0 and then verify that MTC_RX_CF_XP = MTC_RX_CF_FP for all ATM-based MCC channels.
5. Issue the MCC Reset Host command.
6. Re-Initialize MTC PRAM for all MTCs.
7. Issue the MCC Init Host command for all channels that are part of the MTC, including any channels programmed in the SIRAM to be part of a super channel.
8. Re-enable any MTC is to be re-enabled by setting the appropriate bit in the SIxGMR.

38.6.3 Response To CUN

When a channel underrun event occurs, perform the following steps:

1. Clear MTC_MODE[TXEN] for the affected MCC channel. If the channel is part of a super channel, the MCCTSTOP should be issued for the channel that directly relates to the super channels CSP. This is not necessarily the CUN channel.
2. Issue the MCCTSTOP command for the channel that experienced CUN. If the channel is part of a super channel, the MCCTSTOP should be issued for the channel that directly relates to the super channels CSP. This is not necessarily the CUN channel.
3. Issue MCC INIT TX, ONE CHANNEL host command for the affected channel.
4. Software must wait for MTC_STATE_TX[MTCI, IDLE_C] = 0 and then wait for MTC_TX_CF_FP = MTC_TX_CF_XP.
5. Update all the transmit MTC parameters to their default state.
6. Set MTC_MODE[TXEN] to restart the MTC transmitter.

38.7 UCC Initialization

The UCC must be configured for transparent protocol when it is connected to the SAM using the following initialization sequence:

1. Configure parallel I/O for the TDM interface required.
2. Initialize the SIU interrupt controller to mask or enable UCCE interrupts as appropriate.
3. Initialize the UCC registers. The UCC must be programmed to operate in QMC mode in the GUMR_L[MODE] and must be configured as a slow communications controller. Also, GUMR_L[16] should be set to enable serial ATM mode (see Table 29-3).
4. Initialize the SIRAM and SIRAM registers, except SIxGMR.
5. Initialize MTC PRAM.
6. Enable the TDM in the SIxGMR.
7. Enable the transmitter and receiver, GUMR_L[ENT, ENR] = 1.

38.7.1 Disabling the MTC

To disable the MTC transmitter, clear MTC_MODE[TXEN]. Similarly, to disable the receiver, clear MTC_MODE[RXEN]. After these bits are cleared, the MTC PRAM can safely be updated to its default state and the channel re-enabled only after the following conditions are true:

- If MTC TX is to be disabled, software must wait for MTC_STATE_TX[MTCI, IDLE_C] = 0 and then wait for MTC_TX_CF_FP = MTC_TX_CF_XP.
- If MTC_RX is to be disabled, software must wait for MTC_STATE_RX[CFOV_C] = 0 and then check that MTC_RX_CF_XP = MTC_RX_CF_FP.

To re-enable the MTC after the MTC PRAM is updated, set MTC_MODE[TXEN] and/or MTC_MODE[RXEN].

NOTE

It is possible to disable only the transmitter or the receiver and leave the other active. Clear MTC_MODE[TXEN] or MTC_MODE[RXEN] and update only the transmit or receive MTC parameters.

If the MTC and therefore an associated TDM is to be completely disabled, perform the following steps:

1. Clear MTC_MODE[TXEN] and MTC_MODE[RXEN].
2. Software must wait for MTC_STATE_TX[MTCI, IDLE_C] = 0 and then wait for MTC_TX_CF_FP = MTC_TX_CF_XP,
3. Software must wait for MTC_STATE_RX[CFOV_C] = 0 and then verify that MTC_RX_CF_XP = MTC_RX_CF_FP.
4. Disable TDM through the SIxGMR and clear both GUMR_L[ENT] and GUMR_L[ENR].

After these steps are completed, the MTC is entirely disabled and its PRAM area can be updated or reassigned as required. The UCC can then be assigned to another protocol.

38.7.2 Response to GUN or GOV

A GOV or GUN is a non-recoverable event for the UCC. After this event, the following procedure should be performed:

1. For GUN clear MTC_MODE[TXEN], for GOV clear MTC_MODE[RXEN].
2. For GUN disable the UCC transmitter by clearing GUMR_L[ENT], for GOV disable the UCC receiver by clearing GUMR_L[ENR]. If the entire MTC is to be stopped, the TDM should be disabled and both GUMR_L[ENT] and GUMR_L[ENR] cleared.
3. For GUN, software must wait for MTC_STATE_TX[MTCI, IDLE_C] = 0 and then wait for MTC_TX_CF_FP = MTC_TX_CF_XP. For GOV, software must wait for MTC_STATE_RX[CFOV_C] = 0 and then check that MTC_RX_CF_XP = MTC_RX_CF_FP
4. Reinitialize MTC PRAM for the affected UCC.
5. Re-enable any MTC by setting either GUMR_L[ENT] or GUMR_L[ENT].

Chapter 39
Enhanced MSP Microcode

39.1 Introduction

The QUICC Engine multi-service platform derivative (QUICC Engine EMSP) adds ATM layer functionality, suitable for the implementation of various network applications, such as a Port Controller on Subscriber line cards, ATM cell processing, Cable Modem controllers, ATM Multiplexing and concentrating systems and other multiservice and multiprotocol applications especially in the Branch/Enterprise Dial Access Applications.

A T1/E1 Line Card is depicted in Figure 39-1. Eight T1/E1 ports provide the connectivity to the subscribers, and the Utopia is used to connect to the fabric interface of the multi-service platform box. The QUICC Engine EMSP derivative, performs ATM switching functions on the ingress and egress direction.

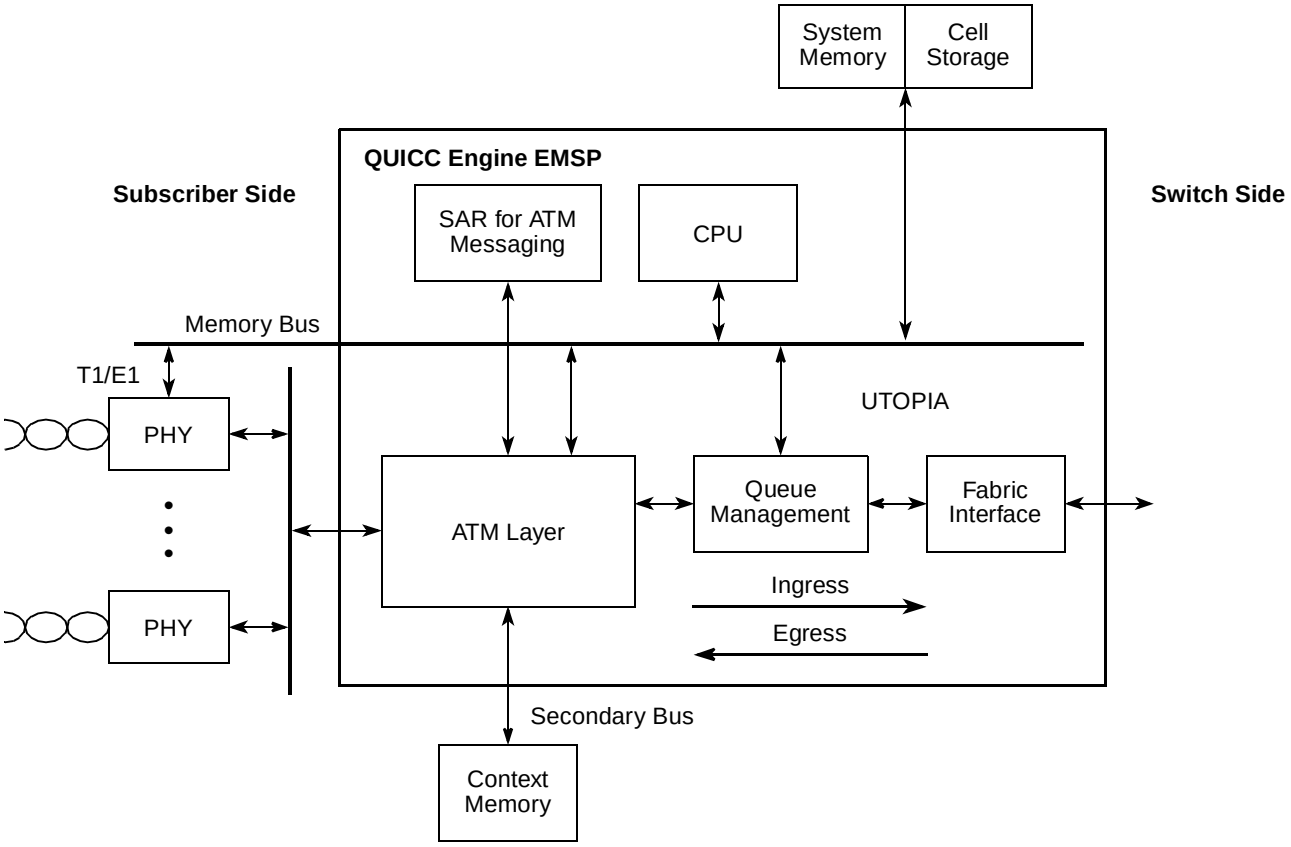

Figure 39-1. Access Line Card Example Using the QUICC Engine EMSP

A DSLAM Access Line Card is depicted Figure 39-2.

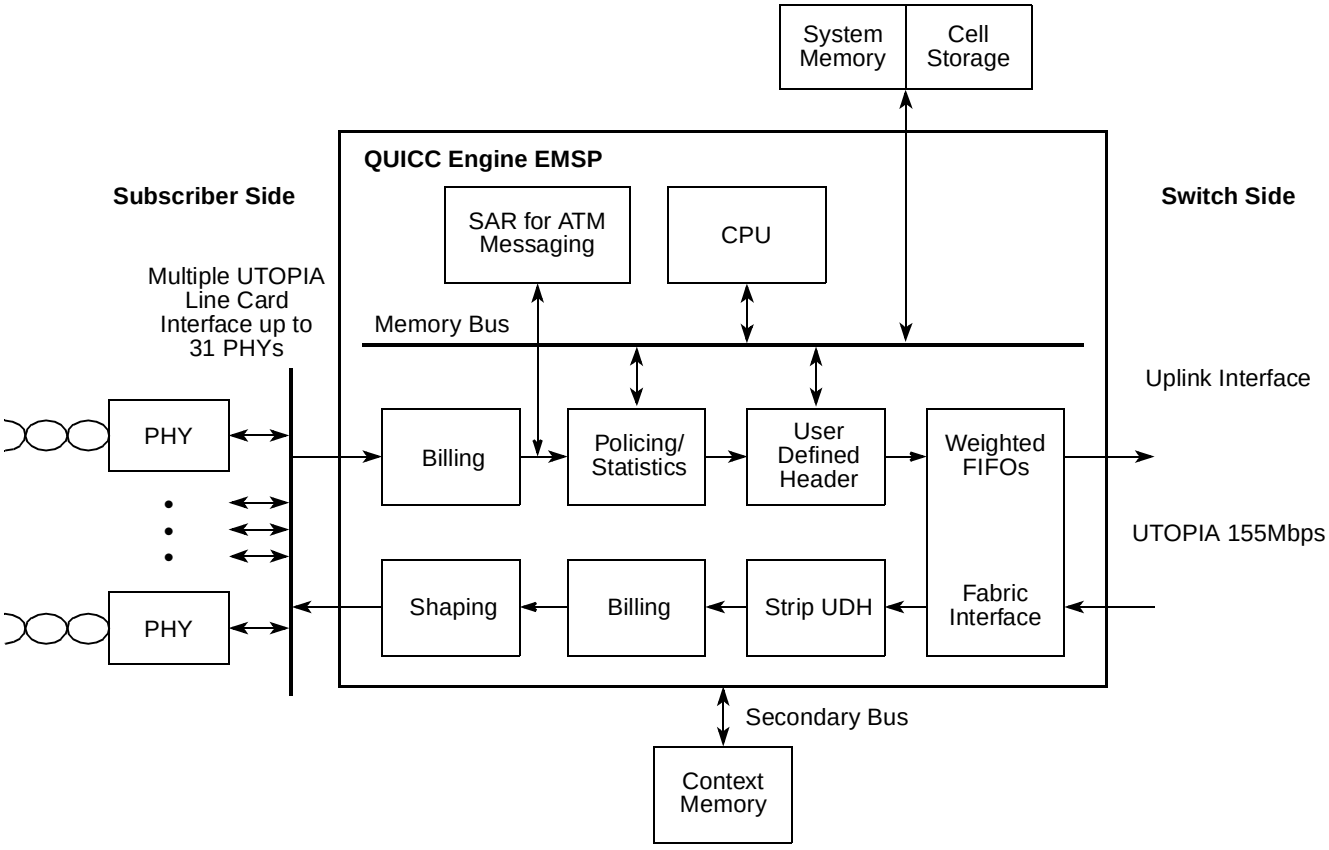

Figure 39-2. DSLAM Access Line Card Example Using the QUICC Engine EMSP

The aggregate bandwidth supported by the QUICC Engine EMSP device depends on the functions enabled in any given configuration. Under certain conditions the device will function as a 155 Mbps switch.

Utopia to Utopia switching functionality is shown in Figure 39-3. An external TC-Layer device performs framing of cells from the T1/E1. Frame-relay, fast Ethernet, and channelized E1/T1 interconnection are provided with the other interfaces on the QUICC Engine EMSP, thus allowing the design of a multi-protocol line card.

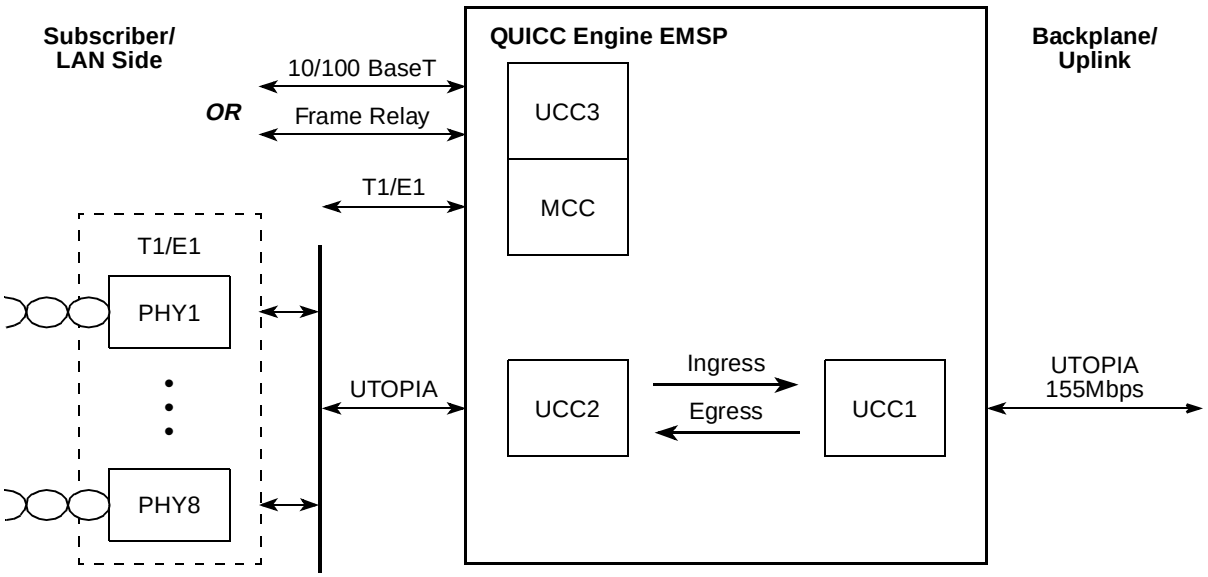

Figure 39-3. General MSP Access Application—External TC Layer

Figure 39-4 shows an implementation of a line card using a single Utopia interface on the QUICC Engine EMSP. The multiphy function on the Utopia interface allows connection to the switch fabric interface, as well as the T1/E1 framer on the same Utopia interface.

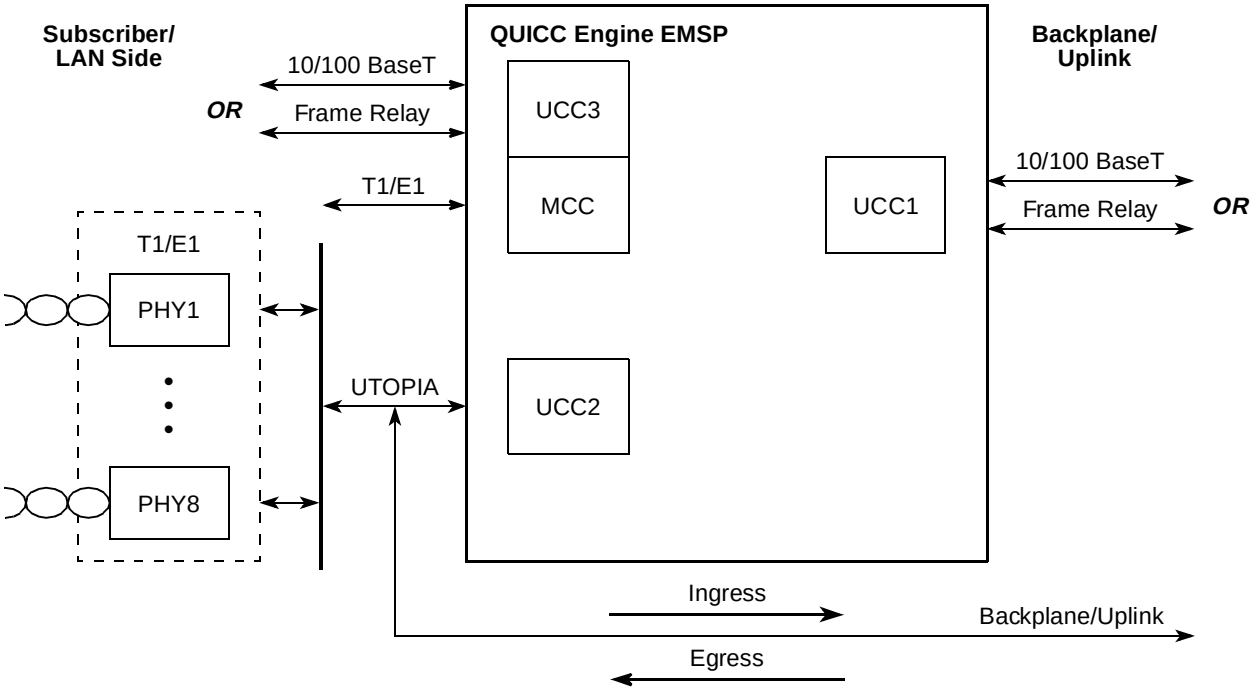

Figure 39-4. General MSP Access Application—Single Utopia

With the QUICC Engine block, it is possible to implement a T1/E1 Dial Access Line card by using the internal ATM TC-layer functionality. The block diagram for such a system is shown in Figure 39-5:

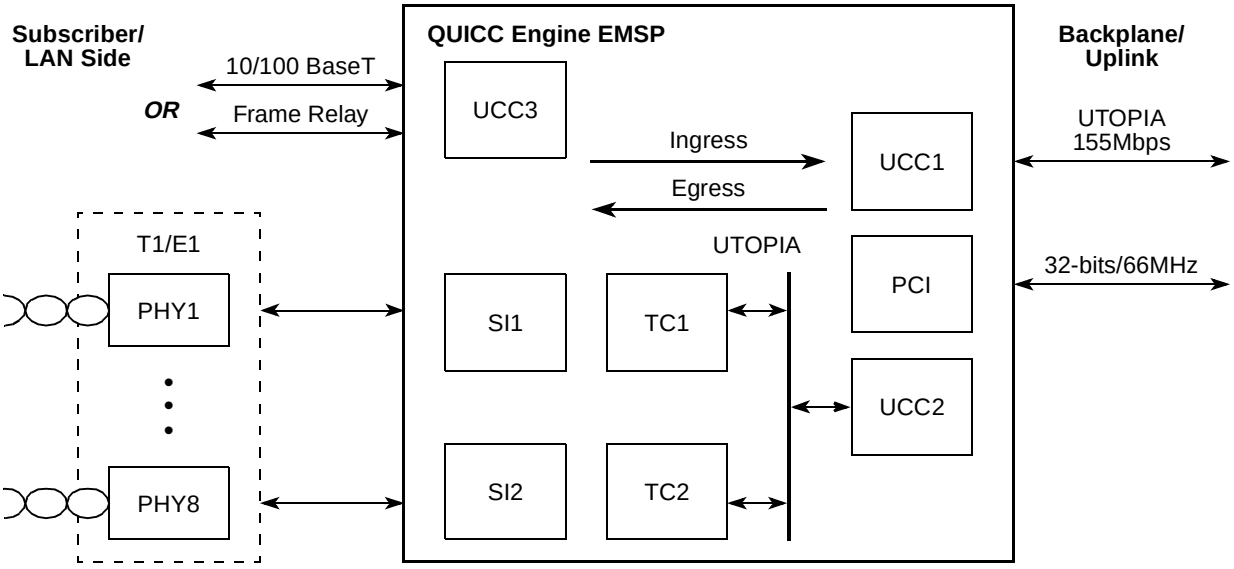

Figure 39-5. General MSP Access Application Internal TC Layer

On the subscriber side, the multi-service platform line card might support a number of different standards like frame relay (1.544 Mbs), T1/E1 (2.048 Mbs), or one or more of the G.lite standards.

On the Backplane side, the MSP transfers the data to the UCC1-Utopia Interface (at 155Mbps peak bit rate). It is possible to add a PCI interface using the internal PCI Bridge. The interface can be used for control/data packets in the system.

Layer 3 (or above) protocol conversion and routing may be done by the internal CPU core, or by an external CPU in the system.

ATM Switching functions like Address Translation, Concentration, Policing and Shaping and Billing are done in firmware without user intervention, except for initial programming and maintenance. ATM cells are SARed on a VC/VP basis, if needed.

The total aggregated bandwidth supported is 8 * 2.048Mbs on the subscriber side, and an average of 8 * 2.048Mb on the Backplane (Utopia interface) side. Peak rate of 155Mbps rate is supported on the Backplane (Utopia interface) side.

The ATM Layer functions which are supported by the QUICC Engine EMSP, and organized in an Access System Line card configuration are shown in Figure 39-6 (Ingress) and Figure 39-7 (Egress).

39.1.1 Ingress Data Flow

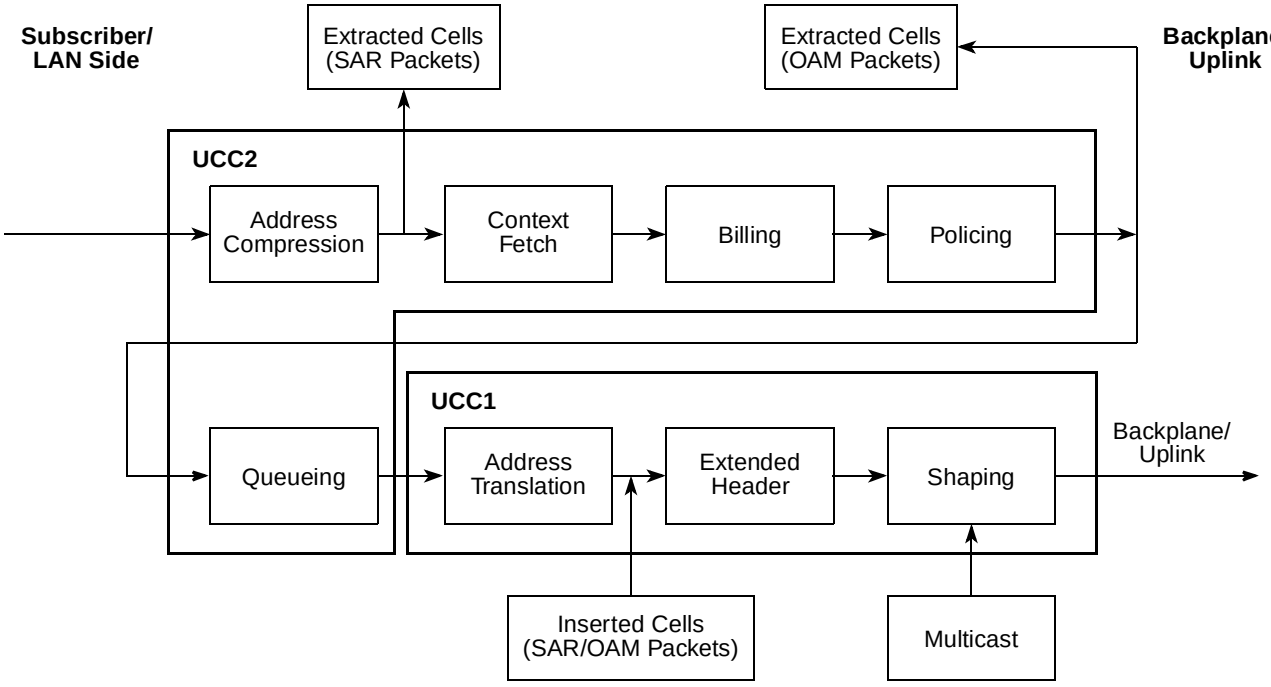

Figure 39-6. QUICC Engine EMSP ATM Layer Functionality—Ingress

Following either PowerQUICC II Pro style Address Compression or Address lookup in a CAM, the connection parameters are fetched. Cell counting is done per connection for billing, and policing operations (if enabled) discard or tags cells or packets. Following address translation, and addition of Switch overhead the cell is placed in a queue for transmission. Cells may be inserted or extracted by the CPU, for OAM management.

Scheduling to the Backplane/Uplink may be done on a per VC basis, or with 4 prioritized FIFO queues. Both mechanisms allow for rate control.

39.1.2 Egress Data Flow

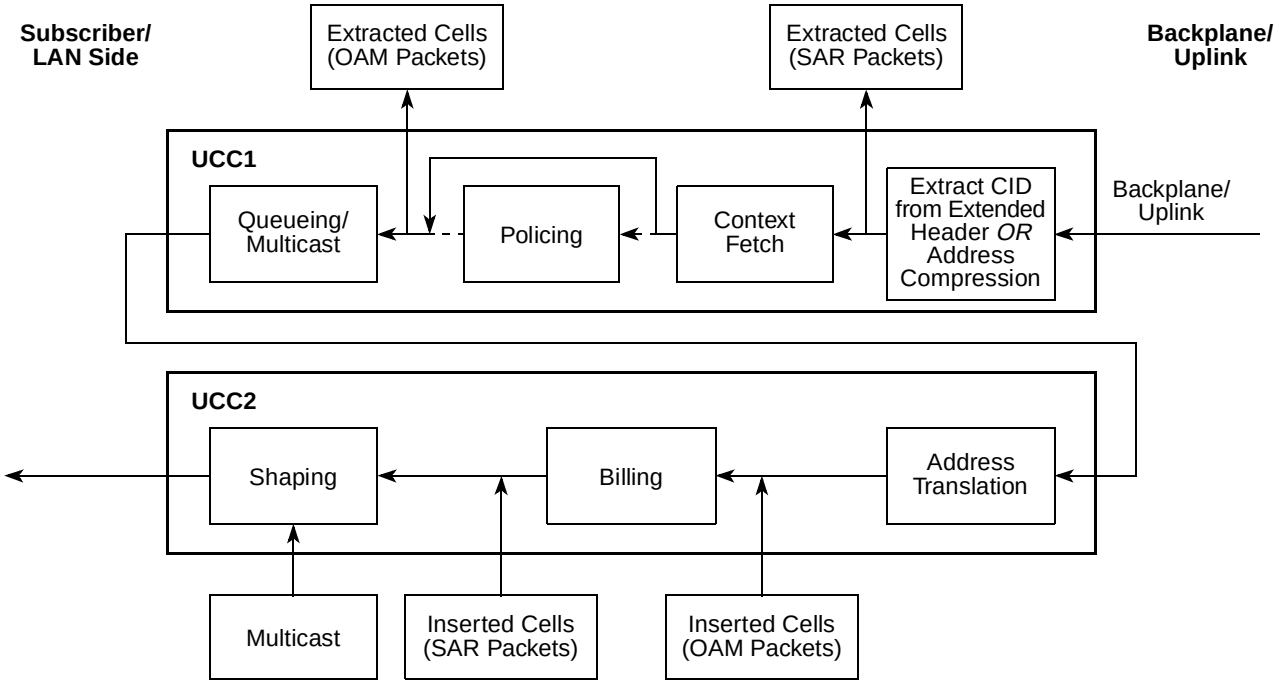

Figure 39-7. QUICC Engine EMSP ATM Layer Functionality—Egress

In the Egress Path, connection context can be defined either by address look-up mechanism or simply can be taken directly from a certain field in a pre-defined user defined header.

The connections are arranged in per VC queues and scheduling is performed with a hierarchical shaper, where VP shaping is performed at top level, and VC shaping at the lower level.

39.2 ATM Switching Functionality

Address Compression, address translation and bundling features of the QUICC Engine EMSP allow for flexible ATM switching features.

39.2.1 VP Switching

This function is supported by ignoring the VCI of the cells. All functions (as policing, queuing, billing, statistics) are performed on a VP basis. Address translation (optionally) alters only the VPI.

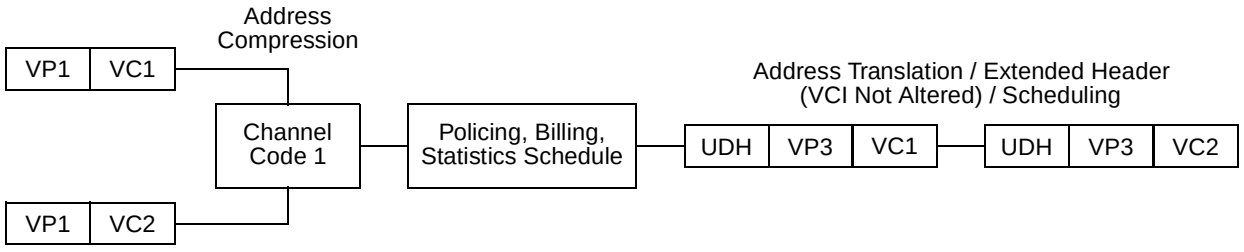

Figure 39-8. VP Switching

39.2.2 VC Switching with Bundling

This feature allows Policing (UPC) on multiple VCIs as one bundle, but perform billing, address translation, Extended Header, scheduling on a per VCC basis.

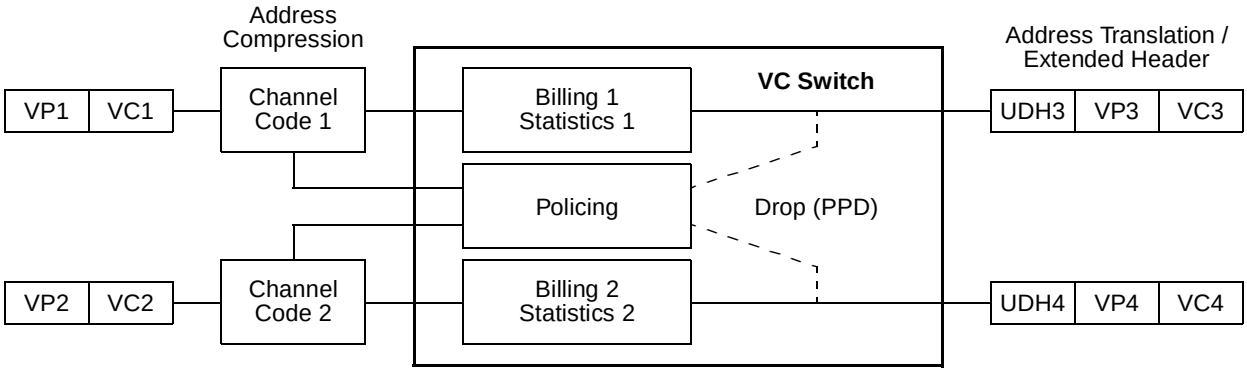

Figure 39-9. VP Switching with Bundling

39.3 Acronyms and Abbreviated Terms

Table 39-1 provides a list of acronyms and abbreviations that are used throughout this chapter.

Table 39-1. Acronyms and Abbreviated Terms

Term	Meaning
APC	ATM pace controller
CAM	Content addresseble memory
CB	Cell body
CLL	Cell linked lists
CLP	Cell loss priority
COV	Cell overhead
EFCI	Explicit forward congestion indication
EPD	Early packet discard
FCP	Free cell pool
FDT	FIFO descriptor table
FTCT	FIFO TCT
GFC	Generic flow control
GFR	Guaranteed frame rate
HTCT	Hierarchical TCT
MPHY	Multi PHY
MRCT	Multicast RCT
MSP	Multi-service platform

Table 39-1. Acronyms and Abbreviated Terms (continued)

Term	Meaning
MTCT	Multicast TCT
NCP	Next cell pointer
OAM	Operation and maintenance
PHY	Physical Layer
PM	Performance Managing
PPD	Partial Packet Discard
PTI	Payload Type Indication
QTLS	Queue Thresholds Level Table
RCC	Receive Channel Code
RCT	Receive Connection Table
CETSCR	QUICC Engine Time Stamp Control Register
TCC	Transmit Channel Code
TCT	Transmit Connection Table
SAR	Segmentation And Reassembly
SRCT	Switched Cells Receive Connection Table
STCT	Switched Cells Transmit Connection Table
STCTE	Switched Cells Transmit Connection Table Extension
VC	Virtual channel
VCI	Virtual Channel Indication
VCT	Virtual Channel Table
VP	Virtual Path
VPI	Virtual Path Indication
VPT	Virtual Path Table
UEAD	User Extended Address
UDC	User Defined Cell
UDH	User Defined Header
UPC	Usage Parameter Control

39.4 EMSP Features

- General ATM switching capabilities
  - Integrates ATM layer functionality and PQII SAR Functionality
  - Per VCC/VPC function select (SAR or Switch Functionality)
  - Executes ATM switching between any pair of PHY devices on the same UL2

  - Executes ATM Switching between two UL2 ports
  - UTOPIA Level 2 up to 127 sub-ports for subscriber side
  - 8/16 bit UTOPIA for Fabric connection and Subscriber Connection
  - VPC/ VCC Switching and Address Translation
  - Supports UPC, Queuing, Shaping and statistics gathering per VPC/VCC
  - Queue Management with Congestion Control
  - Supports up to 64K VCCs
  - Buffer Memory (Data Memory) up to 4GB in external DRAM
  - flexible and efficient memory management method, using the concept of **Cell Linked List (CLL)** and **Free Cell Pool**.
  - Address look-up using either external CAM or address compression
  - ATM Forum Compliant Policing per VC or VC Bundle
- Address resolution
  - Algorithmic Address Compression
  - CAM interface (glueless interface to CAM)
  - Channel code extraction directly from Extra Header
- Cells Filtering Options
  - Per VCC/VPC option to copy cells to Egress Port
  - Per VCC/VPC option to copy cells to SAR engine
  - Per VCC/VPC option to copy cells to Raw Cell and Interrupting host
- Billing
  - CLP0 and CLP1 Count per VCC/VPC
  - Interrupt is generated for Billing Counter expiration
- Policing according to ITU-T I.371 and ATM Forum TM Specification 4.1
  - GFR Conformance and GFR Eligibility testing
  - Policing per VCC/VPC and arbitrary VCCs group bundle
  - Two leaky buckets
  - CLP Marking
  - Cell Discard for CLP0, CLP1, or CLP0+1 optionally
  - PPD discard policy is optional for AAL5 VCCs
- Statistics
  - Statistics per VCC/VPC and arbitrary VCCs group Bundle
  - Non conforming CLP0 Counter with optional expiration interrupt generation
  - Non conforming CLP1 Counter with optional expiration interrupt generation
- ATM Header Translation
  - VPI only translation
  - VCI only translation
  - VPI/VCI translation

- Queue Managements
  - Per VCC/VPC Queuing
  - VCCs Bundle Queuing
  - Sets of thresholds per Queue: EFCI marking, EPD discard, CLP1 discard, CLP0+1 discard
  - Supports PPD for CLP1 and CLP0 discard
  - Controllable Service Level for Non-Eligible GFR frames
- Scheduling
  - Per VCC, Per VPC or arbitrary VCCs group Bundle Prioritized FIFO/Weighted Round Robin / Mixed mode Scheduling
  - Merging of SAR Scheduling system and Switch Scheduling system
  - Bandwidth management by a Calendar Wheel Scheduling scheme (APC)
  - Up to eight priority Calendar Wheels per sub-port
  - Hierarchical Scheduling by a combination of APC (Upper Level) and Prioritized FIFO/Weighted Round Robin / Mixed mode for second level
- Traffic Shaping
  - Peak Cell Rate shaping (PCR)
  - Peak and Sustain Rate shaping (PCR, SCR, BT)
  - Peak and Minimum Rate shaping (PCR, MCR)
  - VBR, UBR+ shaping.
- User defined cells
  - Up to 65 bytes. (fabric side) for per VCC queuing and shaping
  - Up to 63 bytes for VCC Bundle Queuing
- Multicast
  - No duplicating cells in memory
  - Multicast through per VCC/VPC queuing system
  - Multicast through WFQ algorithm.
- OAM (I.610)
  - Detection of F4 Segment and End To End OAM for VPC Switching
  - Detection of F5 Segment and End To End OAM for VCC Switching
  - OAM Received cells are either un-touched, Removed from cell flow, or copy to CPU queue
  - OAM Cells are inserted to cell flow by Host i/f
  - Performance Monitoring support without Host intervention
- Host Controllability by Host Commands
  - Establishing and tearing of new queue from FCP Host Commands
- Applications
  - Multiservice Platform for Access Line Card Applications
  - Concentrators
  - Remote Access Units

- DSLAM Applications: Mux/Demux G.lite subscribers
- Cell Processing, ATM switching, Shaping and UPC controller

39.5 Functional Description and Programming Model

39.5.1 Introduction

The QUICC Engine EMSP functionality adds ATM switching functions. In order to achieve high data rates for the switching functions, new data structures are defined for cells received in switching mode.

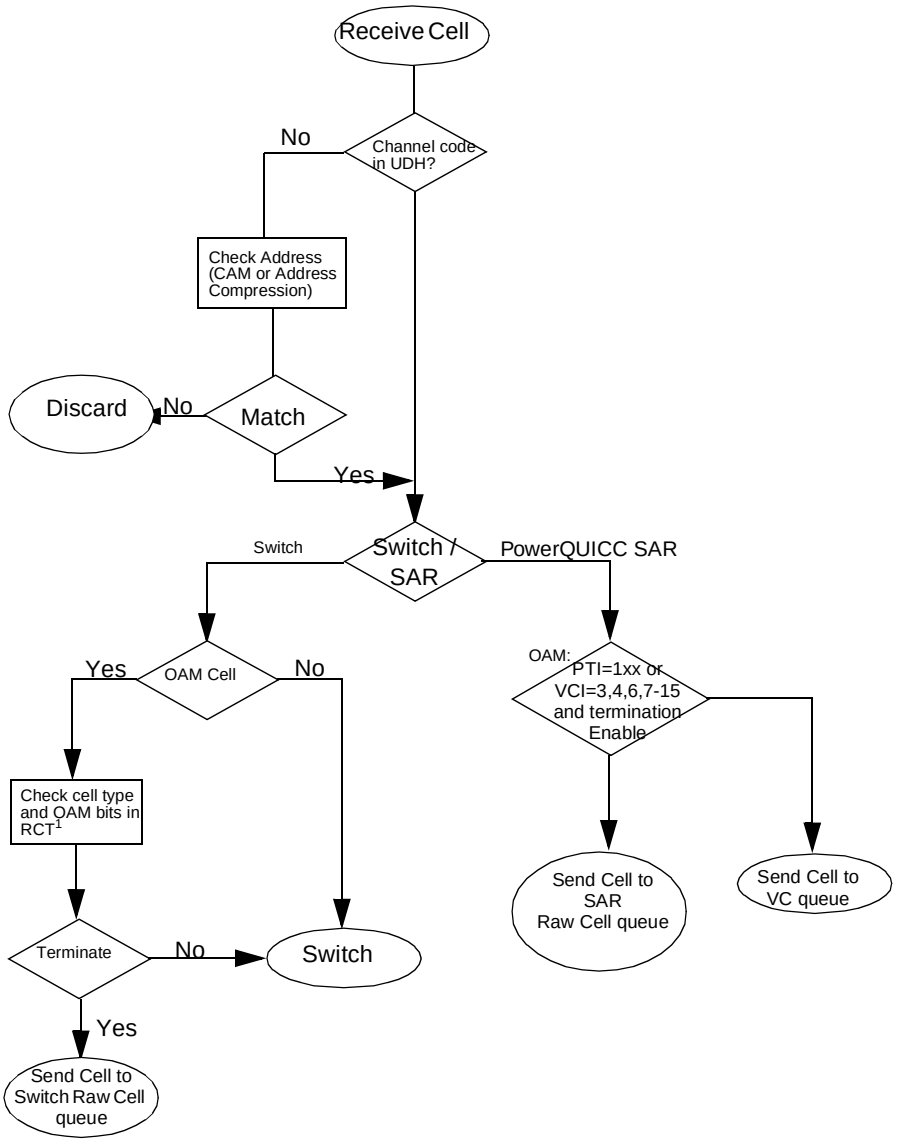
Every cell has an associate channel-code (RCC for arriving cells, TCC for transmitted cells). For incoming cells the channel code can be retrieved in one of three ways (determined in the GMODE register): a) Directly from the extra header which resides before the ATM header on the cell, b) as a result of address compression mechanism performed on the VPI/VCI of the cell, c) as a result of a search in an external CAM. The Channel-code has a connection table entry associated with it (RCT for receive or TCT for transmit). In some cases there are additional parameters in extended tables. In the RCT/TCT AAL=110 indicates that this channel is switched instead of SARed. If switched, the switching data structures are used; if SARed the PowerQUICC II Pro data structures are used. The PowerQUICC II Pro structures are composed of Buffer descriptors-rings which point to Data buffers (which may or may nor be pre-allocated). The switching data structures are composed of cell linked lists (CLLs), and a free cell pool (FCP) of empty linked cells. The Switching function automatically fetches free cells from the free cell pool and returns them after transmission. The following figure (Figure 39-10) shows the flow for SAR or switch modes.

The scheduling mechanism for transmission can be one of two (on a per-PHY basis): Either the PowerQUICC II Pro APC is selected, or a simple eight FIFO system is selected. The PowerQUICC II Pro mechanism has been enhanced to support two level hierarchy; this allows for per VP shaping on the entire link, and per VC shaping for each VC inside the VP. The FIFO mechanism supports three scheduling algorithms: Fixed priority, Weighted Round Robin, and a combination of the two.

Notes about this chapter:

- Figure 39-30 is a general overview of the data structures used for queueing and scheduling in the MSP. This figure can be used as a reference while reading this chapter.
- The term UDC (User Defined Cell), UDH (User Defined Header) and Extra header are used intermittently to describe the cells that have addition bytes prepended to it.

The following figure depicts the flow that distinguishes the PowerQUICC II Pro SARing functionality from the MSP functionality.



OAM Functionality is described in Section 39.15, “OAM Support.”

Figure 39-10. Receive Flow

39.6 Address Resolution

39.7 MSP Buffer Management

The receiver routine in the MSP determines where the cells are routed to. There are three options:

— Cells that are SARed by and stored locally in memory for further processing. Those cells have the RCT[AAL] bits not equal 110. The SARing function is performed by the MPC8260 PowerQUICC II Pro SAR functionality. Some of the SARed cells are stored in the Raw-Cell-Queue

— Cells that are stored in the local Raw cell queue. Those cells may belong to connections which are switched or SARed. Normally those are OAM cells that are terminated in the switch.

— Cells that are switched. Those cells are automatically transferred to the transmitter, after appropriate address translation, and extra header handling has been performed by the RISC. The transmitter automatically sends the cells out the outgoing port. These cells are never handled by the local CPU.

The first two categories of cells are stored in local memory using the QUICC Engine memory model. This model includes Buffer Descriptors rings, that are initialized by the CPU, and data buffers, that may be preallocated, or fetched from a free buffer pool.

The third category is used only for cells that are automatically switched from the receiver to the transmitter. The following discussion pertains only to this category.

The MSP programming model offers a flexible and efficient memory management method, using the concept of **Cell Linked List (CLL)**. The main advantage of this method is it's memory efficiency - Memory allocation is done on a global basis. The user does not have to allocate memory per a connection, or per a specific queue.

The User allocates memory globally for all connections by defining a "**Free Cell Pool (FCP)**". The FCP is a pool of Empty cells pointers. The size of each empty cell is 64 bytes. Some of the bytes beyond the 52 bytes of the ATM cell are used by the RISC. The cells in the free cell pool may reside at any address in the 4Gbyte memory space.

On the receive side, the MSP automatically fetches free cells pointers from the FCP, and links them to the appropriate queue (either a per-VC queue or one of the FIFO queues). On the transmit side, the MSP automatically return free cells pointers to the FCP. The "movement" of cells is done by updating the pointers to the cells. This memory management method enables adaptive memory allocation for each connection.

39.7.1 Free Cell Pool Definition

The user allocates memory globally for all connections by defining a "**Free Cell Pool** (**FCP**)". Up to two free cell pools are available. The UCC Parameter RAM has an entry called FCP_BASE. This entry contains a pointer to the internal multi user RAM, containing the Free-Cell-Pool Descriptor. The free-Cell-Pool descriptor contains pointers to manage the Free-Cell-Pool. A system having one free cell pool should program the FCP-BASE in all UCC's to the same value.

The free cell pool pointer table (See Figure 39-11) includes sets of pointers of empty cells.

All queues in the MSP Switching function are composed CLL's. The queue chosen for storage is determined by the receive process running on each incoming cell. The empty cells in the FCP contain a 52 bytes space of Cell Body (CB) and 12 bytes space of cell Overhead (COV).

The Receiver pools the next Cell pointer using FCP#_Offset_Out located in the Free Cell Pool Descriptor in the parameter ram. The Transmitter returns the Cell pointer to an entry pointed by FCP#_Offset_In in the same structure.

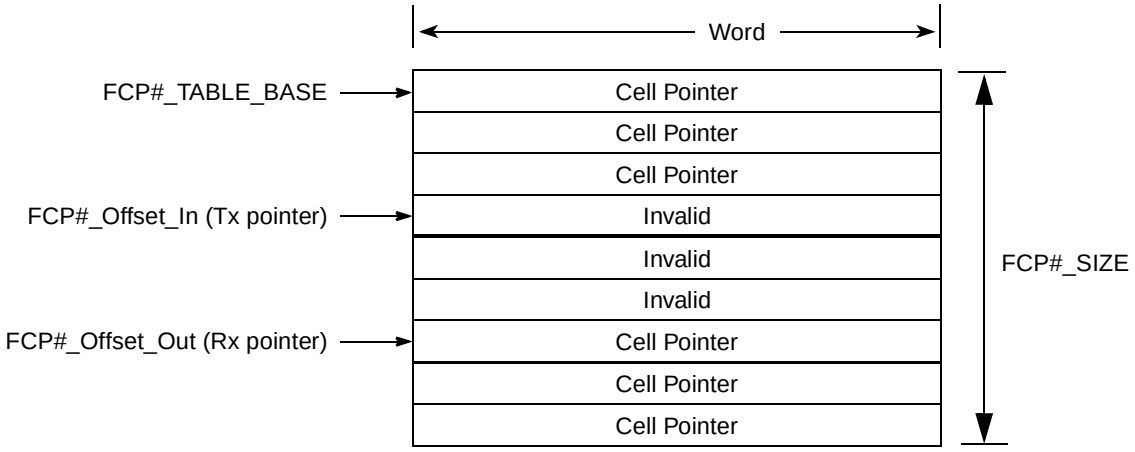


Figure 39-11. Free Cell Pool Pointer Table

39.7.2 Free Cell Pools Descriptor

Two Free Cell Pools are available to the Switch. This allows for more flexible memory allocation for different type of services. The descriptor to the FCPs is located in the multi-user RAM. The base addresses to the descriptor (FCP_BASE) is specified in Parameter RAM for the UCC.

The reserved area is for future microcode expansions.

Table 39-2. Free Cell Pools Descriptor

Offset	Name	Width	Description
0x00	FCP1_TABLE_BASE	Word	Holds the pointer to the first entry in the free cell pool. FCP1_BASE should be word aligned. User-defined.
0x04	FCP1_OFFSET_OUT	Word	Free cell pool Receiver pointer. Offset from the FCP1_BASE to the current entry used by the receiver. The actual address of the current received FCP entry = FCP1_BASE + FCP1_OFFSET_OUT. **Initialize to 0x4**. When the GET command is issued the RISC will take the cell pointer pointed by this entry and will advance the offset to the next entry.
0x08	FCP1_OFFSET_IN	Word	Free cell pool Transmitter pointer. Offset from the FCP1_BASE to the current entry which is being returned to the free cell pool. **Initialize to 0x0**. This implies this entry is empty and available for a returned cell pointer by the transmitter. Note: The actual number of pointers after initialization is less by one. IMPORTANT: The transmitter will never advance this entry so it would match the offset out value. (The RISC will advance it's offset_out value to match offset in and in this case the FCP is fully exhausted a FCPBE interrupt is issued by the RISC). When the PUT command is issued the RISC will return a cell pointer (placed in COMM_INFO field in the parameter ram page) to the FCP entry pointed by offset in and will advance offset in to the next entry.
0x0C	FCP1_RX_TH	Word	When the difference between the Offset_In and Offset_Out cross this value an THRx interrupt is generated. It indicates that the amount of cells left in the system has reached the low watermark.

Table 39-2. Free Cell Pools Descriptor (continued)

Offset	Name	Width	Description
0x10	FCP1_TX_TH	Word	If the difference between Offset_In and Offset_Out cross this value an THTx interrupt is generated. It indicates that the amount of cells in the system has reached the High watermark.
0x14	FCP1_SIZE	Word	User initialized to the Size in bytes of the FCP entries.
0x18	FCP1_IEV	Hword	Interrupt Event Register.(Section 39.7.2.1, “FCPx_IEV Entry”)
0x1A	FCP1_IMASK	Hword	Interrupt Mask Register.(See 39.7.2.2, “FCP_IMASK Entry”)
0x1C-1F			Reserved. Set to zero.
0x20	FCP2_TABLE_BASE	Word	See FCP1_TABLE_BASE description.
0x24	FCP2_OFFSET_OUT	Word	See FCP1_OFFSET_OUT description.
0x28	FCP2_OFFSET_IN	Word	See FCP1_OFFSET_IN description.
0x2C	FCP2_RX_TH	Word	See FCP1_RX_TH description.
0x30	FCP2_TX_TH	Word	See FCP1_TX_TH description.
0x34	FCP2_SIZE	Word	See FCP1_SIZE description.
0x38	FCP2_IEV	Hword	See FCP1_IEV description.
0x3A	FCP2_IMASK	Hword	See FCP1_IMASK description.
0x3C-3F			Reserved. Set to zero.

39.7.2.1 FCPx_IEV Entry

0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
THRxE	THTxE	FCPBE													

Table 39-3 describes the fields.

Table 39-3. FCPx_IEV

Bits	Name	Description
0	THRxE	If (FCP_COUNT <= FCP_RX_TH) this event bit is set, and an interrupt is given to CPU if not masked by THRxM bit.
1	THTxE	If (FCP_COUNT > = FCP_TX_TH) this event bit is set, and an interrupt is given to CPU if not masked by THTxM bit.
2	FCPBE	Free Cell Pool Busy Interrupt Event. This event bit is set, and an interrupt is given to CPU if not masked by FCPBM bit.
3-15		Reserved. Set to zero

39.7.2.2 FCP_IMASK Entry

0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
THRxM	THTxM	FCPBM													

Table 39-4. FCP_IMASK

Bits	Name	Description
0	THRxM	0- Mask THRxE Interrupt. (THRxE is set, but UCCE[FCPI] bit is not set). 1- enable setting of UCCE[FCPI]
1	THTxM	0- Mask THTxE interrupt (THTxE is set, but UCCE[FCPI] bit is not set). 1- enable setting of UCCE[FCPI]
2	FCPBM	0- Mask FCPBE Interrupt (FCPBE is set, but UCCE[FCPI] bit is not set) 1- enable setting of UCCE[FCPI]
3-15		Reserved. Set to zero

39.7.3 Free Cell Format

The Free cells residing in the Free Cell Pool have the following format:

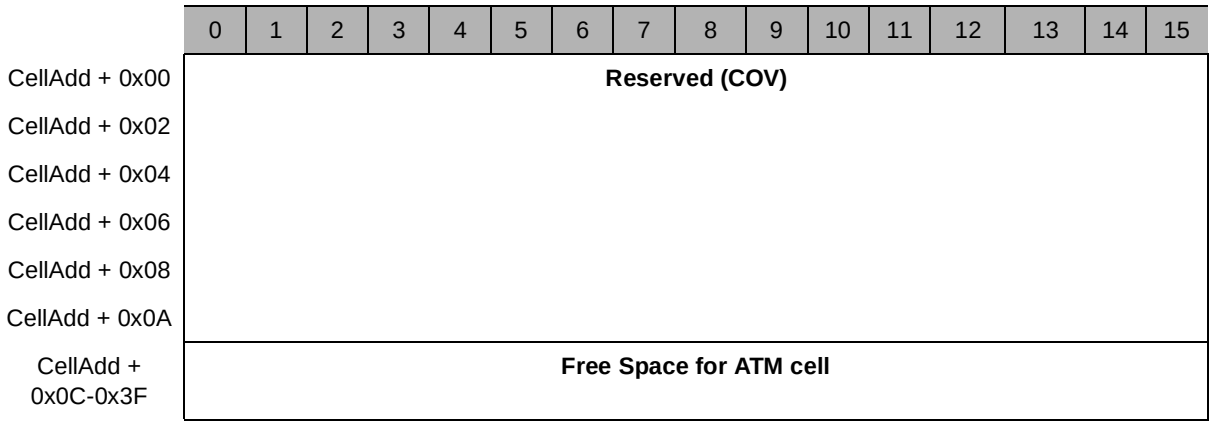

Figure 39-12. Free Cell Format

The user programs the FCP at initialization. Once the MSP starts running the user software must not touch the FCP. The RISC automatically pools and returns cell pointers when it moves the cells around.

39.7.4 Switched Cells Queue definition

The mechanism described below applies to all the queues in the PowerQUICC II Pro MSP. The user initializes at least one Free Cell Pool (FCP) of cell pointers. It is possible to initialize two free cell pools, and allocate cells from one of them on a connection basis. In addition to that for each active queue (either per-VC queue, FIFO queue or Multicast Queue), the user programs the respective TCT and RCT, and allocates one empty cell to the queue. This allocation is done by a special host command see

Section 39.20.1, “MSP FCP Commands” which provides the cell address to the application. The application will initialize RCT[EFDP/QPTRL] and TCT[QPTRLF] or FDTi[FIFO_FIRST] to point to this cell location. Except for this unique cell, all memory allocation is done automatically by the HW during run time. When a channel is being removed from the APC the application can “return” the last remaining cell pointer to the free cell pool by a different host command.

Figure 39-13 and Figure 39-14 show this mechanism as applied in a per-VC queue system. The FCP is full of Empty cell pointers (Number of entries in FCP pointer table -1), as defined previously. The Per VC queue CLL has one empty cell in it. When a cell is received in this connection, one cell pointer is extracted from the FCP and transferred to the Per VC Queue CLL

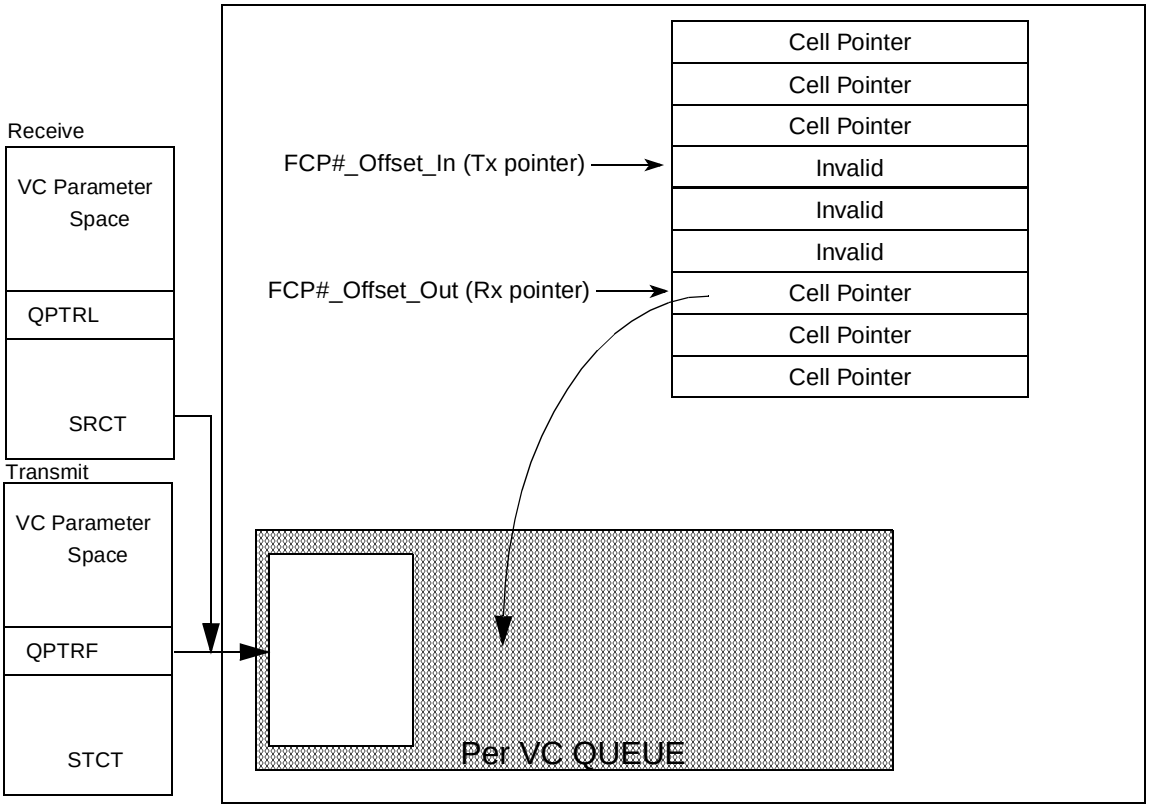

Figure 39-13. Per VC Queue: Initial State

The situation after the cell transfer is shown in Figure 39-14 below.

The first cell pointer from the FCP was extracted and changed to be the last cell in the Per VC Rx Queue Cell-FIFO.

When the scheduler schedules this connection for transmission, the transmitter does the same, but in the opposite direction. It takes the First cell in the Per VC Queue CLL, transmits its data, and returns the cell pointer back to the FCP to an entry pointed by FCP#_Offset_In.

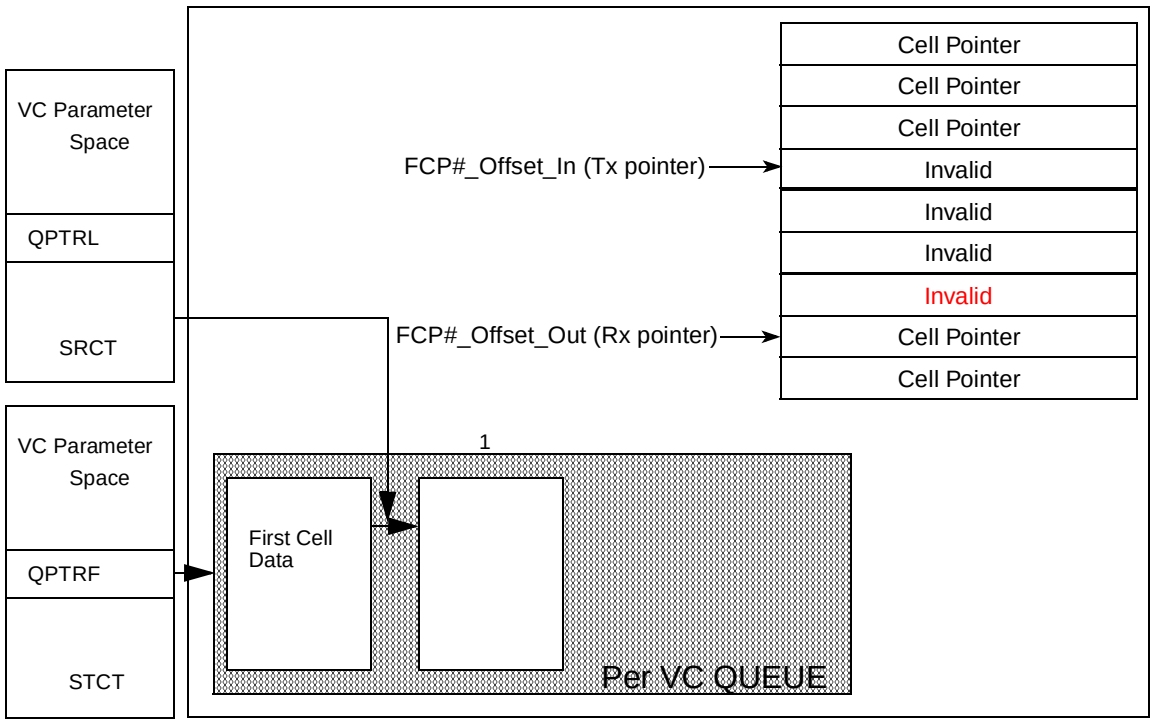

Figure 39-14. Per VC Queue: After Receiving a Cell

In this way, the receiver extracts the cell pointer from the FCP#_offset_out entry, and substitute it as the last cell in the per VC queue CLL. The transmitter extracts the first cell from the Per VC queue CLL, and returns it to an entry pointed by FCP#_offset_in.

When a connection requires more memory than usual, for instance because its transmitter is starving, or its receiver had a moment of peak cell rate, it takes more cells from the FCP. Those cells are returned to the FCP at last after the transmitter completes transmission.

Before pooling a cell from the FCP, the receiver compares FCP#_offset_out to FCP#_offset_in, in the Fifo Descriptor Table (FDT). If they are equal, an Overrun condition occurs, and interrupt is generated to the CPU.

39.7.5 Switched Cells Format

These cells are automatically switched from the receiver to the transmitter. They are organized in CLLs and reside either in VC queues or in FIFOs.

The information in this section is given for informative reasons only, and may be used for debugging purposes. The user software does not access those cells during normal operation.

The cells have the following format:

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
CellAdd + 0x00	**Next Cell Pointer (NCP)**															
CellAdd + 0x02																
CellAdd + 0x04	**TCC (Transmit Channel Code)**															
CellAdd + 0x06	**Reserved**															
CellAdd + 0x08																
CellAdd + 0x0A																
CellAdd + 0x0C-0x3F	**ATM cell**															

Figure 39-15. Switched ATM Cell Format

39.7.6 CPU cells

Switched cells sent to the CPU (OAM cells), are queued in the raw cell queue which is configured to AAL0 mode. The same queue is used by the QUICC Engine SAR function. The user software distinguishes between the cells by examining bits in the AAL0 RxBD. The extended definition of the AAL0 RxBD follows. For information regarding SEGT, ENDT & VPC of this channel the user should refer to the RCT of the specified channel code.

The BD has the following format:

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0x00	**E**	-	**W**	**I**			**CM**		OAMERR		CRE	OAM				
Offset + 0x02	Channel Code															
Offset + 0x04	**Rx Data Buffer Pointer (RXDBPTR)**															
Offset + 0x06																

Figure 39-16. AAL0 RxBD for OAM cells on switched connections

Table 39-5. AAL0 OAM RxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	E	Empty 0 The buffer associated with this RxBD is filled with received data, or data reception was aborted due to an error. The core can examine or write to any fields of this RxBD. The RISC does not use this BD again while E remains zero. 1 The Rx buffer is empty or reception is in progress. This RxBD and its associated receive buffer are owned by the RISC. Once E is set, the core should not write any fields of this RxBD.
	1	—	Reserved
	2	W	Wrap (final BD in table) 0 This is not the last BD in the RxBD table of the current channel. 1 This is the last BD in the RxBD table of the current channel. After this buffer has been used, the RISC will receive incoming data into the first BD in the table. The number of RxBDs in this table is programmable and is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	I	Interrupt 0 No interrupt is generated after this buffer has been used. 1 An Rx buffer event is sent to the interrupt queue after the ATM controller uses this buffer. UCCE[GINT*x*] is set when the INT_CNT reaches the global interrupt threshold.
	4–5	—	—
	6	CM	• Continuous mode 0 Normal operation. 1 The RISC does not clear the E bit after this BD is closed, allowing the associated buffer to be overwritten automatically when the RISC next accesses this BD.
	7	—	—
	8	OAMERR	Rx OAM error. Indicates an OAM cell which is erroneous and was removed terminated by the switch. See Table 39-32 for details.
	9	—	Reserved
	10	CRE	Rx CRC error. Indicates a CRC10 error in the current AAL0 buffer. The CRE bit is considered an error only if the received cell had a CRC10 field in the cell payload.
	11	OAM	Operation and maintenance cell. If OAM is set, the current AAL0 buffer contains an OAM cell. This cell is associated with the channel indicated by the channel code field (CC field).
	12-15	—	Reserved
0x02	—	CC	Channel code. This field functions as Channel code no. which specifies the channel code associated with this OAM cell.
0x04	—	**RXDBPTR**	Rx data buffer pointer. Points to the first location of the associated buffer; may reside in either internal or external memory. This pointer must be burst-aligned.

39.7.7 Multicast Cell Format

For details see Section 39.14.7, “Multicast Cells Format.”

39.8 Queue Management

Each cell queue (VCC, VPC, or any arbitrary bundle of VCCs queue) is associated with a set of 8 thresholds. When the number of cells in the queue exceeds a threshold level, a specific action is taken. Figure 39-20 describes typical threshold setting. The location of the 4 bit threshold field for both Per VCC/VPC queue and VCC bundle queues is the RCT field QTLS

When an incoming cell causes the EFCI threshold to be exceeded, an explicit forward congestion indication is given by the transmitter (The transmitter sets the middle PTI bit of the cell to be transmitted immediately following the reception that caused the EFCI threshold to be exceeded).

Five modes of queue management are available for the user:

c) GFR- This mode is implementing TM4.1. All conditions specified in section 4.5.5.1 for cell conformance definition are checked. Two modes are available for cell's CLP change from 1->0. F-GCRA algorithm is available in the leaky bucket (UPC) implementation. In addition to this, TAGGING and FIFO queue management are implemented as described in Section 39.8.3, "Queue Management for GFR Service."

d) PPD - Partial packet discard. In this mode each cell in a frame is tested for conformance by the UPC (if enabled) and by queue management unit so that it doesn't exceed PPD_CLP1 or PPD_CLP0 thresholds. Once a cell is non-conforming to one of those rules, it is discarded. All following cell in frame will be discarded as well, with no policing at all. The last cell in frame will be transmitted so synchronization won't be lost. If first cell was discarded all the frame including the last cell will be discarded.

e) EPD - Early packet discard. In this mode First cell in frame is tested for conformance by policer (if enabled) and by queue management unit so that it doesn't exceed EPD_CLP1 or EPD_CLP0 thresholds defined by the user. If conformed, all frame will be transmitted. If failed they will be discarded. Once the frame is received the UPC (GCRA) is being updated with no impact on discard decision. When next first cell arrives it is tested for conformance against the GCRA in it's current state.

f) EPD_PPD - Early packet discard on first cell in frame and Partial packet discard on next cells in frame.In this combined mode The first cell in frame is tested for conformance according to EPD mode (Early packet discard) using EPD_CLP1 or EPD_CLP0 thresholds defined by the user. If failed all the frame will be discarded. If the first cell conformed, next cells in the frame are tested according to PPD mode (Partial packet discard) for conformance using PPD_CLP1 or PPD_CLP0 thresholds.

g) Cell based discard mode- In this mode there is no tracking for any frames running over the ATM and the traffic is treated as AAL0 traffic. Each cell is tested for conformance as a "stand alone" cell by the policer and queue management unit using CB_CLP1 or CB_CLP0 thresholds. CB_CLP0 and CB_CLP1 thresholds are used in a non Framed traffic so that the User can differ the thresholds sets between Frame mode traffic and a non Frame mode traffic.

In all of these modes once the queue/FIFO limits are reached i.e. CLP0+1 threshold is exceeded cells will be discarded and PPD mechanism is activated if in AAL5 traffic.

Figure 39-6 summarizes the different thresholds and their induced behavior.

Table 39-6. Queue Threshold Level Set

Name	Description
EFCI	When the number of cells in the queue exceeds this threshold the PTI “middle” bit of the ATM cell header is set.
EPD_CLP0	frames in EPD/GFR mode - When the number of cells in the queue in exceeds this threshold CLP0 cells will be discarded.
EPD_CLP1	frames in EPD/GFR mode - When the number of cells in the queue exceeds this threshold CLP1 cells will be discarded.
PPD_CLP0	frames in PPDmode - When the number of cells in the queue in exceeds this threshold CLP0 cells will be discarded.
PPD_CLP1	frames in PPDmode - When the number of cells in the queue exceeds this threshold CLP1 cells will be discarded.
CB_CLP0	Cell Based mode - When the number of cells in the queue exceeds this threshold CLP0 cells will be discarded.
CB_CLP1	Cell Based mode - When the number of cells in the queue exceeds this threshold CLP1 cells will be discarded.
CLP0+1	When the number of cells in the queue exceeds this threshold all cells associated with this queue will be discarded.

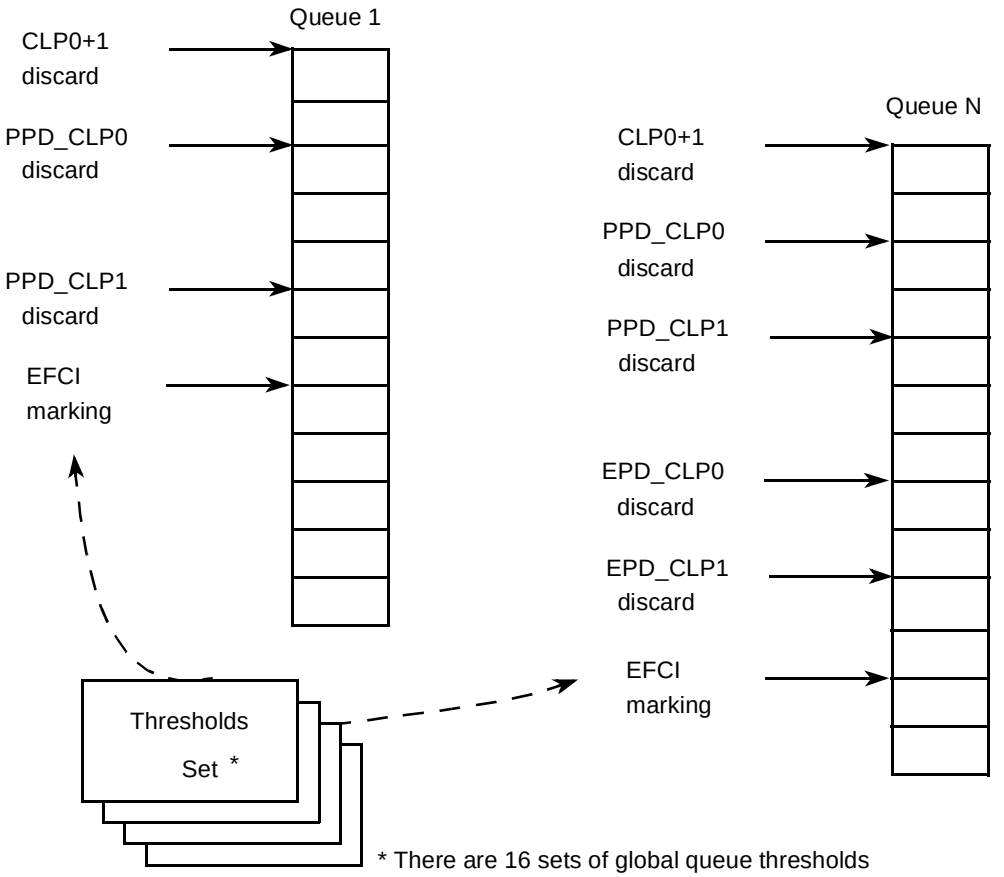

Figure 39-17. Typical Threshold Setting

39.8.1 Queues Threshold Level Table(s)

The Queue thresholds level table includes 16 sets of thresholds levels. Each queue is associated with one set of thresholds. The queue thresholds level tables reside in the multi user RAM. QLTS_BASE entry in the parameter RAM points to the start address of this table. The start address of each thresholds set is: QTLS_BASE + RCT[QTLS]*16.

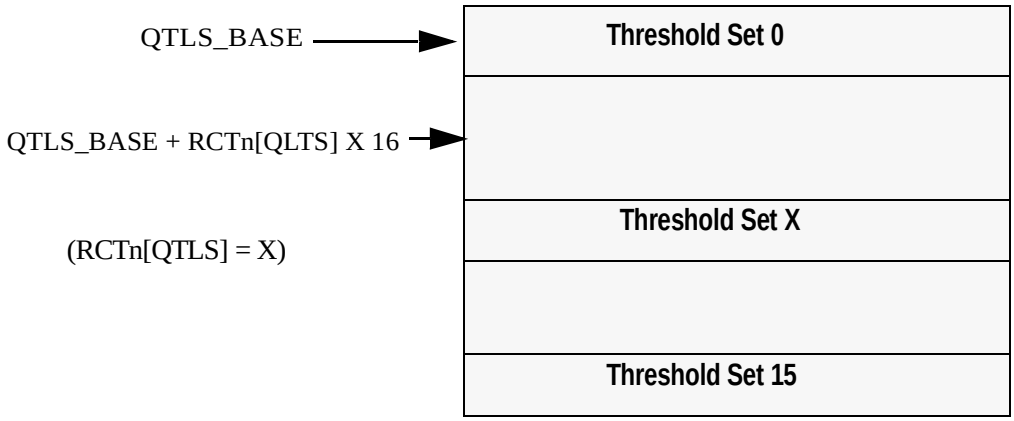

Figure 39-18. Queue Levels Sets Table

Table 39-7. Threshold Sets Memory Location

Address	Name	Width	Description
QTLS_BASE + 00	**EFCI_TH0**	Half Word	EFCI Threshold (Set 0)
QTLS_BASE + 02	**CLP0+1_TH0**	Half Word	CLP0+1 Threshold (Set 0)
QTLS_BASE + 04	**EPD_CLP1_TH0**	Half Word	EPD/GFR CLP1 Threshold (Set 0)
QTLS_BASE + 06	**EPD_CLP0_TH0**	Half Word	EPD/GFR CLP0 Threshold (Set 0)
QTLS_BASE + 08	**PPD_CLP1_TH0**	Half Word	PPD CLP1 Threshold (Set 0)
QTLS_BASE + 0A	**PPD_CLP0_TH0**	Half Word	PPD CLP0 Threshold (Set 0)
QTLS_BASE + 0C	**CB_CLP1_TH0**	Half Word	Cell based CLP1 Threshold (Set 0)
QTLS_BASE + 0F	**CB_CLP0_TH0**	Half Word	Cell based CLP0 Threshold (Set 0)
QTLS_BASE + 10	**EFCI_TH1**	Half Word	EFCI Threshold (Set 1)
QTLS_BASE + 12	**CLP0+1_TH1**	Half Word	CLP0+1 Threshold (Set 1)
QTLS_BASE + 14	**EPD_CLP1_TH1**	Half Word	EPD/GFR CLP1 Threshold (Set 1)
QTLS_BASE + 16	**EPD_CLP0_TH1**	Half Word	EPD/GFR CLP0 Threshold (Set 1)
QTLS_BASE + 18	**PPD_CLP1_TH0**	Half Word	PPD CLP1 Threshold (Set 1)

QTLS_BASE + 1C	**CB_CLP1_TH0**	Half Word	Cell based CLP1 Threshold (Set 1)
QTLS_BASE + 1E	**CB_CLP0_TH0**	Half Word	Cell based CLP0 Threshold (Set 1)
QTLS_BASE + F0	**EFCI_TH15**	Half Word	EFCI Threshold (Set 15)
QTLS_BASE + F2	**CLP0+1_TH15**	Half Word	CLP0+1 Threshold (Set 15)
QTLS_BASE + F4	**EPD_CLP1_TH15**	Half Word	EPD/GFR CLP1 Threshold (Set 15)

Table 39-7. Threshold Sets Memory Location (continued)

Address	Name	Width	Description
QTLS_BASE + F6	**EPD_CLP0_TH15**	Half Word	EPD/GFR CLP0 Threshold (Set 15)
QTLS_BASE + F8	**PPD_CLP1_TH15**	Half Word	PPD CLP1 Threshold (Set 15)
QTLS_BASE + FA	**PPD_CLP0_TH15**	Half Word	PPD CLP0 Threshold (Set 15)
QTLS_BASE + FC	**CB_CLP1_TH15**	Half Word	Cell based CLP1 Threshold (Set 15)
QTLS_BASE + FE	**CB_CLP0_TH15**	Half Word	Cell based CLP0 Threshold (Set 15)

NOTE

The actual values of the thresholds are limited by the maximum number of cells in a queue. This number is determined by the limitations of the programming model. For example in the STCT the QCC value is limited by 14 bits. therefore a relevant threshold value should be a number between 1 - (2^{14}-1).

The threshold mechanism is supposed to ensure that the Queue cells counters (QCC for STCT and FIFO_COUNT for FIFO), do not overflow; this means that cells should be discarded before these counters reach their maximum value. If these counters overflow, cells are discarded.

39.8.2 Adaptive Threshold Levels

It is well understood that there should be a tight relationship between the FCP Memory utilization and the thresholds the MSP uses for accepting, marking or discarding a cell. Due to the dynamic nature of the system and the varying number of connections it is usually desired to use different sets of thresholds for different levels of FCP memory occupancy. For example, if the number of connections is relatively low, it is generally possible to allocate more Queue resources for each connection by using higher threshold levels. The MSP supports this feature by providing software hook-ups for managing the Threshold levels dynamic behavior using any desired algorithm.

The MSP Free Cell Pool descriptors include two programmable thresholds for indicating the FCP usage. Each of these two thresholds generate a maskable interrupt. One threshold (FCP1_TX_TH) generates an interrupt (if not masked) when the number of cell pointers is equal or larger than the threshold, the other threshold (FCP1_RX_TH) generates an interrupt when the number of cell pointers is equal or smaller than the threshold. This mechanism in conjunction with CPU software allows for the implementation of various schemes of buffer management in the system.

Example for implementation of Hysteresis on the free buffer pool:

At initialization, the transmit threshold (FCP1_TX_TH) associated interrupt is disabled and the other (FCP1_RX_TH) is enabled. When the higher threshold is exceeded the situation reverses, the higher threshold associated interrupt is disabled and the other is enabled, and so on. When the host software detects an interrupt it performs an update of the QTLS table or switches to another table as explained above. This introduces a hysteresis like behavior as depicted in the figure below:

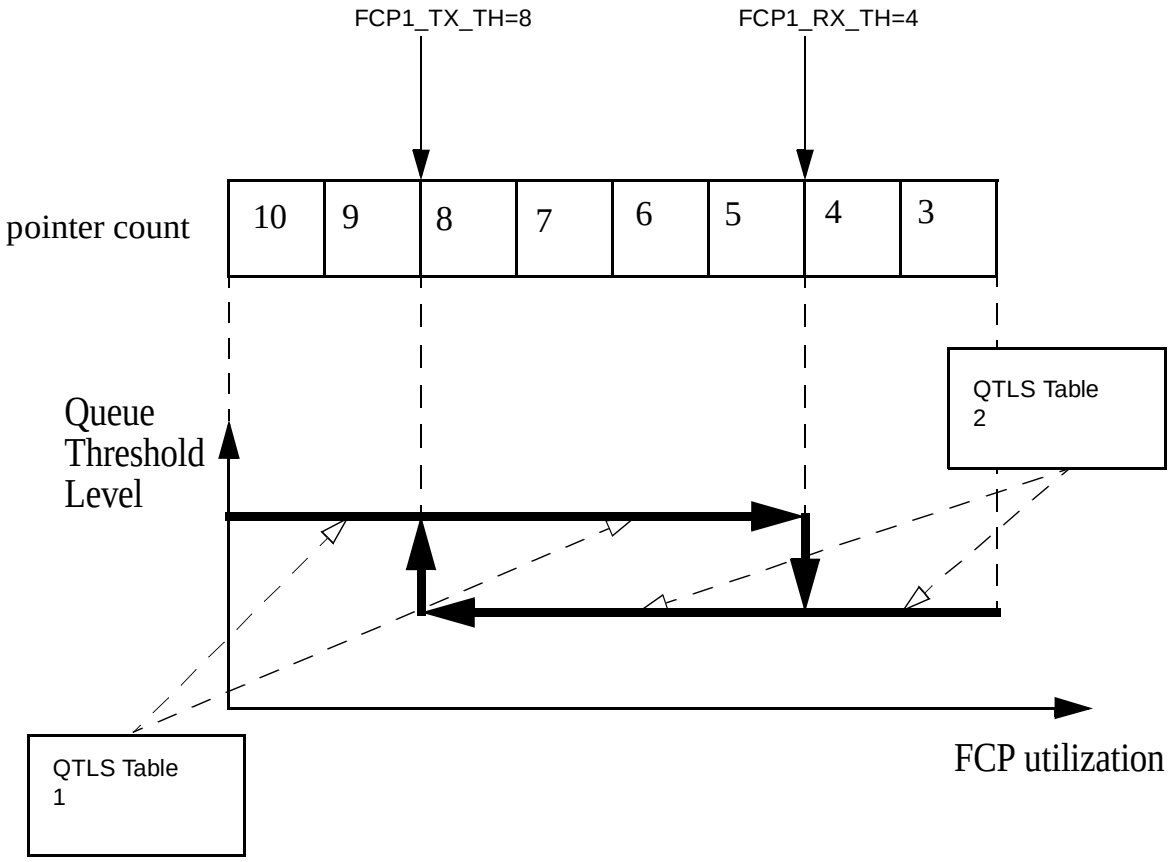

Figure 39-19. Implementing a Hysteresis Mechanism for FCP Thresholds

Note that thresholds can also be modified on the fly, to implement more complex Queue management algorithms.

39.8.3 Queue Management for GFR Service

The GFR service requires a different queue management scheme in order to be effective.

The MSP supports controllable service level for GFR eligibility.

The purpose of the GFR queueing management is to guarantee the service to eligible frames while maintaining best effort service for ineligible ones.

To be consistent with the GFR service, the CLP1 and CLP0 thresholds are being checked only for the first cell of an incoming new frame.

When a start of frame cell is being received its CLP bit is used to determine whether the current frame is eligible for service. As a rule, if the CLP bit is set the frame is considered ineligible by the F-GCRA algorithm. If the option is set to tagging and not to discard mode the cell would still be processes to the Queue management and there the CLP1 threshold would be examined.

Note that because the GFR policy is enabled, the CLP bit is identical for all of the cells in a given frame.

When a start of frame and CLP0 cell is being received, the EPD_CLP0 threshold is used to determine whether to enqueue the received frame or discard it.

For a typical implementation which includes GFR service the EPD_CLP0 threshold should be set above the EPD_CLP1 threshold (as depicted in the figure below).

The EFCI threshold is used by the transmitting side and its functionality remains unchanged.

The CLP0+1 threshold behavior remains the same.

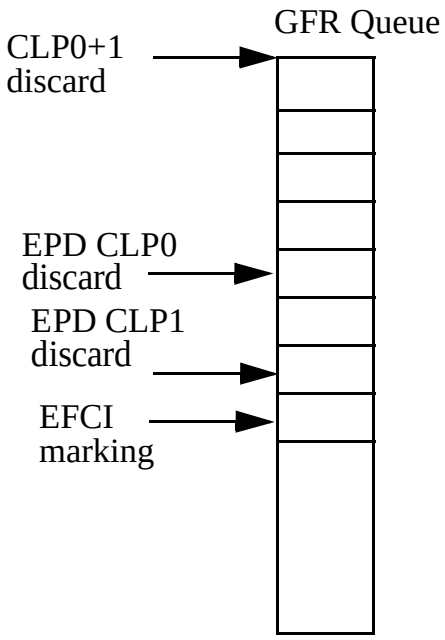

Figure 39-20. Typical Threshold Setting for GFR

39.9 Connection Tables

The receive and transmit connection tables, store host-initialized connection parameters after connection set-up and temporary parameters used during SAR and switch operation. There are a number of different formats for the connection parameters, depending on the functionality of the connection associated with the channel code in question. In some cases there is an extension to the connection table entry. Each connection table entry resides in a 32-byte space. An ATM channel is considered internal if its tables are in an internal multi-user-port RAM; it is considered external if the tables are in external memory.

Figure 39-8 lists the type of RCT, TCT, and TCTE for switched cells. The format of those structures for SARed cells, are specified in Chapter 32, "ATM Controller AAL0, AAL1, and AAL5." Note that the RISC tests the bits mentioned in the table to determine which format is applied to a given RCT/TCT.

Table 39-8. Receive and Transmit Connection Tables

ATM Switch Functionality RCT[AAL]=110 TCT[AAL]=110	Bits to select Function Receive Transmit		Receive no leaky Bucket	Receive Leaky Bucket	Transmit no UDC	Transmit UDC
Switch Unicast APC Shaping	RCTM=00	TCTM=00	**SRCT** UPCM=00	**SRCT + UPCT** UPCM!=00	**STCT** FPSMR[TUDC]=0	**STCT + STCTE** FPSMR[TUDC]=1 or ATT=01,10
Switch Unicast FIFO Shaping	RCTM=10	TCTM=10	**SRCT** UPCM=00	**SRCT + UPCT** UPCM!=00	**FTCT** FPSMR[TUDC]=0	**FTCT** FPSMR[TUDC]=1
Switch Unicast Root of Hierarchy	RCTM=01	TCTM=01	**SRCT** UPCM=00	**SRCT + UPCT** UPCM!=00	**HTCT + FTCT** FPSMR[TUDC]=0	**HTCT + FTCT (+ STCTE)** FPSMR[TUDC]=1 (or ATT=01,10)
Switch Multicast	RCTM=11	TCTM=11	**MRCT** UPCM=00	**MRCT + UPCT** UPCM!=00	**MTCT** FPSMR[TUDC]=0)	**MTCT + STCTE** FPSMR[TUDC]=1 or ATT=01,10

NOTE

To improve performance, store parameters for fast channels in internal multi-user RAM and parameters for slower channels in external memory. Channel codes 0-255 are parameters from internal memory. Connection tables for external channels are read and written from external memory when the RISC processes a cell.

NOTE

In all connection tables, fields which are not used should be initialized to zero.

39.9.1 ATM Channel Code

Each ATM channel is associated with a channel code, an index to the channel's connection table entry. The first channel in the table has channel code one, the second has channel code two, and so on. Codes of 255 or less indicate internal channels; codes greater than 255 indicate external channels. Channel code one is reserved and can't be used by the user. The channel code is used to specify a VCC when sending a TRANSMIT command, initiating the internal, external CAM or address compression tables, and when the RISC sends an interrupt to an interrupt queue.

EXAMPLE

In this example the receive structures are called RCT, and the transmit are called TCT.

Suppose a configuration supports 1,024 regular ATM channels. To allocate 4 Kbytes of multi-user RAM space to the internal connection table, determine that channel codes 0–63 are internal (64 VC * 64 bytes

(RCT+TCT) = 4 K). Channels 0–1 are reserved. The rest (1024 - 62 = 962) are external channels associated with channel codes 256–1217.

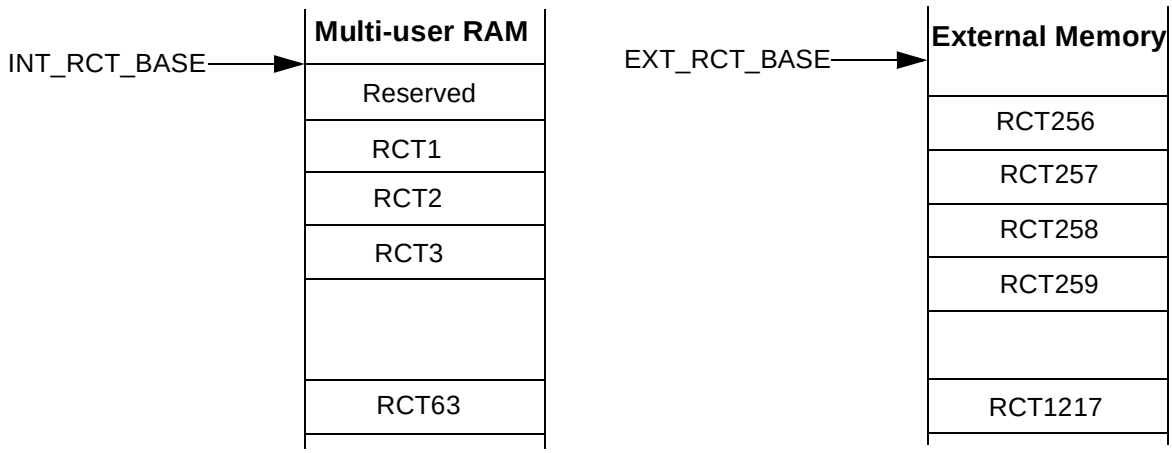

Figure 39-21. Example of a 1024-Entry Receive Connection Table

The real starting address of a RCT entry associated with channel code 3 is as follows:

INT_RCT_BASE+ (3 * 32) = INT_RCT_BASE + 96

The real starting address of a RCT entry which is associated with channel code 256 is:

EXT_RCT_BASE+ (256 * 32) = EXT_RCT_BASE + 8192

The same address calculation is used for TCT and TCTE. The TCT base address is INT_TCT_BASE, EXT_TCT_BASE. The TCTE base address is INT_TCTE_BASE, EXT_TCTE_BASE.

39.9.2 SRCT - Switched Cells Receive Parameter Table

Figure 39-22. SRCT

For an active channel, the RISC uses a burst cycle to fetch the 32-byte RCT and writes back only the first 24 bytes. The user can alter the interrupt enable bits on the fly.

Table 39-9 describes SRCT fields.

Table 39-9. SRCT Field Descriptions

Offset	Bits	Name	Description
0x00	0	—	Reserved. Set to zero.
	1	—	Reserved. Initialize to zero.
	2	GBL	Global. Asserting GBL signal on memory bus, enables snooping of data buffers, BD interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”
	3–4	BO	Byte ordering—used for data buffers. 00, 01, 11 Reserved 10 Big endian

Table 39-9. SRCT Field Descriptions (continued)

Offset	Bits	Name	Description
	5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.
	6	**DTB**	Data buffers bus 0 Cell buffers reside on the coherent system bus. 1 Cell buffers reside on the secondary bus.
	7	**BDB**	Interrupt queues and UPCT bus 0 reside on the coherent system bus. 1 reside on the secondary bus.
	8	**VPC**	Virtual Path Connection (used for OAM termination) 0 This channel is not a VP connection 1 This channel is a VP connection
	9	**AVCON**	Auto VC On. Automatic Scheduling of channel in the APC. Valid only for STCT and HTCT MSP modes. This bit is used when the corresponding transmitter works in auto VC off mode (TCT[AVCF]=1). If set, the receiver automatically schedules the frame in the APC scheduler for transmission. 0 No Automatic rescheduling. 1 Automatic rescheduling.
	10	**EPDE**	Early Packet Discard (EPD) Enable. In this mode first cell of each frame is checked for conformance by the policer (GCRA) and queue management. If conformed, all cells in the frame will be transmitted. Leaky buckets are still being updated with no affect on discard decision. If first was discarded so will the rest of the frame. 0 EPD is disabled. 1 EPD is enabled. Setting this bit implies frame based connection (AAL5). For EPD/PPD combined mode both EPDE and PPDE bits should be set.
	11	**PPDE**	Partial Packet Discard (PPD) Enable. When a single cell is dropped by the policer, or by the queue management then all other cells associated with the current packet are dropped. The last cell in a packet will always be accepted. Only if the first cell is discarded then the Last cell will be discarded as well. Note: This bit should be reset to 0 when using GFR mode. Setting this bit implies frame based connection (AAL5). 0 PPD is disabled. 1 PPD is enabled. For EPD/PPD combined mode both EPDE and PPDE bits should be set.
	12-13	**UPCM**	UPC (Policing) Mode (See Section 39.11, “UPC Policer” for details) 00 UPC is disabled. 01 UPC is enabled, no GFR Mode 10 UPC is enabled in GFR Mode. Drop cells if CLP bit in frame changes from 1 to 0 11 UPC is enabled in GFR Mode. Set CLP bit in cells if CLP bit in frame changes from 1 to 0. Note:1. In GFR mode, if CLP bit changes from 0 to 1 cells are always dropped. See ATM forum, TM 4.1, Section 4.5.5.1 and other related sections. 2. For UPCM=1x (GFR mode), EPDE/PPDE should be cleared.
	14–15	**INTQ**	Points to one of four interrupt queues available.

Table 39-9. SRCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0-1	**RCTM**	RCT Mode 00 This RCT is used for a switched channel shaped by the APC. 32 bit QPTRL is placed in address 0x4 of RCT. 01 This RCT is used for a switched channel shaped by external FIFOs. 32 bit EFDTP FIFO Descriptor Pointer to external memory is placed in address 0x4 of RCT. 10 This RCT is used for a switched channel shaped by internal FIFOs. 16 bit FDTP FIFO Descriptor Pointer to internal Multi-user RAM is placed in address 0x4 of RCT. 11 This RCT is an MRCT and is used for Multicast shaping. See Section 39.14, “Multicast.”
	2	**FCP**	Free Cell Pool 0 Use Free Cell Pool 1 1 Use Free Cell Pool 2
	3	**—**	Reserved. Set to zero.
	4	**—**	Reserved. Set to zero.
	5	**—**	Reserved. Set to zero.
	6	**—**	Reserved. Set to zero.
	7	**—**	Reserved. Set to zero.
	8	**—**	Set to zero.
	9-12	**QLTS**	Queue Level Threshold Set. This entry picks one of sixteen threshold sets for the queue. For FIFO and Hierarchical modes this entry is not valid. Instead, in the FDT (Fifo descriptor table) the entry FIFO_MODES has the QLTS entry which point to the thresholds set.
	13-15	**AAL**	AAL type: 000 AAL0 Reassembly with no adaptation layer. 001 AAL1 ATM adaptation layer 1 protocol. 010 AAL5 ATM adaptation layer 5 protocol. 011 AAL3. 100 AAl2. 101 CES. 110 MSP-Multi ServIce Protocol - switched ATM cells.
0x04	32 16	**EFDTP/QPTRL** **FDTP**	(RCT[RCTM]=01). In this mode the entry is initialized to point to the appropriate descriptor. EFDP: External FIFO descriptor Pointer (32 bits). Points to a queue descriptor in external memory. This is used to bundle multiple connections to one FIFO queue (RCT[RCTM]=10), in hierarchical mode. QPTRL: Queue Pointer Last (32 bits): Points to a buffer where the last cell received on this VCC resides. This is used for per VCC queueing (RCT[RCTM]=0). In this mode the entry is updated by the RISC. FDP: FIFO Descriptor Pointer (16 bits): Points to a queue descriptor residing in internal memory. This is used to bundle multiple connections to one FIFO queue
0x06	16	**WFTMINiP**	FOR FIFO MODE ONLY (2’nd half word): This is a pointer to the WFTMINi which is associated with the Transmitter phy FIFO Descriptor Pointer Table. See Table 39-35
0x8	—	**HTCT TCC**	Valid only for HTCT with AVCON mode enabled. Transmit Channel Code. This entry is used to schedule the cell for transmit, if the channel is not currently active. It provides the receiver with the transmitter channel number to which the received cell is forwarded.

Table 39-9. SRCT Field Descriptions (continued)

Offset	Bits	Name	Description
0xA	0-15	**HTCT TAPTR/**	Valid only for HTCT with AVCON mode enabled. **Traditional APC mode:** TAPTR: Transmitter APC Pointer. This entry is the pointer to the APC priority Table entry in multi-user RAM. This is used by the RISC to automatically add a connection to the APC (if it was previously removed since its 8 FIFOs were empty). The user must allocate place for the ATM_AVCON_BASE table, since this HTCT AVCON mode for traditional APC, uses this table to indicate if the HTCT channel is active or not. Also the user must clear the VCON bit in the HTCT table in this mode.
	0-13	**GCRA Scheduler PHY Parameter Table ptr**	**DRR APC mode:** 14 most significant bits of the pointer to the GCRA Scheduler PHY Parameter Table.
	14-15	**GCRA Scheduler PRI**	GCRA Scheduler Priority.
0x0C	—	**QDCC**	Queue Dropped Cell Count. Cells dropped due congestion in the queue.
0x0E	—	**CLP1 Count**	CLP1 cells Count.
0x10	—	**CLP0 Count**	CLP0 cells Count.
0x14	—	**GFRT**	Threshold for Maximum AAL5 packet size (MFS) for GFR. GFRT should be programed to (MFS - 1)
0x16	—	**GFRL**	Current length of AAL5 packet for GFR policing. Should be initialized to 0.
0x18	—	**UPCPTR**	Index Pointer to external UPC Parameter Table (UPCT). Aligned to 32 byte addresses. See Section 39.11, “UPC Policer” for details.
0x1A	—	**TCC**	Transmit Channel Code. This entry is used to schedule the cell for transmit, if the channel is not currently active. It provides the receiver with the transmitter channel number to which the received cell is forwarded. For RCT[RCTM]=0, TCC means STCT Channel Code, and for RCT[RCTM]=01 and for RCT[RCTM]=10 modes, TCC means FTCT Channel Code. For RCT[RCTM]=0, this information provides the receiver the pointer to the TCT info of the transmitter channel number to which the received cell is forwarded.

Table 39-9. SRCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x1C	0-15	**TAPTR/**	Valid only for RCT[RCTM]=0 and AVCON mode is enabled. **Traditional APC mode:** TAPTR: Transmitter APC Pointer. This entry is the pointer to the APC priority Table entry in multi-user RAM. This is used by the RISC to automatically add a connection to the APC (if it was previously removed since its queue was empty). **GCRA Scheduler mode:** 14 most significant bits of the pointer to the GCRA Scheduler PHY Parameter Table.
	0-13	**GCRA Scheduler PHY Parameter Table ptr**	GCRA Scheduler Priority.
	14-15	**GCRA Scheduler PRI**	For RCT[RCTM]=01 and for RCT[RCTM]=10 modes, this entry is defined as: FSDEF: See section Section 39.9.2.1, “FSDEF (FIFO Status Definition)” for bit definition.
		FSDEF	
0x1E	0	**MS**	Match Status. Valid only for CC in UDH mode. 0 Match was found. 1 Match was not found. Cell will be discarded without updating the SRCT in external memory. The CPU can use this mechanism when performing dynamic changes in the SRCT/MRCT, without the interfering of the QUICC Engine block.
	1	**NCCLPIE**	Non-Conforming CLP1 or CLP0 counters overflow interrupt enable.
	2-7	**PMT**	Performance Monitoring Table Index. One of 64 performance monitoring parameter tables is chosen fir this channel.
	8	**SEGT**	Segment OAM termination (used for OAM termination) 0 Do not terminate segment OAM cells. 1 Terminate segment OAM cells (OAM cells are sent to Raw Cell Queue).
	9	**ENDT**	End-to-end OAM termination (used for OAM termination) 0 Do not terminate end-to-end OAM cells 1 Terminate end-to-end OAM cells (OAM cells are sent to Raw Cell Queue).
	10	**GCRA Sched_AVCON**	GCRA Scheduler AVCON. Valid only if AVCON bit is set. Indicates which type of APC is used to activate the channel. 0 - Traditional APC. 1 - GCRA Scheduler
	11	**—**	
	12	**QTHIE**	Any queue threshold violation Interrupt enable not including EFCI marking.
	13	**QDCCIE**	QDCC Counter overflow Interrupt Enable
	14	**CLPIE**	CLP0C Counter or CLP1C Counter overflow Interrupt Enable
	15	**PME**	Performance monitoring Enable 0 No performance monitoring on this channel 1 Performance monitoring is enabled on this channel

39.9.2.1 FSDEF (FIFO Status Definition)

The format of the FSDEF entry in SRCT is as follows. This entry is

MODE	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Hiera.	FIFOID			FSOff												
FIFO	FIFOID			-												

Figure 39-23. FSDEF bits

Table 39-10 describes the bits if the FSDEF entry.

Table 39-10. FSDEF Field Descriptions

Bits	Name	Description
0–2	**FIFOID**	Valid for Hierarchical and FIFO mode. This is the ID (0-7) of the FIFO pointed by the FDT/EFDT. This number is used by the RISC to turn on the correct bit in the FS (FIFO State) in the Multi-user RAM. User should program this entry to point to which of the 8 FIFO's to insert the incoming cell.
3-15	**FSOff**	FIFO Status Offset- For Hierarchical mode this is the Offset to FIFO status (FS) structure from FS_BASE in the multi-user RAM. The FIFO status has one bit set for each FIFO that has a non-empty queue. The user program this entry to point to the selected 8 FIFO structure.

39.9.3 Multicast Cells MRCT

AAL=110, TCTM=11

See Section 39.14, "Multicast."

39.9.4 STCT - Switched Cells Non Hierarchical Scheduling

AAL=110, TCTM=00

The STCT is used to transmit cells that are scheduled by the APC.

Figure 39-24 shows the general layout for the STCT cell that is scheduled.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Figure 39-24. STCT

The RISC updates only entries 0x00-0x17 (24 bytes), and 1 byte located in 0x1e; other bytes are read by the RISC but are not updated by it. The CPU controlling the connection can change relevant bits from entries 0x18-0x1F (not including 0x1e) on the fly, and the RISC will act upon the new value, next time the TCT is used. The CPU shouldn't change the content of the byte located in address 0x1e, but can only read the status of this byte.

Table 39-11 describes general STCT fields.

Table 39-11. STCT Field Descriptions

Offset	Bits	Name	Description
0x0	0-1	—	Reserved. Initialize to zero.
	2	**GBL**	Global. Asserting GBL enables snooping of data buffers, BD, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	**BO**	Byte ordering. This field is used for data buffers. 00, 01, 11 Reserved. 10 Big endian.
	5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.
	6	**DTB**	Data buffers bus. Cell location (where the FCP resides) If Insert cell mode is enabled and the cell resides in external memory, this bit should reflect the bus location of the cell to be transmitted. 0 Data buffers reside on the coherent system bus. 1 Data buffers reside on the secondary bus.
	7	**BDB**	Interrupt queues bus. If Insert cell mode is enabled and the CC>255 this bit should reflect the bus location of the Insert Cell pointers Table see Section 39.15.3, "Insert Cell Mode." 0 Resides on the coherent system bus. 1 Resides on the secondary bus.

Table 39-11. STCT Field Descriptions (continued)

Offset	Bits	Name	Description
	8	**AVCF**	Auto VC off. Determines APC behavior when the last buffer associated with this VC has been sent and no more cells are queued. The number of cells in the VC queue is specified in the TCT[QCC] field. 0 The APC does not remove this VC from the schedule table and continues to schedule it to transmit. This mode is used for root nodes in hierarchical APC. Root nodes cannot be removed from the scheduler, since there is no mechanism to determine if there are cells scheduled in the leaves beneath the root (the assumption is that there are always cells to be scheduled under the root nodes which schedule to VPs). 1 The APC removes this VC from the schedule table, if TCT[QCC]=0, the VC queue has been empty for one cell interval time for this connection. When the APC remove this VC it resets TCT[VCON] (VCON=0). The VC is automatically activated by the receiver, if a cell arrives, setting TCT[VCON] (VCON=1). See Table 39-13 in the explanation of HCTC[AVCF]
	9	—	Reserved. Set to zero.
	10-11	**ATT**	ATM traffic type 00 Peak cell-rate pacing. The host must initialize PCR and the PCR fraction. Other traffic parameters are not used. 01 Peak and sustain cell rate pacing (VBR traffic). The APC performs a continuous-state leaky bucket algorithm (GCRA) to pace the channel-sustain cell rate. The host must initialize PCR, PCR fraction, SCR, SCR fraction, and BT (burst tolerance). 10 Peak and minimum cell rate pacing (UBR+ traffic). The host must initialize PCR, PCR fraction, MCR, MCR fraction, and MDA. If Scalable APC is enabled, then the user should allocate an additional 4-6 bytes (depend on the alignment) for the APC scheduling table. 11 Reserved.
	12	—	Reserved. Set to zero.
0x00	13	**VCON**	Virtual channel is on. In non AVCON/AVCOFF Mode: Should be set by the host before it issues an ATM TRANSMIT command. When the host sets TCT[STPT] (stop transmit), the RISC deactivates this channel and clears VCON when the channel is next encountered in the APC scheduling table. The host can issue another ATM TRANSMIT command only after the RISC clears VCON. In AVCON/AVCOFF Mode: Should be cleared by the host. If TCT[QCC]=0 and TCT[AVCOFF] bit is set the APC is automatically removes this VC from the APC slots and resets TCT[VCON] bit, (VCON=0) When cell arrives on the Receiver side and RCT[AVCON] bit is set The VC is automatically activated by entering the VC to an APC slot and sets TCT[VCON] bit, (VCON=1).
	14-15	**INTQ**	Points to one of four interrupt queues.

Table 39-11. STCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0-1	**TCTM**	TCT Mode 00 This is a STCT used as a leaf node for APC shaping 01 This is a HTCT used for a root node of hierarchical shaping 10 This is a FTCT used for Fast FIFO shaping 11 This is a MTCT used for Multicast shaping
	2	**FCP**	Free Cell Pool 0 Use Free Cell Pool 1 1 Use Free Cell Pool 2
	3-8	—	Reserved. Initialize to zero
	9-12 .	**QLTS**	Queue Level Threshold Set. This entry picks one of sixteen threshold sets for the queue
	13-15	**AAL**	AAL type: 000 AAL0 Reassembly with no adaptation layer. 001 AAL1 ATM adaptation layer 1 protocol. 010 AAL5 ATM adaptation layer 5 protocol. 011 AAL3. 100 AAl2. 101 CES. 110 MSP-Multi ServIce Protocol - switched ATM cells.
0x04		**QPTRF**	Queue Pointer First (32 bits): Points to a buffer where the first cell to be transmitted on this queue resides.
0x08	0-15	**QCC**	Queue Cell Count: The number of cell buffers currently queued for this channel. Used by RISC. If QCC=0 there are no cells in the queue. If TCT[VCON]=0 the channel has been deactivated by the RISC. Initialize to zero.
0x0A	0-15	**Reserved**	Reserved. Initialize to zero.
0x0C	0–7	**Rate Remainder**	Rate remainder. Used by the APC to hold the rate remainder after adding the pace fraction to the additive channel rate. Initialize to 0.
	8–15	**PCR Fraction**	Peak cell rate fraction. Holds the peak cell rate fraction of this channel in units of 1/256 slot.
0x0E	—	**PCR**	Peak cell rate. Holds the peak cell rate (in units of APC slots) permitted for this channel according to the traffic contract.
0x10	—	**CLP0 Count**	CLP0 cell count. Initialize to 0.
0x14	—	**CLP1 Count**	CLP1 cell count. Initialize to 0.
0x16	—	**APCLC**	APC Linked Channel. Used by RISC. Initialize to zero.
0x18	0-11	**TVPI**	Transmit VPI. Replaces VPI of cell if CVP bit is set (including GFC bits if CGFC is set)
	12-15	**TVCI**	Most significant bits of Transmit VCI. Replaces VCI of cell if CVC bit is set

Table 39-11. STCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x1A	0-11	**TVCI**	Least significant bits of Transmit VCI. Replaces VCI of cell if CVC bit is set
	12	**Reserved**	Reserved. Initialize to zero.
	13-15	**CVP/CVC/CGFC**	CVP/CVC/CGFC (address translation, part of ATM header) 000 no translation 001 NOT valid 010 Change VCI Portion of ATM address 011 NOT valid 100 Change VPI Portion of ATM address (including GFC) 101 Change VPI Portion of ATM address (NOT including GFC) 110 Change VCI & VPI Portion of ATM address (including GFC) 111 Change VCI & VPI Portion of ATM address (NOT including GFC)
0x1C	0-1	—	Reserved. Set to zero
	2-7	**PMT**	Performance monitoring Table Index. One of 64 performance monitoring parameter tables is chosen for this channel
	8-15	—	Reserved. Set to zero
0x1E	0	**INS_CELL_Flag**	Insert Cell Flag. Initialized to 0. Set by the RISC when insert cell host command is performed by the user, for inserting a cell to this connection. See Section 39.20.2, “MSP Insert Cell Command“. Reset by the RISC on completion of the inserted cell operation. See 39.15.3, “Insert Cell Mode”. The CPU can only read this status bit in order to verify that the inserted cell was actually transmitted for this channel. Only after this bit was cleared another insert cell host command for this channel could be issued.
	1-11	—	Reserved. Set to zero
	12	**efcie**	EFCI threshold interrupt enable.
	13	**STPT**	Stop transmit. Initialize to 0. When the host sets this bit, the RISC deactivates this channel and clears TCT[VCON] when the channel is next encountered in the APC scheduling table. The RISC reads 32 bytes of TCT, but writes back only 24 bytes. Therefore this bit is not altered by the RISC.
	14	**CLPIE**	CLP0C Counter or CLP1C Counter overflow Interrupt Enable
	15	**PME**	Performance monitoring Enable 0 No performance monitoring on this channel 1 Performance monitoring is enabled on this channel

39.9.5 FTCT - FIFO TCT

TCTM=10

The FTCT is used to transmit switched cells that are scheduled by the FIFOs.

Figure 39-25 shows the general layout for the FTCT.

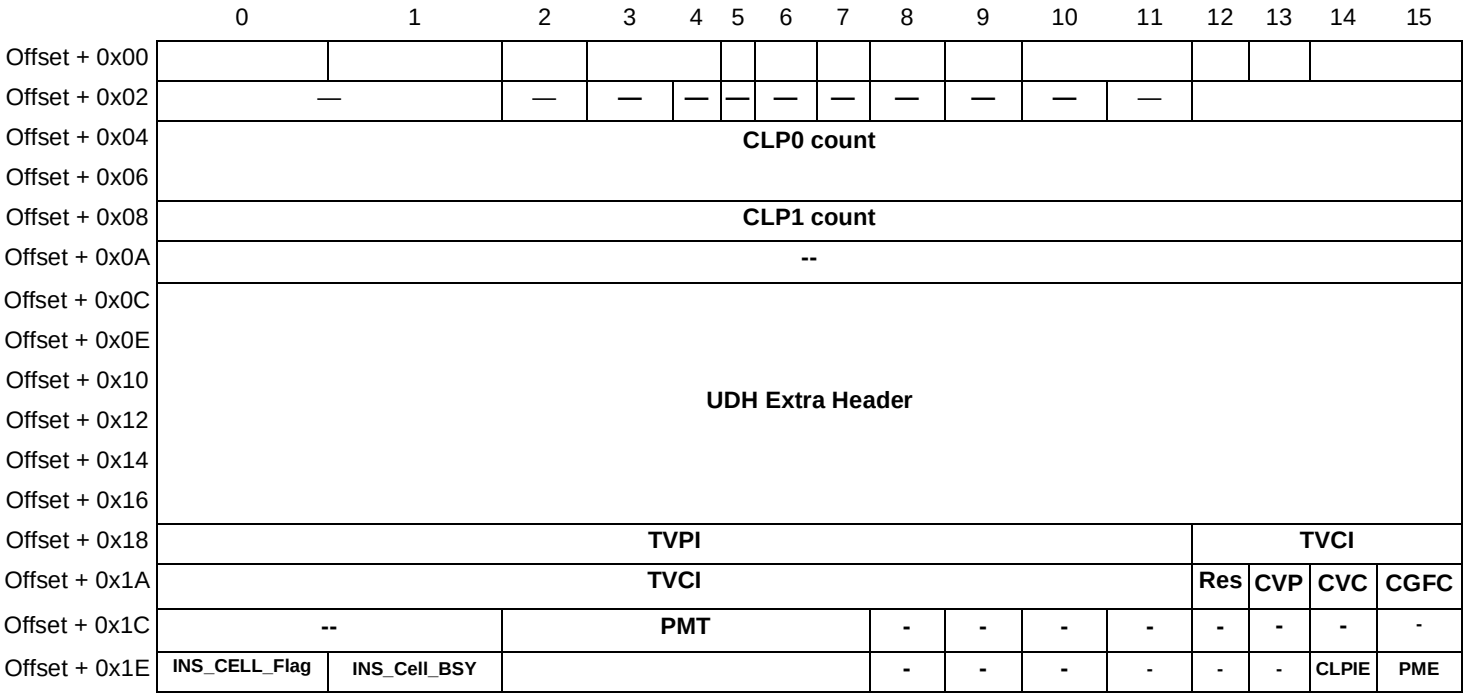

Figure 39-25. FTCT

The RISC updates only entries 0x00-0xB (12 bytes) and 1 byte located in 0x1e; other bytes are read by the RISC but are not updated by it. The CPU controlling the connection can change relevant bits from entries 0xC-0x1F (not including 0x1e) on the fly, and the RISC will act upon the new value, next time the TCT is used. The CPU shouldn't change the content of the byte located in address 0x1e, but can only read the status of this byte.

Table 39-12 describes general FTCT fields.

Table 39-12. FTCT Field Descriptions

Offset	Bits	Name	Description
0x00	0-15		Reserved. Set to zero.
0x02	0-15		Reserved. Set to zero.
0x04		**CLP0 Count**	CLP0 cell count. Initialize to 0.
0x08	—	**CLP1 Count**	CLP1 cell count. Initialize to 0.
0x0A			Reserved. Initialize to zero
0x0C-0x17	-	**UDH**	User defined header (extra header) to be transmitted before cell.
0x18	0-11	**TVPI**	Transmit VPI. Replaces VPI of cell if CVP bit is set (including GFC bits if CGFC is set)
	12-15	**TVCI**	Most significant bits of Transmit VCI. Replaces VCI of cell if CVC bit is set

Table 39-12. FTCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x01A	0-11	**TVCI**	Least significant bits of Transmit VCI. Replaces VCI of cell if CVC bit is set
	12	**Reserved**	Reserved. Initialize to zero.
	13-15	**CVP/CVC/CGFC**	CVP/CVC/CGFC (address translation) 000 no translation 001 NOT valid 010 Change VCI Portion of ATM address 011 NOT valid 100 Change VPI Portion of ATM address (including GFC) 101 Change VPI Portion of ATM address (NOT including GFC) 110 Change VCI & VPI Portion of ATM address (including GFC) 111 Change VCI & VPI Portion of ATM address (NOT including GFC)
0x1C	0-1	—	Reserved. Set to zero
	2-7	**PMT**	Performance monitoring Table Index. One of 64 performance monitoring parameter tables is chosen for this channel
	8-15	—	Reserved. Set to zero
0x1E	0	**INS_CELL_Flag**	Insert Cell Flag. Initialized to 0. Set by the RISC when insert cell host command is performed by the user, for inserting a cell to this connection. See Section 39.20.2, "MSP Insert Cell Command". Reset by the RISC on completion of the inserted cell operation. See 39.15.3, "Insert Cell Mode". The CPU can only read this status bit in order to verify that the inserted cell was actually transmitted for this channel. Only after this bit was cleared another insert cell host command for this channel could be issued.
	1	**INS_CELL_BSY**	Insert Cell Busy flag. Set by the RISC after Insert Cell host command for FTCT/HTCT modes (see Section 39.20.2, "MSP Insert Cell Command") was issued for this FTCT channel, and the FCP was in busy condition. When set means that the insert cell host command will not insert the requested cell due to the lack of FCP resources. When it is set the CPU should allocate more memory for the FCP, and after that to issue again the insert cell host command for this channel.
	2-13	**-**	res
	14	**CLPIE**	CLP0C Counter or CLP1C Counter overflow Interrupt Enable
	15	**PME**	Performance monitoring Enable 0 No performance monitoring on this channel 1 Performance monitoring is enabled on this channel

39.9.6 HTCT–Root of Hierarchy Parameters

TCTM=01

This TCT is used as a root of a hierarchical branch (bit HTCT=1), in Switch mode, and in non multicast mode. No actual cell is transmitted with this TCT, rather a FIFO structure which is pointed by an external Fifo descriptor (EFDT) is accessed from external memory and a cell is sent from there.

Figure 39-26 shows the general layout for the HTCT cell that is scheduled.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Figure 39-26. HTCT

The RISC updates only entries 0x00-0x17 (24 bytes), other bytes are read by the RISC but are not updated by it. The CPU controlling the connection can change relevant bits from entries 0x18-0x1F on the fly, and the RISC will act upon the new value, next time the TCT is used.

Table 39-13 describes general HTCT fields.

Table 39-13. HTCT Field Descriptions

Offset	Bits	Name	Description
0x00	0	—	Reserved. Set to zero.
	1	—	Reserved. Set to zero.
	2	**GBL**	Global. Asserting GBL enables snooping of data buffers, BD, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	**BO**	Byte ordering. This field is used for data buffers. 00, 01, 11 Reserved. 10 Big endian.
	5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.

Table 39-13. HTCT Field Descriptions (continued)

Offset	Bits	Name	Description
	6	**DTB**	Data buffers bus. Cell location (where the FCP resides) If Insert cell mode is enabled and the cell resides in external memory, this bit should reflect the bus location of the cell to be transmitted. 0 Data buffers reside on the coherent system bus. 1 Data buffers reside on the secondary bus.
	7	**BDB**	EFDT and Interrupt queues bus. If Insert cell mode is enabled and the CC>255 this bit should reflect the bus location of the Insert Cell pointers Table see 39.15.3, “Insert Cell Mode. 0 Resides on the coherent system bus. 1 Resides on the secondary bus.
	8	**AVCF**	Auto VC off. Determines APC behavior when the last cell associated with this HTCT has been sent and no more cells are queued under this HTCT, see Table 32-19, in the Global ATM Parameter Table, ATM _AVCON_BASE. 0 The APC does not remove this VC from the schedule table and continues to schedule it to transmit. 1 The APC removes this VC from the schedule table and resets TCT[VCON] bit, when there is no cell to transmit under this VC. The VC is automatically activated by the receiver, if a cell arrives, and sets TCT[VCON] bit.
	9	—	Reserved
	10-11	**ATT**	ATM traffic type 00 Peak cell-rate pacing. The host must initialize PCR and the PCR fraction. Other traffic parameters are not used. 01 Peak and sustain cell rate pacing (VBR traffic). The APC performs a continuous-state leaky bucket algorithm (GCRA) to pace the channel-sustain cell rate. The host must initialize PCR, PCR fraction, SCR, SCR fraction, and BT (burst tolerance). 10 Peak and minimum cell rate pacing (UBR+ traffic). The host must initialize PCR, PCR fraction, MCR, MCR fraction, and MDA. If Scalable APC is enabled, then the user should allocate an additional 4-6 bytes (depend on the alignment) for the APC scheduling table. 11 Reserved.
	12	—	Reserved. Set to zero.
0x00	13	**VCON**	Virtual channel is on. In non AVCON/AVCOFF Mode: Should be set by the host before it issues an ATM TRANSMIT command. When the host sets TCT[STPT] (stop transmit), the RISC deactivates this channel and clears VCON when the channel is next encountered in the APC scheduling table. The host can issue another ATM TRANSMIT command only after the RISC clears VCON. In AVCON/AVCOFF Mode: Should be cleared by the host.
	14-15	**INTQ**	Points to one of four interrupt queues.

Table 39-13. HTCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0-1	**TCTM**	TCT Mode 00 This is a STCT used as a leaf node for APC shaping 01 This is a HTCT used for a root node of hierarchical shaping 10 This is a FTCT used for Fast FIFO shaping 11 This is a MTCT used for Multicast shaping
	2	**FCP**	Free Cell Pool 0 Use Free Cell Pool 1 1 Use Free Cell Pool 2
	3-12		reserved set to 0.
	13-15	**AAL**	AAL type: 000 AAL0 Reassembly with no adaptation layer. 001 AAL1 ATM adaptation layer 1 protocol. 010 AAL5 ATM adaptation layer 5 protocol. 011 AAL3. 100 AAl2. 101 CES. 110 MSP-Multi ServIce Protocol - switched ATM cells.
0x04-0x07		—	Reserved. Set to zero.
0x08	Hword	**FFS_TMP**	initialize to zero. used by RISC only
0x0A	0-2	**Reserved**	initialize to zero.
	3-15	**FSOff**	FIFO Status Offset. Offset to FIFO status (FS) from **FS_BASE** in the multi-user RAM. The FS is initialized to zero, and is changed by the RISC. The FIFO status has one bit set for each FIFO that has a non-empty queue.
0x0C	0–7	Rate Reminder	Rate remainder. Used by the APC to hold the rate remainder after adding the pace fraction to the additive channel rate. Initialize to 0.
	8–15	**PCR Fraction**	Peak cell rate fraction. Holds the peak cell rate fraction of this channel in units of 1/256 slot.
0x0E	—	**PCR**	Peak cell rate. Holds the peak cell rate (in units of APC slots) permitted for this channel according to the traffic contract.
0x10	Word	—	Reserved. Set to zero.
0x14	Hword	—	Reserved. Set to zero.
0x16	—	**APCLC**	APC Linked Channel. Used by RISC. Initialize to zero.
0x18	Word	**EFDT_FIRST**	Pointer to First entry in External FIFO Descriptor Table.
0x1C	-	—	Reserved. Set to zero.
0x1E	0-12	—	Reserved. Set to zero.
	13	**STPT**	Stop transmit. Initialize to 0. When the host sets this bit, the RISC deactivates this channel and clears TCT[VCON] when the channel is next encountered in the APC scheduling table. The RISC reads 32 bytes of TCT, but writes back only 24 bytes. Therefore this bit is not altered by the RISC.
	14-15		Reserved. Set to zero.

39.9.7 MTCT—Multicast TCT

TCTM=11

See Section 39.14, “Multicast.”

39.9.8 Switched/Multicast Transmit Connection Table Extension (STCTE/MTCTE)

Figure 39-27 shows the general layout for the STCTE/MTCTE.

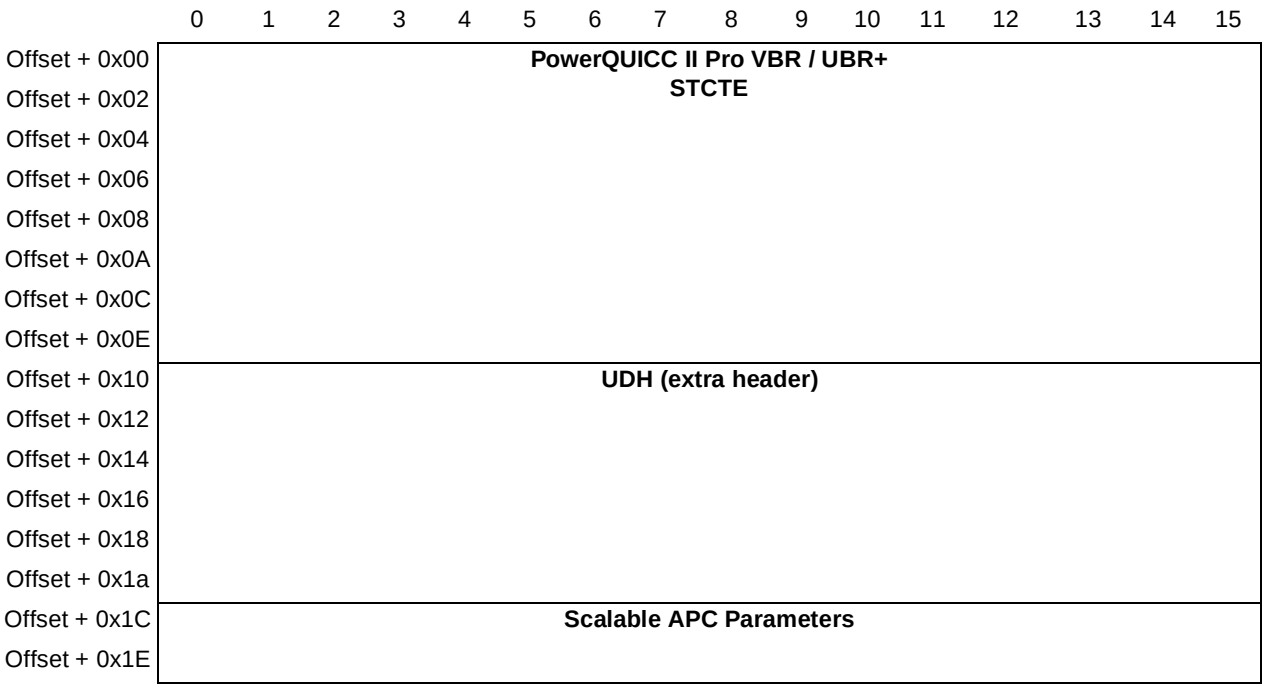

Figure 39-27. STCTE/MTCTE

Table 39-14 describes general STCTE fields.

Table 39-14. STCTE/MTCTE Field Descriptions

Offset	Bits	Name	Description
0x00-0x0E	—	**Param**	PowerQUICC II Pro param for VBR / UBR+. Valid only for APC mode (for multicast working in FIFO-MODE this entry isn't valid).
0x10-0x1B	—	**UDH-EXTRA HEADER**	Holds the channel Extra header for User Defined Cell mode (UDC)
0x1C-0x1F		**Scalable APC Parameters**	Holds the APC scalable Mode parameters

39.10 Scheduling

The PowerQUICC II ProMSP allows for multiple configurations of the scheduler. The scheduler at any point in time selects a cell to be transmitted. For multiphy systems there is a separate scheduler for each PHY on the Utopia. The modes of operations per PHY are as follows:

Eight FIFOs which can be configured as fixed priority or Weighted Fair Queuing or a mixed mode. In this configuration all ATM connections are scheduled into one of the eight FIFOs. In this mode there is no per VC queueing, and the queues contain cells from many different connections. Nevertheless billing, address translation, extra-header and PM functions are still performed on a per-connection basis.

OR

Hierarchical APC, which includes eight prioritized Power QUICC II like APCs at the top level of the hierarchy, and optionally under each slot of the APC, eight FIFOs that can be configured only in fixed priority. Connections scheduled in the APC itself, are dealt as per-VC queueing (like the MPC8260). Connections in hierarchical mode are scheduled as a bundle (normally per-VP) by the APC, and then inside the bundle, the scheduling is done by the FIFOs, according to a Fixed priority scheme. Note that the allocation of connection to different queues is implementation dependent.

Hierarchical shaping can be used in the following way: VPs are shaped at the top level of the hierarchy by allocating a slot in the APC at the frequency needed by the rate of the VP. The VCCs under the VP are scheduled in the FIFOs, allowing for bandwidth allocation for groups of VCs. A VC that does not have cells to send gives its bandwidth to other VCs in the FIFO (which means that FIFO scheduling is a work conserving mechanism). CES connections that need exact shaping, are scheduled by the APC in the top level of the hierarchy.

Figure 39-28 depicts a scheduling system with APC and (optionally) FIFO at the lower level of the hierarchy.

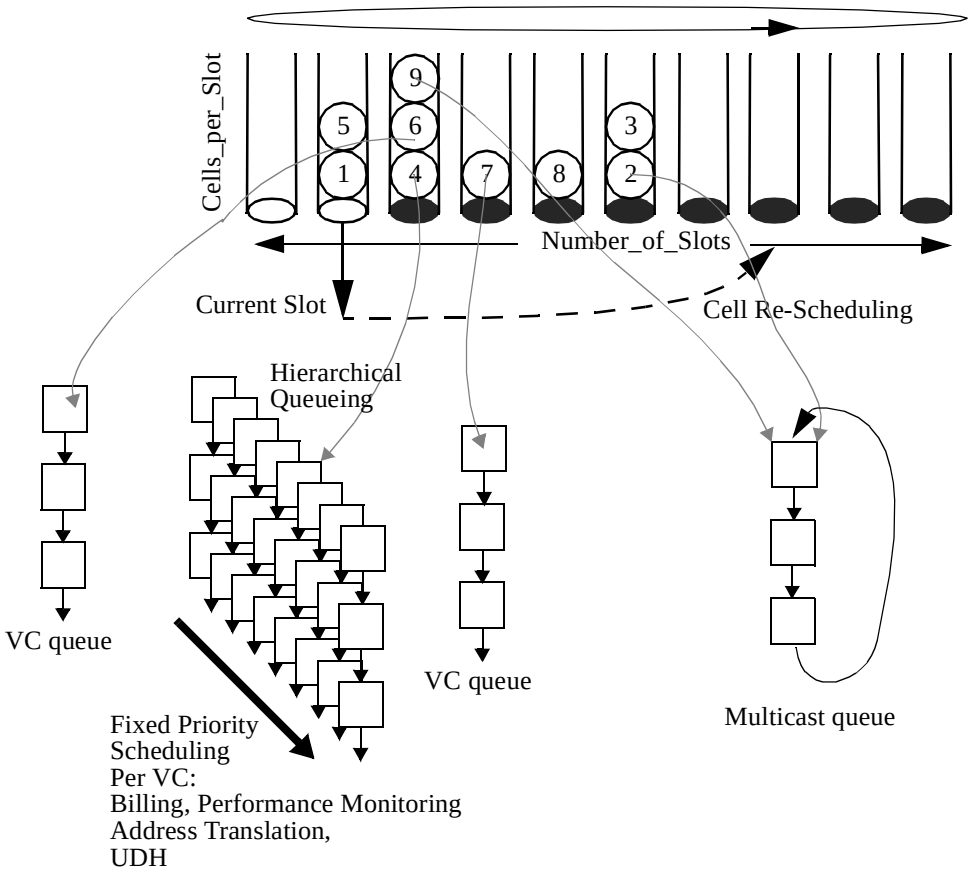

Figure 39-28. APC with Hierarchical FIFOs

Figure 39-29 depicts the WFQ scheduling mode.

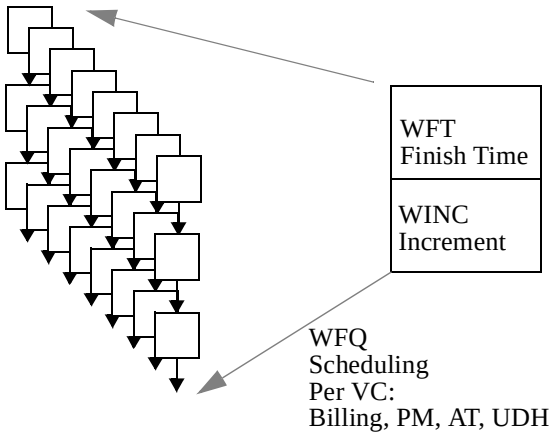

Figure 39-29. WFQ Mode

Note that the Scheduling mode is determined by the user on a per-PHY basis.

39.10.1 WFQ Weighted Fair Queueing

In weighted fair queueing, all queues are examined, and a cell from the queue with the smallest finish is transmitted. The relative data rate for the queues is determined by the WINC parameter as programmed in the Scheduler Parameter Table (see Section 39.10.3.2, “Scheduler Parameter Table in WFQ Mode (AFM=0)”). An example of programming the WINC value Is given at Section 39.10.3.3, “Examples of settings.”

39.10.2 Transmitter: Scheduler Data Structure

Each PHY has a Scheduling Parameter Table associated with it (this table is also called “APC Parameter Table,” see Section 32.3.6.1, “APC Parameter Tables”). In this table there is an entry that distinguishes between the two scheduling mechanisms (APC or eight FIFOs). APC data structure consists of three elements: Scheduler Parameter Table, the APC priority table, and the APC scheduling tables.

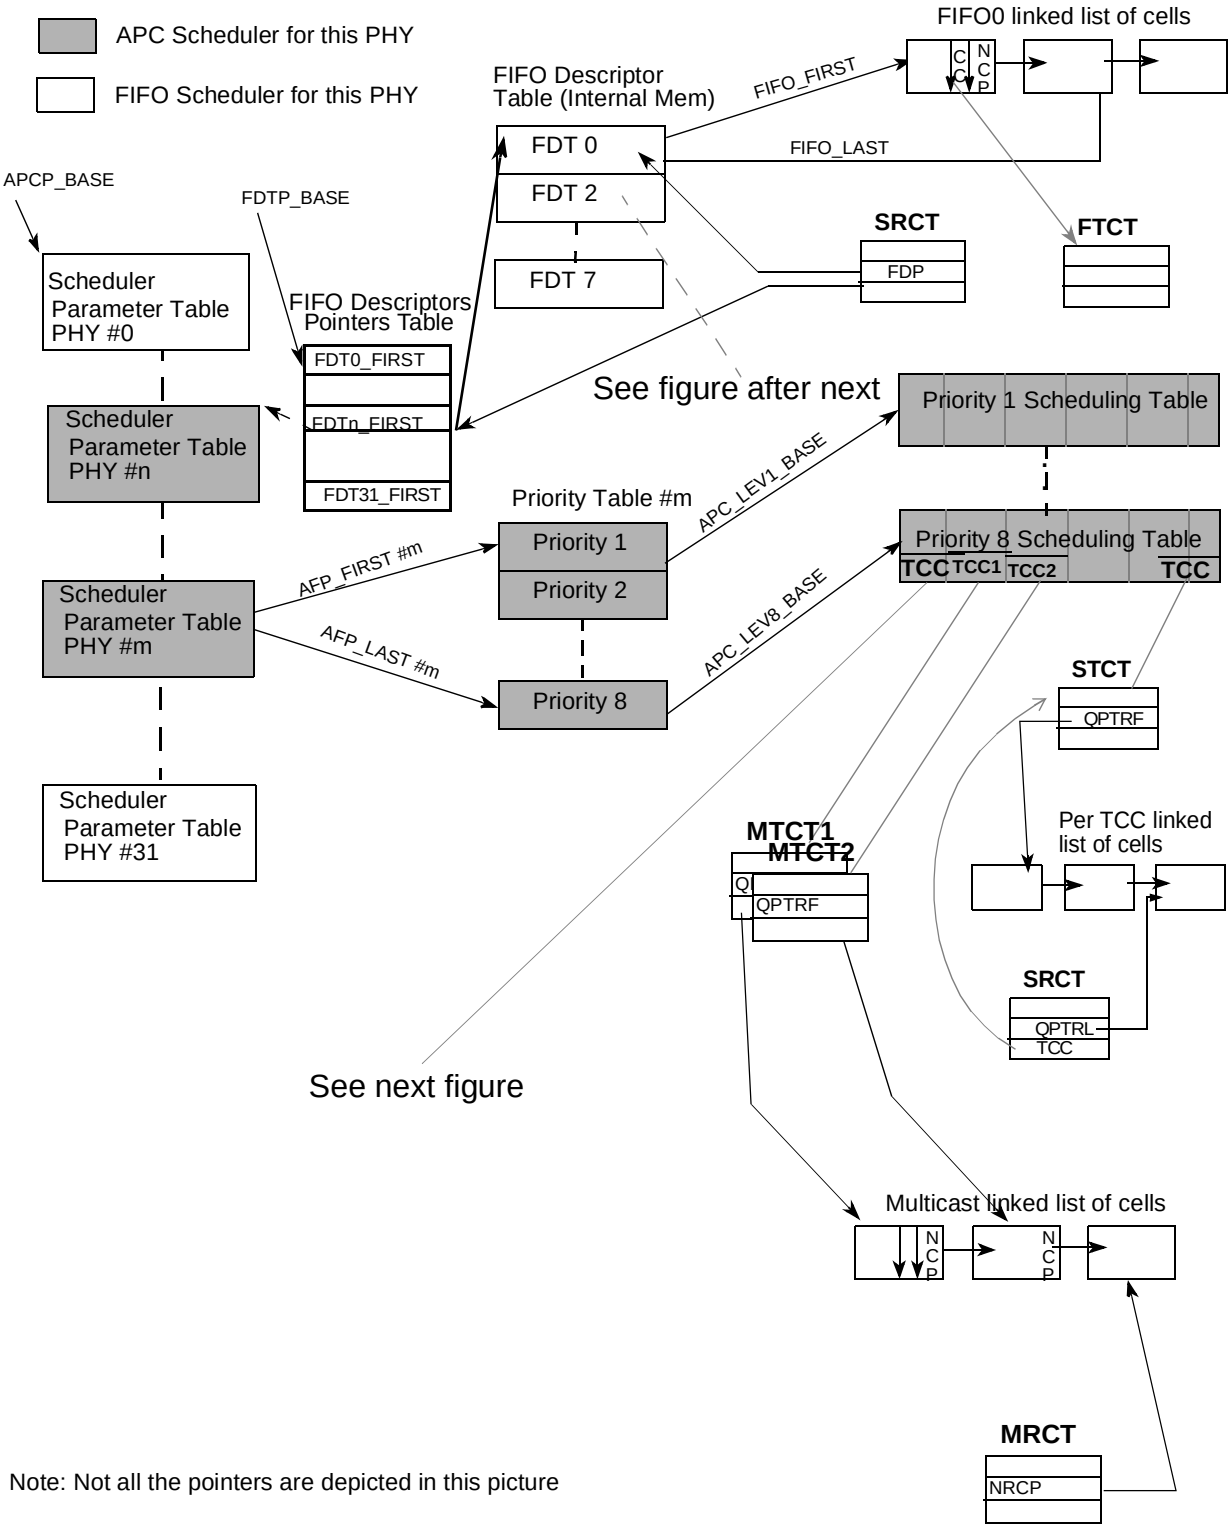

Figure 39-30. Switch Data Structures

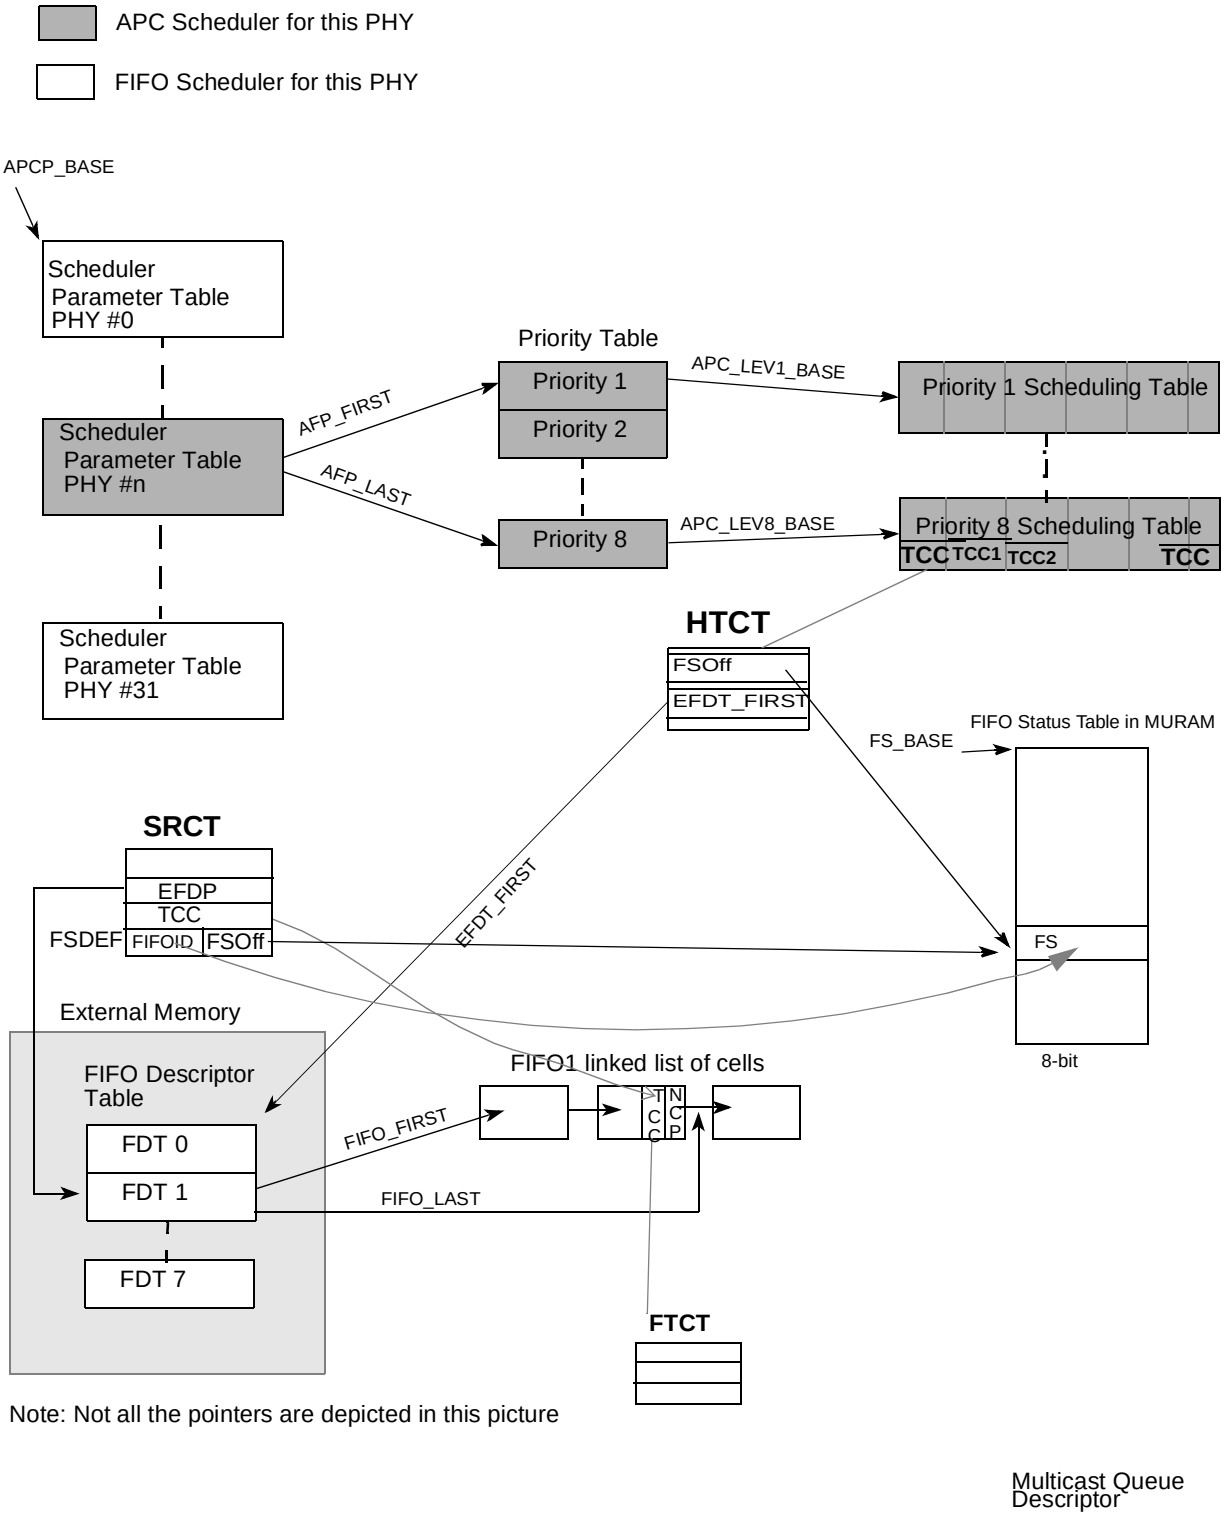

Figure 39-31. Detailed Hierarchical Switch Data Structures

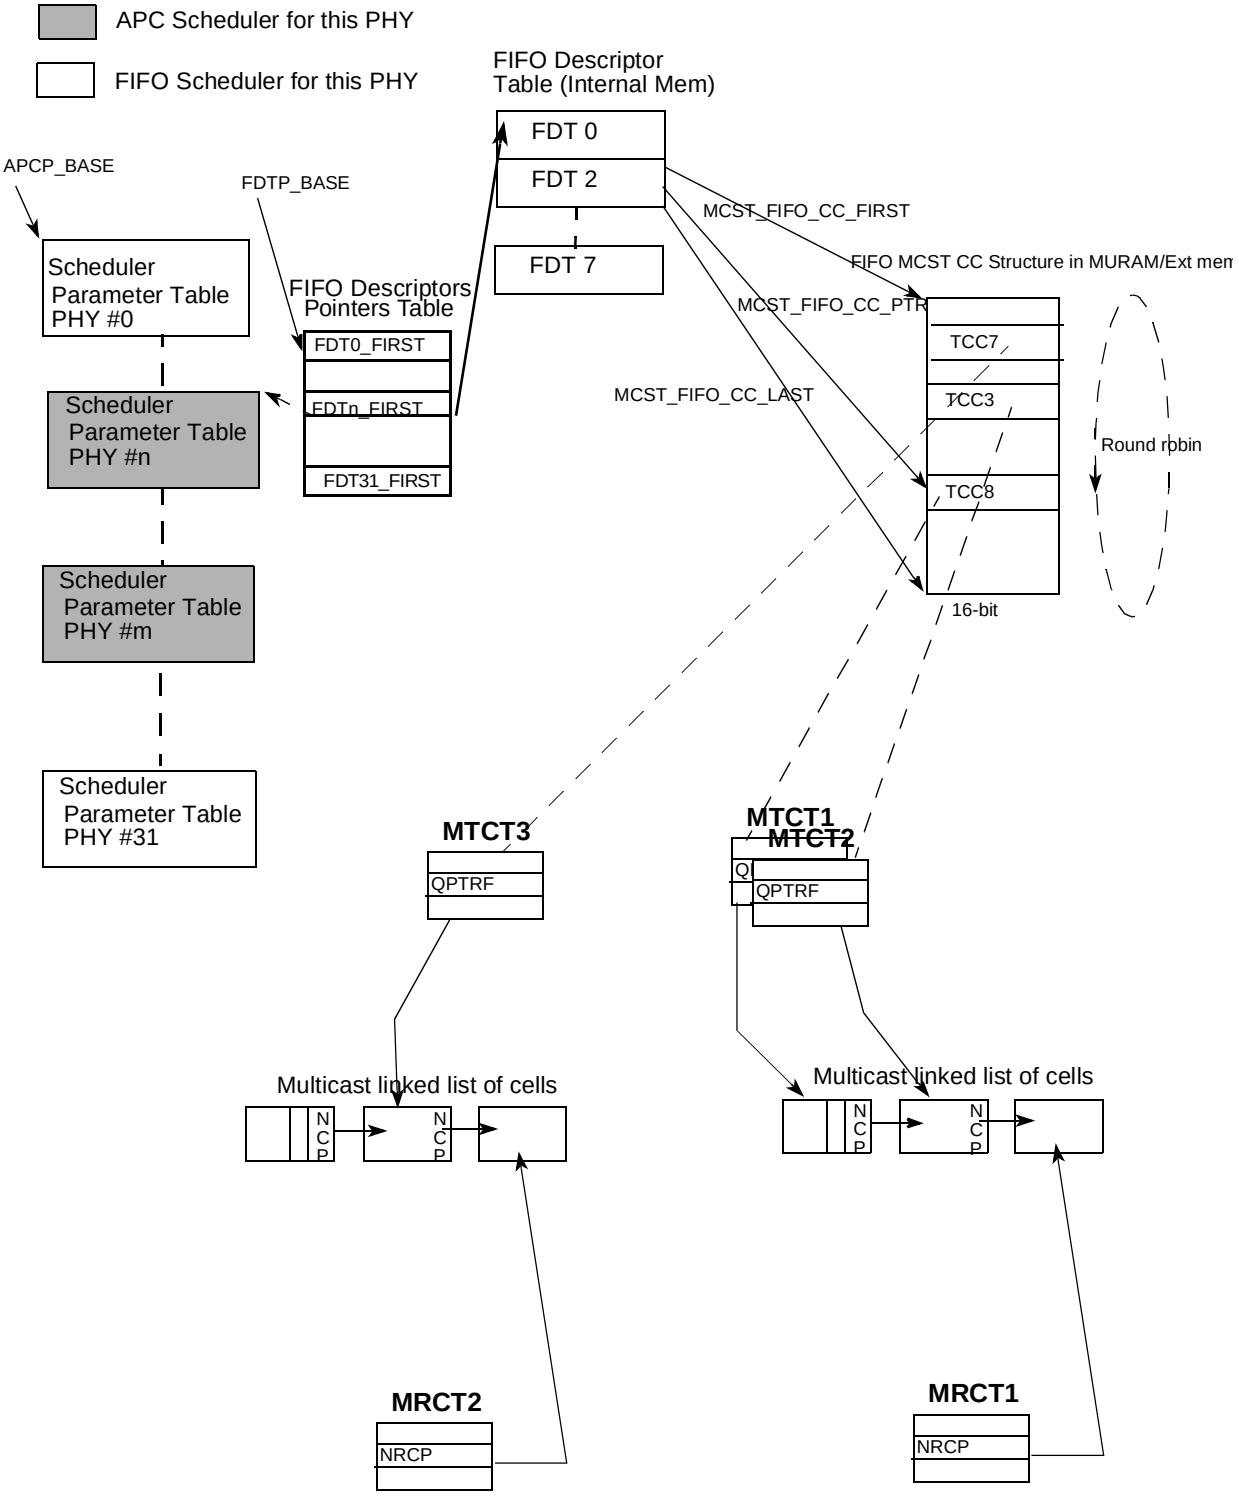

Note: Not all the pointers are depicted in this picture

Figure 39-33. Multicast FIFO Data Structure

39.10.3 Scheduler Parameter Table

Each PHY's Scheduler parameter table holds parameters that define the priority table location, the number of priority levels, and other APC parameters. The table resides in the multi-user RAM. The parameter APCP_BASE, described in Section 39.17, "ATM Parameter RAM Map," points to the base address of PHY#0's parameter table.

For multiple PHYs, the table structure is duplicated. Each table resides in 32 bytes of memory. The starting address of each Scheduler Parameter Table is given by APCP_BASE + PHY# *32.

Figure 39-34 shows the general layout for the Scheduler Parameter Table

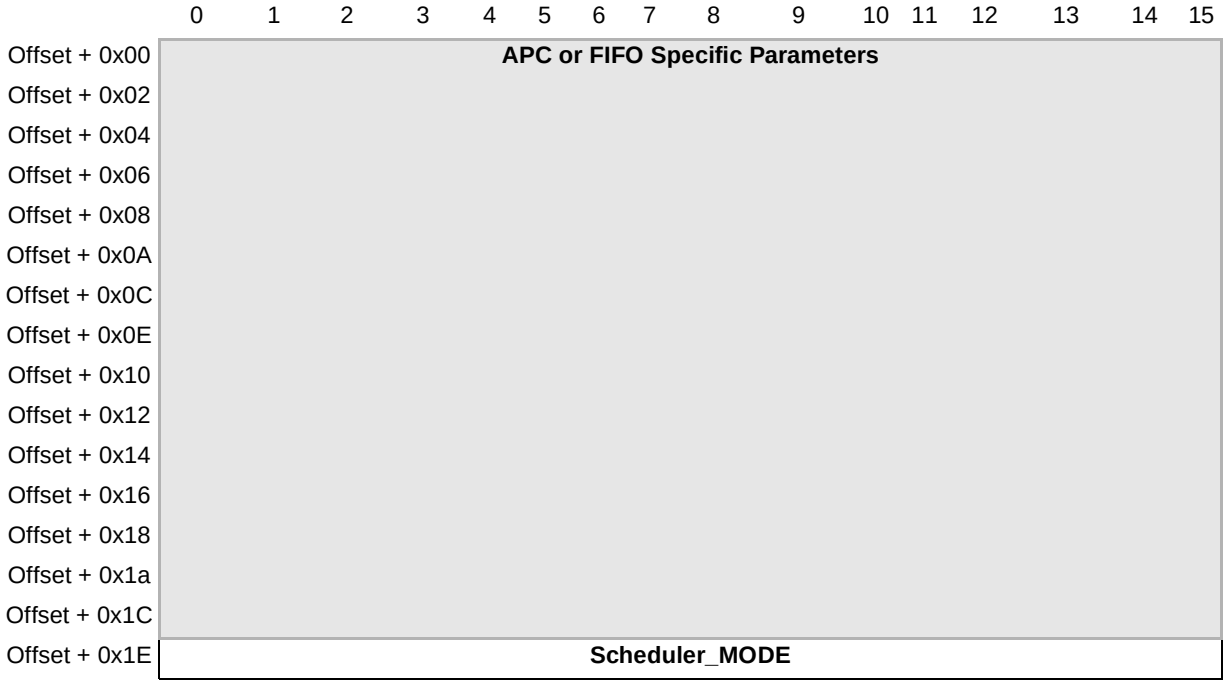

Figure 39-34. Scheduler Parameter Table

39.10.3.1 Scheduler_MODE Entry

Figure 39-35 shows the layout of the Scheduler_MODE entry in the Scheduler Parameter Table.

The functionality of this entry is determined by the setting of the AFM bit.

Bit	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	**AFM**	Function Specific Bits														

Figure 39-35. Scheduler_MODE

Table 39-15. Scheduler_MODE Field Descriptions

Bits	Name	Description
0	**AFM**	Scheduler Mode (Used only if GMODE[MSP]=1) 0 This PHY scheduling is eight FIFO queues. 1 This PHY scheduling is PowerQUICC II Pro APC Like.
1-15		Function specific entries described in the following paragraphs.

39.10.3.2 Scheduler Parameter Table in WFQ Mode (AFM=0)

The following table describes the FIFO specific Parameters in the Scheduler Parameter Table when the Scheduler_MODE entry is configured as FIFO in WFQ mode - for multicast or non-multicast modes. This format is used when AFM=0.

Table 39-16. Scheduler Parameter Table

Offset[1]	Name	Width	Description
0x00-0x0F	WFTi (i=0..7)	Hword	Weighted Finish Time. Eight 16-bit FTMs, one for each FIFO. The FTM is used to determine the finish time of the next cell being transmitted from the queue. FTM at offset zero corresponds to FDT0 (FIFO number 0), FTM at offset 0x0E corresponds to FIFO7. See instructions for initialization in field description, Section 39.10.3.2.1, "WFT."
0x10-0x1D	WINCi (i=0..6)	Hword	Weighted Increment. Eight 16 bit increments, one for each FIFO. INC at offset 0x10 corresponds to FDT0 (FIFO number 0), INC at offset 0x1C corresponds to FIFO6.
0x1E	Scheduler_MODE	Hword	This entry also includes INC7. See description in Section 39.10.3.2.2, "Scheduler_MODE Entry for WFQ AFM=0. "

[1]Offset values are to APCP_BASE+PHY# × 32

39.10.3.2.1 WFT

Figure 39-36 shows the format of the Weighted Fair Queueing (WFQ) Finish Time entry in the Scheduler Parameter Table. There are eight such entries in the table, one for each queue. These entries are initialized by the CPU, and are not accessed when the switching function is enabled.

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0x00,.. 0x0E	**FE**	**FTM**												**FID**		

Figure 39-36. WFT Entry

Table 39-17 describes the WFT fields

Table 39-17. WFT Field Descriptions

Bits	Name	Description
0	FE	FIFO Empty. Unicast mode/Multicast mode with AUTO FE Mechanism - This bit is set automatically by the RISC if the corresponding FIFO has no cells to transmit. This bit should be initialized to 1 by the CPU. Multicast mode without AUTO FE Mechanism - This bit should be initialized to 1 by the CPU. Since this bit is not changed automatically by the RISC, the user should clear this bit to activate the FIFO, only after verifying that all the related Multicast structures are properly initialized. See Section 39.14, "Multicast." The CPU also clears the FE bit before it issues a FIFO_EN event. See Section 39.14.5.2, "On-Line Modification of FIFO WFQ Multicast Mode without Auto FE Mechanism."
1-12	FTM	Finish time. This bit is automatically updated by the RISC. Initialize with WINC[INC] value.
13-15	FID	FIFO ID. The CPU initializes the number of the FIFO in these bits; the value is determined by the offset of the entry from the Scheduler Parameter Table base for this PHY: Offset Value 0000 - 000 0010 - 001 0100 - 010 0110 - 011 1000 - 100 1010 - 101 1100 - 110 1110 - 111

Figure 39-37 shows the format of the Weighted Fair Queueing (WFQ) Increment entry in the Scheduler Parameter Table. There are seven such entries in the table, one for each queue except for queue number 7. The INC value for this queue resides in the Scheduler_MODE entry. These entries are initialized by the CPU, and are not accessed when the switching function is enabled.

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0x10,.. 0x1E	--	INC												--		

Figure 39-37. WINC Entry

Table 39-18 describes the WINC fields.

Table 39-18. WINC Field Descriptions

Bits	Name	Description
0		Reserved. Initialize to zero.
1-12	**INC**	Weighted Increment value. This value determines the relative bit rate for the FIFO. If all FIFOs are backlogged the absolute bit rate of each FIFO is 1/INC. If some of the FIFOs do not have cells to transmit, the total bandwidth of the port is divided among the backlogged FIFOs according to their relative INC values. For strict/fixed priority among FIFOs program INC=0 for all 8 FIFOs in the PHY - FIFO 0 has the highest priority. For round robin priority among FIFOs set INC=1 for all the FIFOs. Note-When using fixed priority, with combination of Multicast FIFOs and Unicast FIFOs, it is preferred to use AUTO_FE mode for the multicast connections. This in order to prevent a condition where a multicast FIFO with FID=0, for example, which its FE isn't dynamically changed by the RISC, be always chosen by the RISC even if it is empty.
13-15		Reserved. Initialize to zero.

39.10.3.2.2 Scheduler_MODE Entry for WFQ AFM=0

Figure 39-38 shows the layout of the Scheduler_MODE entry in the Scheduler Parameter Table. This format is valid when AFM=0.

Bit	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	**AFM**	**INC7**												**--**		

Figure 39-38. Scheduler_MODE

Table 39-19 describes Scheduler_MODE fields.

Table 39-19. Scheduler_MODE for WFQ Field Descriptions

Bits	Name	Description
0	**AFM=0**	Scheduler Mode 0 This PHY scheduling is eight FIFO queues
1-12	**INC7**	Weighted Increment value for FIFO number 7.
13-15		Reserved. Initialize to zero

NOTE

PHYs that do not have switched cells, and are running the MPC8260 SAR must set this bit.

39.10.3.3 Examples of settings

39.10.3.3.1 WFQ among all FIFOs

The WFQ mechanism can be used to implement many scheduling schemes of Weighted Fair Queueing among all eight FIFOs. In this mode each FIFO has a INC associated with it.

For example:

Table 39-20. Example of WFQ Among All FIFOs

	FIFO0	FIFO1	FIFO2	FIFO3	FIFO4	FIFO5	FIFO6	FIFO7
INC	3	5	2	30	2	5	30	3

The formula for getting the bandwidth for each FIFO, assuming FIFO #i has INC Ki (i=0-7)

FIFO #i BW = line_rate * (1/Ki)/[1/K1+1/K2+..+1/Kn]

For the above example FIFO0 receives 0.16 of the line rate, FIFO1 receives 0.09 and etc. The algorithm implement true WFQ, in the sense that at any given time all FIFOs are examined, and the one with the smallest finish time is chosen.

39.10.3.3.2 Strict Priorities Among all FIFOs

Strict priority is a mode in which as long a high priority FIFO has cells queued to be transmitted this FIFOs is chosen. To implement strict priority among all FIFOs (FIFO0 is highest, and FIFO7 is lowest priority) program all INC values to zero.

39.10.3.4 Mixed mode

To implement mixed mode where a number of FIFOs are strict, and others are scheduled with WFQs: The strict priority FIFOs are assigned to the low numbered FIFOs (starting from FIFO number 0 - FIFO0), these FIFOs are assigned INC=0. Other FIFOs are assigned INC according to their relative weight.

Table 39-21. Example of Mixed Mode WFQ

	FIFO0	FIFO1	FIFO2	FIFO3	FIFO4	FIFO5	FIFO6	FIFO7
INC	0	0	2	30	2	5	30	3

In this example FIFO0 and FIFO1 are strict; as long as FIFO0 has cells it is chosen to transmit. If it has no cells, FIFO1 is chosen and if it is also empty, one of FIFO2 to FIFO7 is chosen. Of the remaining bandwidth (after FIFO0 and FIFO1) the remaining FIFOs are allocated the bandwidth according to their relative weight.

39.10.4 FIFO Descriptor Table (FDT/EFDT)

39.10.4.1 FDT/EFDT for Non-Multicast FIFO

Each PHY's FIFO descriptor Table table holds pointers to the cells link list associated with this FIFO (refer to Figure 39-29). This table resides in multi-user RAM. Table 39-22 shows the structure of a FIFO descriptor table For Hierarchical connection the same data structure is used. The difference is that it reside in the external memory, therefor called External FDT (EFDT).

Table 39-22. FIFO Descriptor Table Entry (FDT/EFDT)

Offset	Name	Width	Description
0x00	FIFO_FIRST	Word	Pointer to the first Cell in FIFO
0x04	FIFO_MODES	Hword	DMA modes and bus selection. This Hword is valid for non hierarchical FIFO mode ONLY and is used for getting the cell's data and the FTCT associated with them.see Section Figure 39-39., "FIFO_QLTS Entry."
0x06		Hword	Modes of operation for this FIFO. See section Section 39.10.4.2, "FIFO_MODES Entry."
0x08	FIFO_LAST	Word	Pointer to the last cell in FIFO
0x0C	--	Hword	Reserved. Initialize to Zero.
0x0E	FIFO_COUNT	Hword	Number of cells in FIFOi (Limited to 2^15-1entries per queue)

39.10.4.2 FIFO_MODES Entry

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0x04	—	—	GBL	BO		CETM	DTB	BDB	FCP					EFCIE	INTQ	
0x06	-	-	--						-	QLTS				--		

Figure 39-39. FIFO_QLTS Entry

Table 39-23. FIFO_MODES Table Entry

Offset	Bit	Name	Description
0x04	0-1	-	Reserved. Initialize to zero.
	2	GBL	Global. Asserting GBL enables snooping of data buffers, BD, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	BO	Byte ordering. This field is used for data buffers. 00, 01, 11 Reserved. 10 Big endian.
	5	CETM	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.
	6	DTB	Data buffers bus. Cell location (where the FCP resides) If Insert cell mode is enabled and the cell resides in external memory, this bit should reflect the bus location of the cell to be transmitted. 0 Data buffers reside on the coherent system bus. 1 Data buffers reside on the secondary bus.
	7	BDB	Interrupt queues bus. If Insert cell mode is enabled and the CC>255 this bit should reflect the bus location of the Insert Cell pointers Table see Section 39.15.3, "Insert Cell Mode." 0 I reside on the coherent system bus. 1 reside on the secondary bus.
	8	FCP	Free Cell Pool 0 Use Free Cell Pool 1 1 Use Free Cell Pool 2
	9-12		reserved. Initialize to zero.
	13	EFCIE	EFCI indication set interrupt enable
	14-15	INTQ	Points to one of four interrupt queues.

Table 39-23. FIFO_MODES Table Entry (continued)

Offset	Bit	Name	Description
0x06	0	-	reserved, initialize to zero.
	1	-	reserved, initialize to zero.
	2-7	-	reserved, initialize to zero.
	8	-	reserved, initialize to zero.
	9-12	**QLTS**	Queue Level Thresholds Set. One of 16 Threshold Sets is chosen. From sets located at QLTS_BASE
	13-15	**Reserved**	Reserved. Set to zero.

39.10.4.3 FDT for Multicast FIFO

Each PHY's FIFO descriptor Table holds pointers to a structure which contains a list of channel codes that are scheduled for transmission in FIFO multicast mode (refer to Figure 39-33). The FDT resides in multi-user RAM (see Table 39-24). This FIFO Descriptor table is only relevant for FIFO WFQ working in multicast mode (see Section 39.14.3.2, "Multicast Mode Based on FIFO WFQ").

Table 39-24. FIFO Descriptor Table Entry (for Multicast mode only)

Offset	Name	Width	Description
0x00	MCST_FIFO_CC_FIRST	Word	Should be initialized by the user to point to the first CC in the CC Multicast structure for this FDT. Could be external address (if FIFO_MODES[FDT_MCST_EXT_CC]=1) or internal address. When internal mode is used it should be programmed to Multi-user RAM offset of 2 bytes only
0x04	FIFO_MODES	Hword	DMA modes and bus selection (only if using external CC structure)
0x06		Hword	Modes of operation for this Multicast FDT. See section Section 39.10.4.4, "FIFO_MODES Entry for Multicast Mode."
0x08	MCST_FIFO_CC_LAST	Word	Should be initialized by the user to point to the last CC in the CC Multicast structure for this FDT. Could be external address (if FDT_MCST_EXT_CC=1) or internal address.
0x0C	MCST_FIFO_CC_PTR	Word	Should be initialized by the user to point to the current CC in the CC Multicast structure for this FDT, which is identical to the MCST_FIFO_CC_FIRST entry initialization. Could be external address (if FDT_MCST_EXT_CC=1) or internal address.

39.10.4.4 FIFO_MODES Entry for Multicast Mode

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0x04	—	—	GBL	-		—	-	BDB						-	-	
0x06	MCST_ext_cc	MCST_DISFIFO_INT_EN	FE_AUTO_SET	No_Iterations					No_Iterations_mirror					MCST_MODE	EN_FIFO	DIS_FIFO

Figure 39-40. FIFO_Modes Entry for Multicast mode

Table 39-25. FIFO_MODES Table Entry for Multicast Mode

Offset	Bit	Name	Description
0x04	0-1	-	Reserved. Initialize to zero.
	2	GBL	Global. Asserting GBL enables snooping of CC structure (if external). To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3-6	-	Reserved. Initialize to zero.
	7	BDB	CC Structure bus (if external) 0 reside on the coherent system bus. 1 reside on the secondary bus.
	8-15	-	Reserved. Initialize to zero.
0x06	0	FDT_MCST_EXT_CC	Indicate if CC structure is external if 1, or internal if 0.
	1	FDT_MCST_DISFIFO_INTEN	Indicates if the QUICC Engine block generates an interrupt after Disabling the FIFO. In the interrupt queue entry the bits that are set are the EFCI and the MCER bits simultaneously.
	2	FE_AUTO_SET	0 Auto FE set transmitter mechanism is disabled. 1 Auto FE set transmitter mechanism is enabled.
	3-7	No_Iterations	Valid only if FE_AUTO_SET=1. Determines the number of iterations -1 on the Channel Code structure, needed by the transmitters which reside in this FIFO, to set the corresponding FE bit - if there are no valid cells to transmit.
	8-12	No_Iterations_Mirror	Should be initialized to No_Iterations. Used only by the RISC.
	13	FDT_MCST_MODE	Indicate that working in Multicast mode.
	14	FDT_EN_FIFO	Semaphore set by the core to indicate the RISC to enable this fifo again. When the Core wants to reactivate a Multicast FDT, it should assign its WFT[FTM]=0 WFT[FE]=0, and WFT[FID] =FID. The RISC resets this bit upon completion.
	15	FDT_DIS_FIFO	Semaphore set by the Core to indicate the RISC to disable this FIFO. The RISC Resets this bit to indicate the core the completion of disabling the FIFO. An interrupt could be generated if FDT_MCST_DISFIFO_INTEN is set.

39.11 UPC Policer

The MSP UPC policer implements ATM forum's TM4.1 Virtual Scheduling algorithm. Providing a dual leaky bucket policing scheme, the MSP can detect cells that violates the traffic agreement (non-conformed cells) and optionally tag (i.e changes CLP field from 0 to 1) or discard them from the cell flow.

A Leaky Bucket parameter structure is defined either on a per connection (VCC) basis, per VPC basis, or per any arbitrary group of VCC's. Any VCC Receive Connection Table (RCT) contains a pointer to a Dual Leaky bucket parameter structure (UPC parameter structure) which is residing in the external memory (Figure 39-41).

When policing has to be done for a group of VCC's (VCC's Bundle), than all the RCTs of the connections which are belonging to the same group have to point to the same UPC parameter structure. In this case the Policer controls the traffic stream generated by the unification of those VCC's.

The UPC parameter structure is depicted in Figure 39-41. The RCT[UPCPTR] field indicates the offset from UPC_BASE field in the MSP Extended Page (see Table 39-9), in which the UPC_TABLE resides in external memory. e.g. UPC_TABLE Pointer = UPC_BASE + RCT[UPCPTR]*32.

[1] Bold Parameters are initialized by the user. All the rest should be initialized to 0.

Figure 39-41. UPC Parameter Structure

Both leaky buckets independently performs the ATM Forum's TM4.1 **GCRA(I,L)** algorithm, where I and L express Bucket Increment and Bucket Limit respectively. In the MSP programming model, I is defined by **B1I** and **B2I** (Bucket 1 increment and Bucket 2 increment respectively). B1I (B2I) is divided to an integer part, **B1II** (**B2II**), and a fraction part, **B1IF** (**B2IF**).

B1I (B2I) and **B1Lim** (B2Lim) represent the space between cells arrival times and the limits for leaky bucket 1 (2). Both have to be initialized by the user. The time units for both, the bucket increments and the bucket limits are identical to one-count time interval of the PowerQUICC II Pro**CETSCR** - the **QUICC Engine Time Stamp Control Register** (See Section 20.3.9, "QUICC Engine Time-Stamp Control Register (CETSCR)").

The Theoretical arrival times for bucket 1 and bucket 2 (**B1T** and **B2T**) are internal variables which are maintained by the Leaky Bucket mechanism.

The **LBF** (Leaky Bucket Filter) field (LBF1 for Leaky Bucket #1 and LBF2 for Leaky Bucket #2) determines the cell flow handled by the bucket (see Table 39-26 below). Both LBF1 and LBF2 have to be initialized by the user. Notice that the LBF field relates to the incoming Cells stream, i.e. if there are 2 serial Leaky buckets, the LBF field of the second Leaky bucket relates to the CLP bit of the cells that enter to the first Leaky bucket.

The **TAG** (Leaky Bucket tag) bit (TAG1 for Leaky Bucket #1 and TAG2 for Leaky Bucket #2) determines bucket's operation for non conformed cells, according to Table 39-27..

The MSP Policer supports Packet oriented discard mode (PPD). This mode is enabled by setting **RCT[PPDE]** bit. When this mode is enabled and a single cell is dropped by the policer, then all other cells associated with the current packet are dropped. The last cell of the packet (PTI[0]=1) is policed normally.

39.11.1 UPC Programming

Before enabling the UPC for any channel, the CETSCR must be initialized. The CETSCR defines the time unit which is common to all leaky buckets and Time Stamps in the PowerQUICC II Pro. Following that, each individual leaky bucket is programmed independently.

Each one of the dual leaky buckets has four user defined parameters:

- LBF - Leaky Bucket filter. (See Table 39-26)
- TAG/Discard bit (See Table 39-27)
- Bucket Increment (BI)
- Bucket Limit (BLim)

The LBF field and the TAG bit are programmed according to the definitions in Table 39-26 and Table 39-27 respectively.

Table 39-26. LBF—The Leaky Bucket Filter

Cell type monitored	LBF coding
Disable policing	000
CLP0 cell policing. CLP1 cells are bypassing this bucket	001
CLP1 Cell Policing. CLP0 cells are bypassing this bucket	010
CLP0+1 Policing. All cells are tested by this bucket	011
F-GCRA Policing. Only First cell of each packet is tested for conformance. All the rest of the cells gets the same conformance result as first cell.	100
Reserved	101
Reserved	110

Table 39-27. TAG Bit Interpretation

Cell type monitored	TAG
Drop non-conformed cells	0
Tag non-conformed Cells	1

The formula for the decimal representation of the Bucket Increment is:

A) BI = CellSize/(BitRate x TimeUnit)

Where **BI** is the decimal expression for the bucket's increment, **CellSize** is the size of a cell on the physical media considered (in units of bits), and **TimeUnit** is the time interval of one count of CETSR. Since CETSR is global for all connections, TimeUnit has to be programed to be not bigger than the time required for one cell on the fastest connection.

After BI computation, it has to be converted to hexadecimal Fixed Point representation.

Example

We have to program the leaky bucket for a connection with rate of 16Kbps, where the fastest connection in the system is 155Mbps. Let's find the value of BI, assuming cell size of 53 bytes.

B) TimeUnit <= 53x8/155Mbps = 2.735us

So CETSR is programmed to, say, 2.7us.

Substituting the value in (A) we get:

BI = (53x8)/(16kbps x 2.7us) = 9814.8148

Converting it to Hexadecimal, we get: BI = 0x2656.D09. This implies the following programming:

B1II[0:11] = 265, B1II[12:15] = 6, B1IF[0:11] = D09

The smallest data rate which is given by the substitution of BI=64K in (A), is 2400bps. The resolution is at least 0.02%.

The formula for the Bucket Limit is:

C) BLim = CDVT/TimeUnit

Where **BL** is the decimal expression for the bucket's Limit, and **TimeUnit** is the time interval of one count of CETSR. For details about TimeUnit definition please refer to the explanation about BI programming above.

Following the calculation in (C), the result is rounded to the closest integer and converted to hexadecimal representation. The smallest value of L is 1 TimeUnit (2.7us in the above example). The highest value is 190min.

39.11.2 Example For Using PCR, CDVT

Highest Frequency: 16Mbps

PCR=1536Kbps

CDVT=0.5sec

TimeUnit <= 53x8/16Mbps = 26.5us.

This value of TimeUnit is larger than the highest possible in CETSR. So we program CETSR to TimeUnit=5us.

BI = (53x8)/(1536kbps x 5us) = 55.2083 -> BI= H37.355 -> BII=0037, BIF=355

BL = 0.5/5us = 100,000 -> BL=0x186A0

39.11.3 Relationship Between Two Instances of GCRA(I,L)

Up to two instances of Leaky Bucket with a different pairs of Bucket Increment (BI) and Bucket Limit (BL) might be applied to the data belonging to the same VCC, VPC, or any arbitrary bundle of VCCs.

The Leaky Bucket pair implies a certain coupling between the buckets. The MSP supports Leaky Bucket instances coupling according to the ITU-T recommendation I.371 and ATM Forum TM4.1 Specifications.

Each of the leaky buckets might be programmed to test conformance of CLP0, CLP1 or CLP0+1 cell streams. A cell which is tested by both buckets, is conformed only if it found conformed by both of the leaky buckets. The bucket state is updated only if a cell is conformed. Only a leaky bucket that found a cell conformance updates its state.

The exact behavior of Two Leaky Bucket instances is depicted in Figure 39-42 and Figure 39-43 below.

In the flows, a cell is processed by a certain instance of a leaky bucket if the LBF field selects a certain cell for this bucket. If a cell is conformed, this bucket will update its state if the cell will be accepted.

For F-GCRA (LBF=100), the conformance test is done only for the first cell of a packet. All the rest of the cells in the packet are processed by the Leaky Bucket, but assume conformance result similar to that of the first cell.

When the PPDE (Partial Packet Discard Enable) in the RCT is set, then the UPC policer is working at PPD mode. In this mode, if a cell is dropped, the rest of the cells in the packet except for the last one are dropped as well, and assume the same policing result as the first dropped cell.

Some Leaky Bucket instances examples are shown in Table 39-28. The examples show Leaky Bucket programming for all ATM Forum TM Specification 4.1 service Categories and ITU-T I.371 ATM Transfer Capabilities.

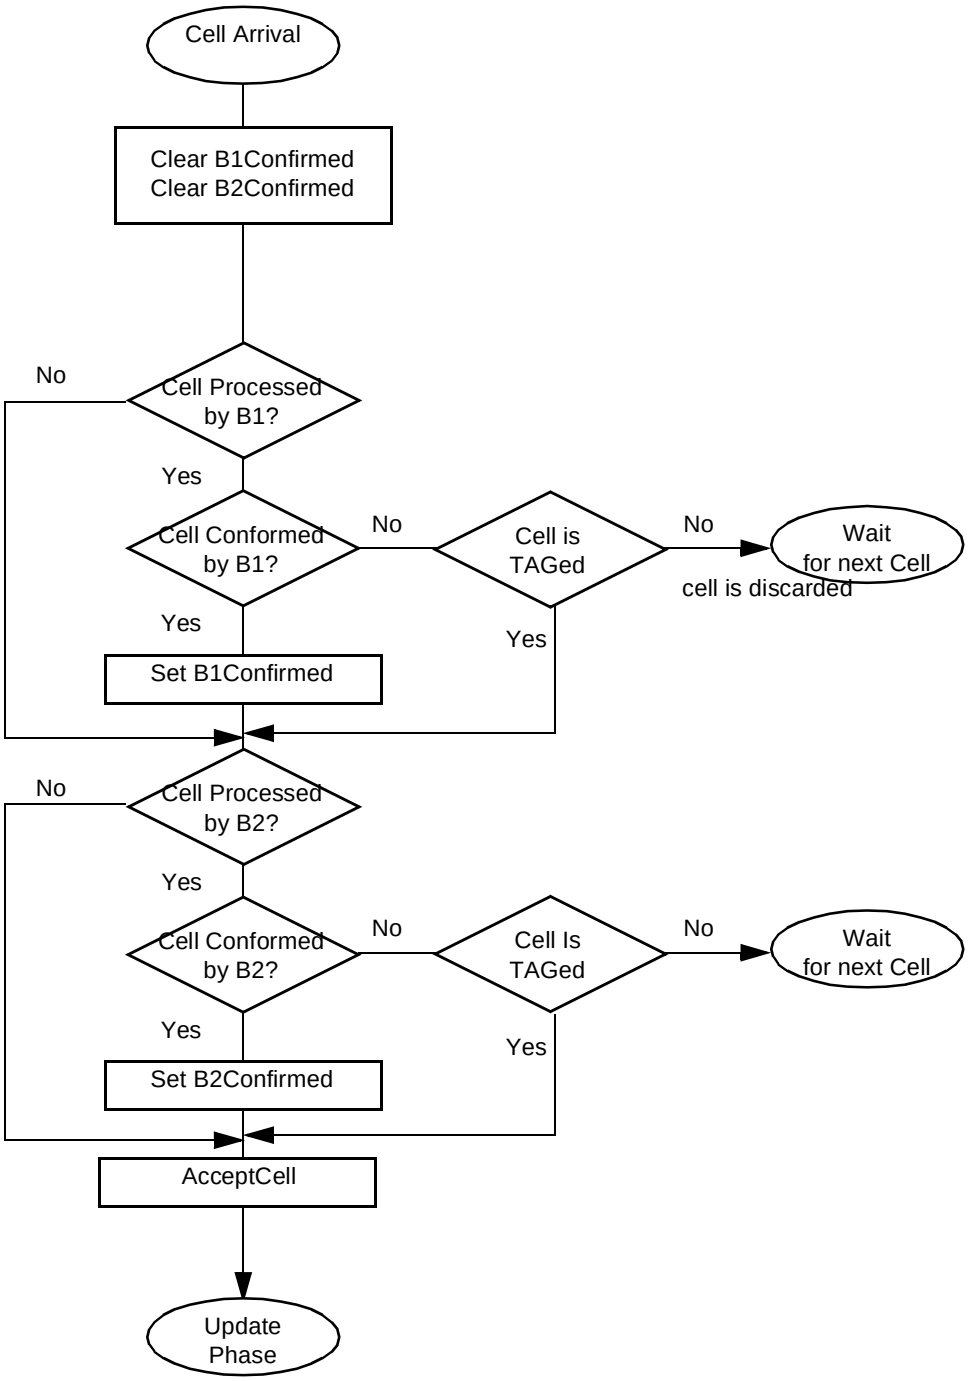

Figure 39-42. Coupling Between Two Leaky Buckets

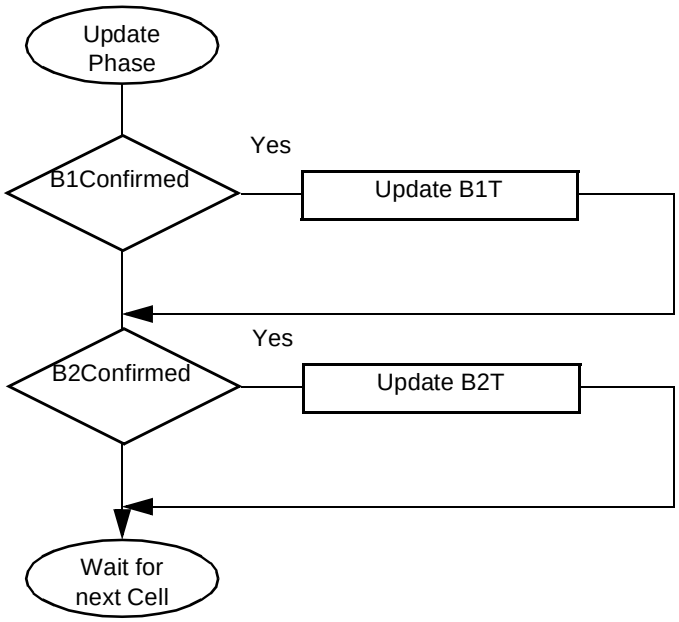

Figure 39-43. Updating B1T and B2T

39.11.4 GFR Conformance

The MSP supports GFR conformance testing according to the ATM Forum TM4.1 Specifications for GFR.1 and GFR.2 service categories. A frame is conforming if all its cells are conforming. GFR conformance implies the following conditions:

(1) The cell conforms to GCRA(1/PCR, CDVT) for the CLP0+1 cell stream

(2) The CLP value of any cell in the frame is identical to the CLP in the first cell

(3) The frame is shorter or equal to the MFS (Maximum Frame Size)

Condition (1) is tested by programming a leaky bucket to test flow CLP0+1, and drop any non-conformed cell. If a cell is dropped, a PPD policy is taken for the rest of the frame.

For Condition (2) testing, two user defined policies are available in GFR mode. The first is to discard any cell which has a CLP value different than the value of the CLP in the first cell. In this case, a PPD policy is taken for the rest of the frame. The second policy is similar to the first, except that for frames in which the first cell has a CLP value of 1, all the rest of the cells are tagged.

Condition (3) is enabled while GFR mode is selected in the RCT. The accumulated frame length is compared to a threshold, GFRT, which is located in the RCT. If the accumulated length is bigger then the threshold, a PPD policy is taken for the rest of the frame.

39.11.5 GFR Frame-Eligibility

A frame is said to be “eligible” if and only if it is conformed, un marked, and passes the F-GCRA test (ATM Forum TM specifications Version 4.1 Annex B.5). The agreed QoS level is guaranteed only for eligible frames.

The MSP Policer supports the F-GCRA. Selecting the F-GCRA mode is done by programming the filter LBF to be 100 and TAG=1 (See Table 39-26 and Table 39-27).

In this mode, the F-GCRA(1/MCR, BT+CDVT) Leaky Bucket (Typically the second Leaky Bucket in double leaky bucket instances) will TAG a complete frame if it finds the first cell of the frame non eligible, and change frame’s eligibility status.

Another case where a status of a frame can be changed from non-conformed to non-eligible is when the CLP test marks the cells in a frame which has its first cell marked.

A non-eligible frame can be either dropped or getting a lower level service in the Queue Management (See Section 39.8, “Queue Management). If the network requires to drop non-eligible frame, it can be done by programming the TAG bit in the F-GCRA Leaky Bucket to 0 (Non TAG mode).

Table 39-28. Example to Double Leaky Bucket Configurations

ATM Forum TM4.1 Service Categories	ITU-T I.371 ATM Transfer Capability	LB1		LB2	
		LBF	TAG	LBF	TAG
CBR.1	DBR Configuration 1	011	0	000	0
VBR.1	SBR Configuration 1	011	0	011	0
VBR.2	SBR Configuration 2	011	0	001	0
VBR.3	SBR Configuration 3	011	0	001	1
GFR.1	—	011	0	100	0
GFR.2	—	011	0	100	1
UBR.1	—	011	0	0	0
UBR.2	—	011	1	0	0

39.12 Billing

In order to support a billing mechanism the MSP performs cell counting for Ingress/Egress connections.

For Ingress connections the billing is performed for all incoming switched cells (as described in the general Ingress Data Flow, see Section 39.1.1, “Ingress Data Flow”), therefore the cell counting is done in the SRCT (See Section 39.9.2, “SRCT - Switched Cells Receive Parameter Table”). For Egress connections billing is performed for all transmitted cells, therefore the cell counting is done in the STCT (See Section 39.9.4, “STCT - Switched Cells Non Hierarchical Scheduling).

For both Ingress/Egress connections two Cell counters are supported, 32bit CLP0 count and 16 bit CLP1 count. Whenever one of these counters overflows, a maskable interrupt is generated to the host.

39.13 Statistics

In Addition to the Ingress/Egress Cell counters used for billing purposes, the MSP manages a set of counters for statistics, on a per connection basis.

Note that the CLP0 and CLP1 Cell count (as explained in the Billing section) is performed always at both receiving and transmitting sides.

If the UPC policer is enabled (on a per connection basis) additional two counters are introduced: non conforming CLP0 counter (NCCLP0) and non conforming CLP1 counter (NCCLP1). Both are 16-bit counters and reside in the UPC parameter table (see Figure 39-41).

An additional counter QDCC (resides in the SRCT) is used for monitoring the number of cell which were dropped by the Policing/ Queue management mechanism. Whenever a cell is dropped by the Queue management mechanism, this counter is updated. Whenever one of these counters overflows, a maskable interrupt is generated to the host.

39.14 Multicast

The QUICC Engine EMSP is capable of performing **MULTICAST** operation.

When the cells which are being received over a certain connection has to be duplicated and transmitted over an arbitrary set of other connections and PHYs transmission path, a **MULTICAST** operation is executed.

39.14.1 Definitions

The cell which has to be duplicated is received by the QUICC Engine EMSP through the S**ource Connection**, and sent out through a group of **Destination Connections**.

The connection code (CC) of the receiving cells is called **Source Connection**, the group of TCCs of the connections which the cell has to be duplicated over is called the **Destination Group**. Each **Destination Group** contains two or more **Destination Connections** up to 32 connections are available.

If, for instance, the cells received over CC #1000 has to be transmitted to connections with Channel Codes (CCs) 2000, 3000, 4000 then CC #1000 is the Source CC and CCs 2000, 3000 and 4000 are the members of the destination group.

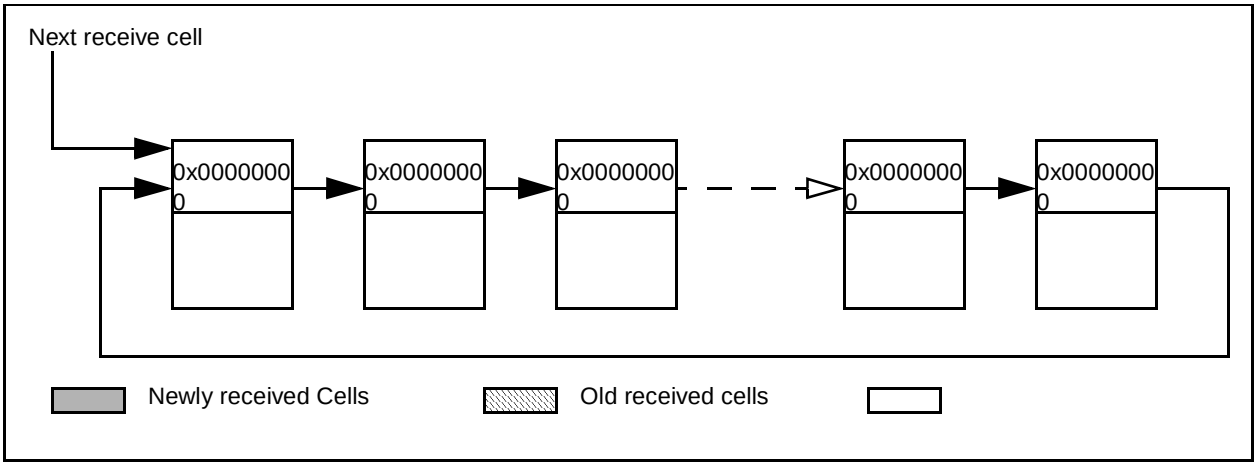
The **Source connection**'s linked list of received cells is called **Source Queue.**

The above terms and the multicast implementation are depicted in Figure 39-44 below.

39.14.2 Multicast Source Queue

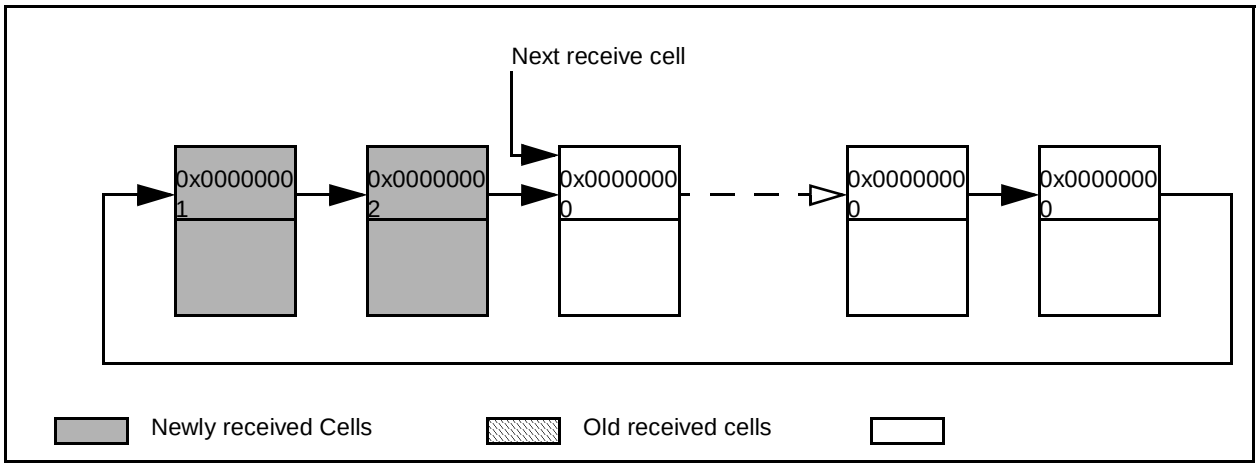
All multicast cells (cells which have RCT[RCTM]=11) are stored in a special multicast queue. There is one queue for each multicast group; the queue is common to all connections and all PHYs. The length of the queue is determined by the application SW, and should be larger than the maximum delay (in cell time) between receiving and transmitting a cell to an output port. The Multicast Source Queue is a cyclic queue, therefore, new incoming cells will override older cells after the first wrap of the Queue. Depicted below is an example of an initialized Multicast Source Queue, which size is 1000(hex) cells. All of the cells are

empty and have a serial number of 0x00000000. The Queue is allocated and initialized by the application SW.



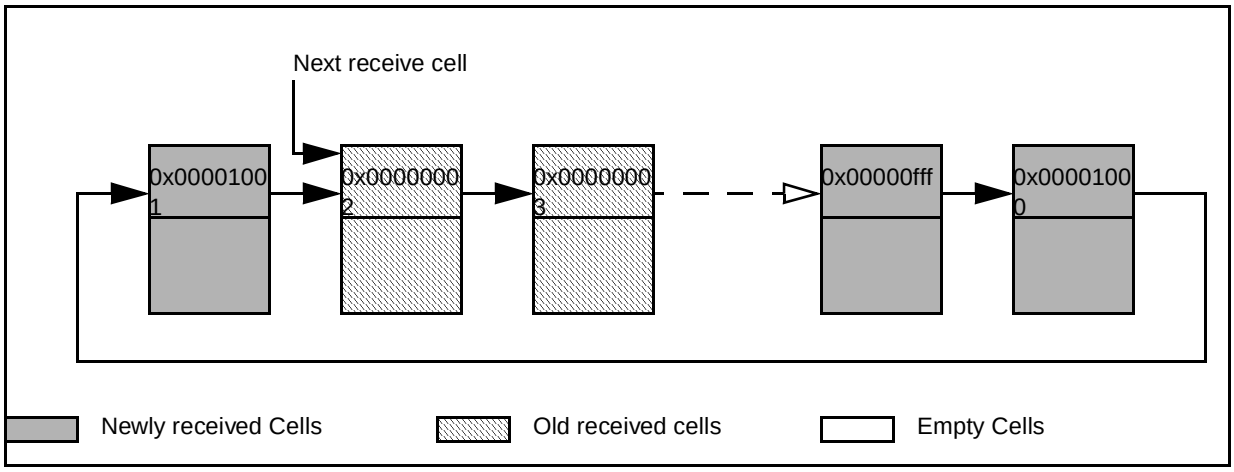
The ‘Next receive cell pointer’ points to a ‘free’ cell to which the receiver will accept a new incoming cell. This pointer should be initialized by the host SW to point to any of the free cells in the cyclic Source Queue.

After receiving two cells, the Queue should look like this:



Note that each received cell is associated with a serial number. The purpose of the serial number will be explained later.

After receiving 1001 cells, the Queue should look like this:



It is easily seen that new incoming cells override older cells, which should have been transmitted already by all of the Destination members.

39.14.3 Multicast Operation Modes

39.14.3.1 Multicast Mode Based on APC Shaping

When working with Multicast using APC Shaping (MTCT[FIFO_MODE]=’0’), the Multicast transmitter members are chosen using the APC of each PHY. This enables that transmitters from different PHYs could use the same Multicast source list. it’s the user’s responsibility to issue a host command to activate each member of the Destination Group in the APC.

This mode enables that on the same PHY there could be unicast APC connections and at the same time Multicast APC connections.

39.14.3.2 Multicast Mode Based on FIFO WFQ

When working with Multicast using FIFO WFQ (MTCT[FIFO_MODE]=’1’), the multicast transmitter members are chosen using the FIFO WFQ of each PHY. When a ‘FIFO’ is chosen by the FIFO WFQ algorithm, and it is a multicast FDT, then the CC are chosen using the CC structure pointed by this FDT by round robin algorithm (see Figure 39-33) Then, the MTCT is read instead of the FTCT, to identify which linked list this channel code belongs to. This enables that transmitters from different PHYs could use the same Multicast source list.

This mode enables that on the same PHY there could be unicast FIFO WFQ connections and at the same time Multicast FIFO WFQ connections.

39.14.3.3 Multicast Operation

After cell processing by the receiver, the cell is placed in the appropriate multicast Queue. Each one of the Destination Connections is pointing to the next cell to be transmitted from the multicast Queue. When a cell is transmitted by a member of the destination group, the member’s pointer is changed to point to the

next cell in the multicast Queue. Each destination group member has its own pointer to the multicast queue, so there is a complete isolation between the destination connections. If one destination member fails to perform transmit operation from some reason, all other destination group members continue to transmit normally.

When receiving a new cell to the Source Queue, the receiver will write two additional fields to the COV area of the cell. One is an incremental serial number, copied from the MRCT and the other is the Multicast members mask (also copied from the MRCT).

Each destination group member keeps a serial number counter. When attempting to transmit, this serial number should match the one in the COV of the cell to be transmitted. The transmitter compares these two serial numbers. If they match, then the transmit operation will continue normally. If a mismatch occurs there are two possible reasons for this to happen: If the transmitter is faster then the receiver, the SN- serial number of the cell is smaller then the expected SN of the transmitter, the transmitter could try to transmit a cell that already has been transmitted (See above figures describing the Cyclic Source Queue). The use of the serial numbers prevents this from happening by causing the transmitter to stop and wait until new cells are received. Alternatively, if for some reason a destination member could not perform transmit operation for a long time and its pointer to the Multicast Queue is no longer valid (i.e the cell to which the MTCT points was already overwritten by a new cell thus the cell SN is bigger then this in the MTCT), a mismatch will occur between the transmit serial number in the MTCT and the receive serial number stored in the COV area. In this case the behavior is programmable. If the MTCT[AVCOF]=’1’ then the destination channel could be automatically removed from being scheduled by the APC, or in case of FIFO WFQ mode the transmitter will wait endlessly, and the user should remove it from the corresponding CC structure. If MTCT[AVCOF]=‘0’, then the transmission continues and the new serial number is adopted by the transmitter. In either case, the RISC will generate a maskable MCET error interrupt to the host indicating to the application which of the destination channels was stuck. Adding the channel back should be performed by the host as described in Section 39.14.5, “On-Line Modification of the Multicast Destination Group.”

In order to alert the host SW that one or more of the destination group members stopped performing transmit operation, an additional mechanism is being used. This mechanism is necessary in cases where one or more of the destination members is stuck for a long period of time. Each of the destination group members has an I.D number ranging from 0-31. This unique number is determined in the MTCT[MCIDN]. In normal operation each destination member, upon transmission of a cell, clears the bit associated with it’s ID number in the Multicast members field in the COV area of the cell (see Figure 39-47). For example a destination channel with MCIDN = 8 will clear bit 8 in the cell COV[Multicast members] word. It is expected that upon transmission of a cell by all of the destination members this word is zero.

The source connection is aware of the number of destination group members. This is achieved by the Multicast Members Mask word in the MRCT. This is a mask where each bit represents a destination member ID. In normal operation, upon receiving a cell the receiver check that the [Multicast members] word in the COV area of the current cell location is zero. This implies that the cell was transmitted by all of the destination group members. The receiver detects a situation in which an old cell that is going to be overwritten and generates a maskable MCER interrupt to the host SW. In either case the source channel updates the Multicast Members field in the COV area to the Multicast Members Mask in it’s MRCT, and writes the new cell to this location. The information regarding which of the destination channels is “stuck” is described in Section 39.14.6, “Multicast Receiver Event.”

Also note that because the Source Queue uses a different mechanism than a Unicast VC or VP Queue, NO other Queue management is applicable (The Unicast Queue Thresholds do not apply for a Multicast connection).

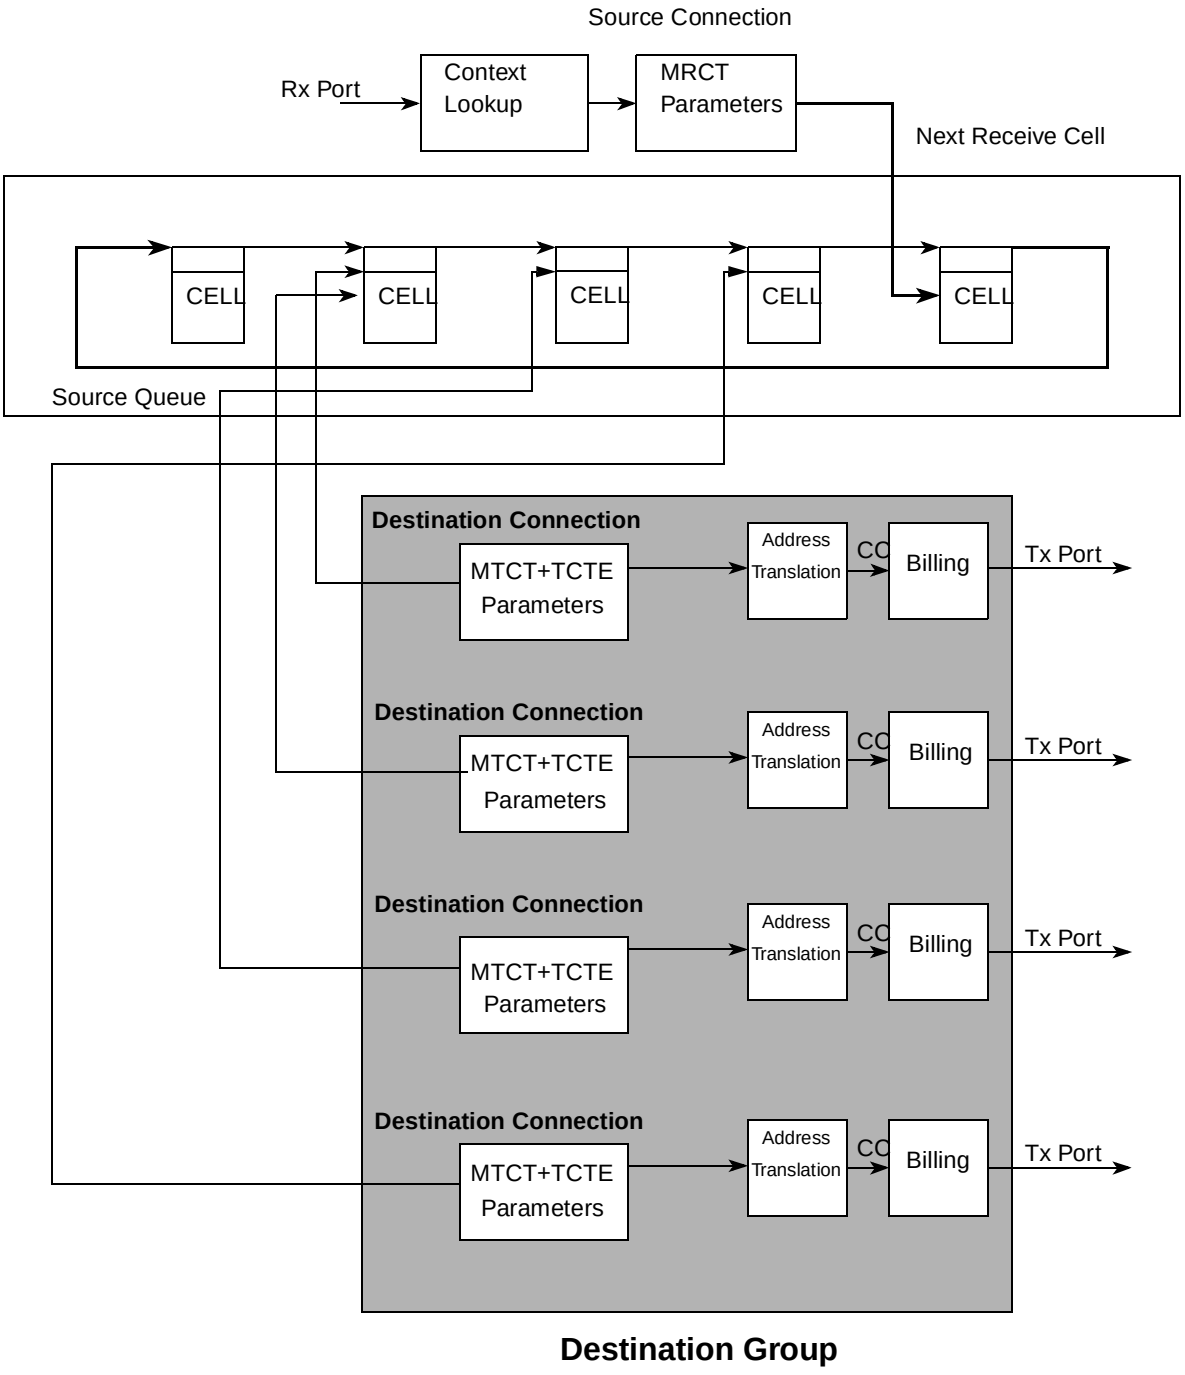


Figure 39-44. Multicast: Address Translation and Billing is Done Independently for Each Member in the Destination

39.14.3.4 Auto FE mechanism for FIFO Multicast Mode

The Auto FE set/clear mechanism for multicast FIFO operation, is enabled by setting MRCT[FE_AUTO_CLR], FDT[FIFO_MODES]: FE_AUTO_SET and NO_ITERATION fields. This mode is designed to emulate FIFO Empty mechanism, for applications that use Strict/Fix priority modes, for example. This mode is the preferred mode of working, when using FIFO mode scheduling for Multicast connections.

When auto FE mechanism is on, on each receive of cell using MRCT, the RISC reads the Pointer to the WFT Pointer Table from FEPTR_BASE + MRCT[MCGID]*2 offset in multi-user RAM. This WFT Pointer Table consists of all the WFTs entries needed to be accessed by the RISC, in order to clear their corresponding WFT[FE] bits. This WFT Pointer Table also resides in multi-user RAM. The COUNT in the beginning of this table indicates the number of WFT entries minus 1. See Figure 39-45.

On the transmitter side, each time that a MTCT is selected from a certain FIFO, and there is no valid cell to transmit from its Multicast list, then the FDTs FIFO_MODES[NO_ITERATION] field, is used to determine when to set the corresponding FE bit, see Section 39.10.4.4, “FIFO_MODES Entry for Multicast Mode”. Only after the Channel Code structure was scanned NO_ITERATION + 1 times, and still there is no valid cell to transmit, then the corresponding FE bit is set and the FIFO is disabled.

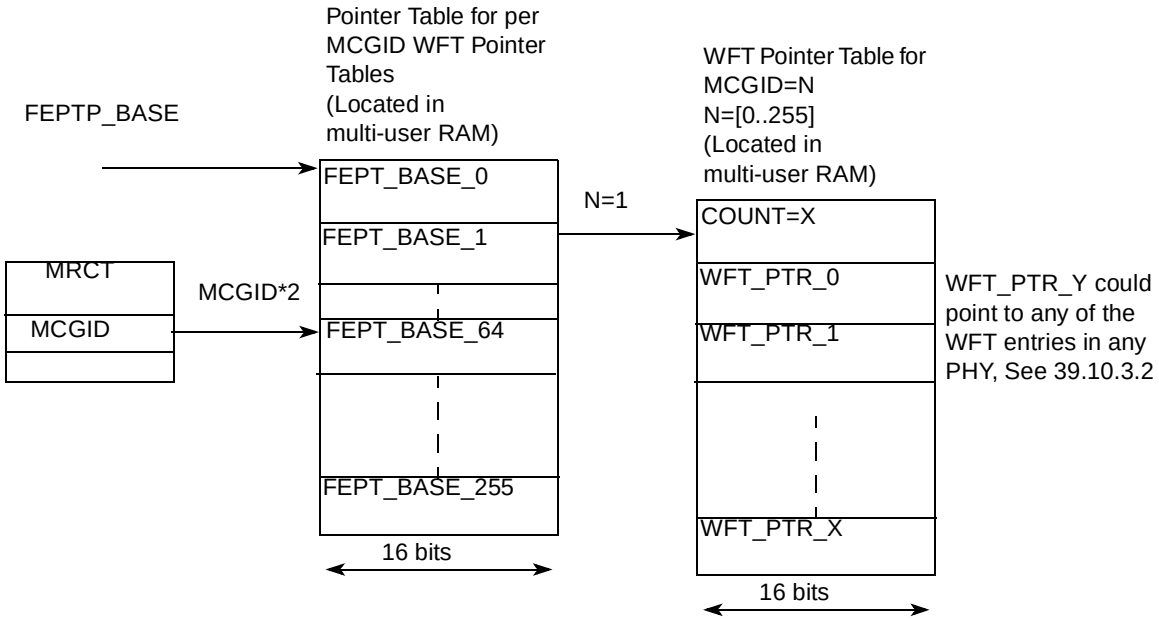

Figure 39-45. WFT Pointer Table

39.14.4 MSP Multicast Main Features

- 32 channels of Destination Connections per source connection.

Note - If the user wants more than 32 Destination group per source connection, it is possible to use the same MCIDN value for all Channels which reside in the same PHY - this way the user could still have the

knowledge of which PHY failed on a multicast receiver event, see Section 39.14.6, "Multicast Receiver Event."

- 256 available source channels per UCC.
- Per Destination CLP1 and CLP0 statistics.
- Arriving cells are stored in a queue per destination group.
- User Defined Address Translation for each Destination Connection Independently
- Cells are not duplicated in Memory.
- No Extra performance cost except for regular transmission performance cost per additional Destination Group member.
- Supports On-Line (Run-Time) Destination-Group modification.

39.14.5 On-Line Modification of the Multicast Destination Group

On line modification enables the application to exclude a member or include a new member in the Destination Group without interfering with the multicast operation. It is important to notice the difference between On-Line modification and normal power up setup:

When setting up the connections on power up, the following steps are performed:

- In order to avoid the receiver from start receiving cells before the Transmitters are configured, the user should disable the receiver by setting the MS bit in the corresponding CAM or Address Compression output entry, or set the MRCT[MS], when working with CC in UDH mode.
- MTCT[MQPTR]=MRCT[Next Receive Cell Pointer], MTCT[SN]=MRCT[SN]=0, MTCT[ADDCH]=0.
- For FIFO non-auto FE mode, clear the FE bit in the WFT entry. For FIFO with auto FE mode - set the FE bit.
- For APC mode issue an ATM transmit command.
- Enable the MRCT connection, by clearing the MS bit.

For dynamic modification see the following sections.

39.14.5.1 On-Line Modification of Multicast APC Mode

Adding a destination member to the destination group is done in the following way:

1. Allocate MTCT entry for the new channel with MTCT[TCTM] =11.

2. Set the MTCT pointer to point to the Cell in the linked list which is not currently pointed by the MRCT. i.e. the MTCT pointer should point to a cell which lags the source pointer by at least one cell. This, in order to prevent synchronization problems between Rx and Tx. Leave the SN entry in the MTCT uninitialized.

3. Set the ADDCH bit in the MTCT. MTCT[SN] field value would be taken from the COV of the cell and would be adopted automatically by the RISC- so this field could be cleared.

4. Update the Multicast Member Mask field (word) in the MRCT of the source queue.

5. Issue an ATM Transmit host command to enable the scheduling of the channel in the APC.

Upon completion of the insertion of this new destination member the ADDCH bit in MTCT is cleared.

Removing a destination member from the destination group is done in the following way:

1. Update the Multicast Member Mask field (word) in the MRCT of the source queue.

2. Set the STPT bit in the MTCT of the destination member to be removed.

39.14.5.2 On-Line Modification of FIFO WFQ Multicast Mode without Auto FE Mechanism

Adding a destination member to the destination group is done in the following way:

1. Setting the FDT[MCST_FIFO_DIS] bit of the Multicast FIFO.
2. Wait till FDT[MCST_FIFO_DIS] is cleared or till an interrupt is issued, with bits EFCI and MCER set to 1, depending on FDT[FDT_MCST_DISFIFO_INTEN] (see Figure 39-25
3. Add the required channel code to the Channel code structure of the Multicast FIFO.
4. Allocate MTCT entry for these new channels with MTCT[TCTM] =11, MTCT[FIFO_MODE]=1 and set the ADDCH bit. MTCT[SN] field value would be taken from the COV of the cell and would be adopted automatically by the RISC- so this field could be cleared.
5. Set the MTCT pointer to point to the Cell in the linked list which is not currently pointed by the MRCT. i.e. the MTCT pointer should point to a cell which lags the source pointer by at least one cell. This, in order to prevent synchronization problems between Rx and Tx. Leave the SN entry in the MTCT uninitialized.
6. Update the Multicast Member Mask field (word) in the MRCT of the source queue.
7. Activate the Multicast FIFO by setting the WFT of the corresponding FIFO to the following value: WFT[FE]=0, WFT[FT]=0 and WFT[FID]=FID, and after that setting FDT[MCST_FIFO_EN] bit to 1. The reason for setting ‘FIFO_EN’ bit, is to enable the UP to update the current minimum WFT to the added FIFO. The RISC will reset this bit upon completion.

Upon completion of the insertion of the new destination member the ADDCH bit in the MTCT is cleared. It’s possible to add some channel codes which belong to the same FIFO (the same CC structure) simultaneously.

Removing a destination member from the destination group is done in the following way:

1. Setting the FDT[MCST_FIFO_DIS] bit of the Multicast FIFO.
2. Wait till FDT[MCST_FIFO_DIS] is cleared or till an interrupt is issued, with bits EFCI and MCER set to 1, depending on FDT[FDT_MCST_DISFIFO_INTEN] (see Table 39-25, “FIFO_MODES Table Entry for Multicast mode.”
3. Remove the required channel codes from the Channel code structure of the Multicast FIFO.
4. Update the Multicast Member Mask field (word) in the MRCT of the source queue.

If the Channel Code structure isn’t empty at this point, then step no. 5 should be performed, in order to reactivate this FIFO WFT mechanism. On the Contrary, if the Channel Code structure is empty, then the following step shouldn’t be performed.

5. Activate the Multicast FIFO by setting the WFT of the corresponding FIFO to the following value: WFT[FE]=0, WFT[FT]=0 and WFT[FID]=FID, and after that setting FDT[MCST_FIFO_EN] bit to 1. The RISC will reset this bit upon completion.

It is possible to remove some channel codes which belong to the same FIFO (the same CC structure) simultaneously.

39.14.5.3 On-Line Modification of FIFO WFQ Multicast Mode with Auto FE Mechanism

The mechanism of On Line modification described in the previous section, must be changed for Auto FE FIFO Multicast mode. This is because the manual enable/disable operations, that changes the value of the FIFO FE bit, can interfere with the automatic set/clear of the same FE bit. Therefore the user shouldn't use the FIFO_DIS operation anymore.

The sequence of adding a CC to the destination group is -

1. Allocate MTCT entry for these new channels with MTCT[TCTM] =11, MTCT[FIFO_MODE]=1 and set the ADDCH bit. MTCT[SN] field value would be taken from the COV of the cell and would be adopted automatically by the RISC- so this field could be cleared.
2. Set the MTCT pointer to point to the Cell in the linked list which is not currently pointed by the MRCT. i.e. the MTCT pointer should point to a cell which lags the source pointer by at least one cell. This, in order to prevent synchronization problems between Rx and Tx. Leave the SN entry in the MTCT uninitialized.
3. Update the Multicast Member Mask field (word) in the MRCT of the source queue.
4. Modify the CC structure, so that the new CCs would be added to the end of the list.
5. Modify the MCST_FIFO_CC_LAST in the FDT, see Section 39.10.4.3, "FDT for Multicast FIFO."
6. Update the No_Iterations field in the FDT, if necessary.
7. If it is a new CC leaf of a specific MRCT, then the user should update the MRCT's WFT Pointer Table, so now the entry for this FIFO's WFT will be added- see Section 39.14.3.4, "Auto FE mechanism for FIFO Multicast Mode"
8. Enable the FIFO if it is the first CC in the CC list, by setting WFT[FT]=0,WFT[FID]=FID (no need to clear WFT[FE] bit) and setting FDT[FIFO_EN]. The reason for setting 'FIFO_EN' bit, is to enable the UP to update the current minimum WFT to the added FIFO. The RISC will reset this bit upon completion.

The sequence of deleting a CC from the destination group is -

1. Update the Multicast Member Mask field (word) in the MRCT of the source queue.
2. Rearrange the CC structure such that removing the CC, which is intended to be deleted, wouldn't create spaces ('holes') in the CC list.
3. If the Channel to be removed is the last Tx destination member of a specific MRCT in this FIFO, then update the MRCT's WFT Pointer Table, so now the entry for this FIFO's WFT will be deleted - see Section 39.14.3.4, "Auto FE mechanism for FIFO Multicast Mode"

If it is the last CC deleted from the CC list then perform stages 4-5 -

4. Update the MCST_FIFO_CC_LAST field in the FDT to be equal to the MCST_FIFO_CC_FIRST value.
5. Set the Last CC value to zero and the No_Iterations field in the FDT to zero. This will cause the FIFO to be disabled automatically. Wait till the FE bit in the corresponding WFT entry will be actually set by the RISC. NO need to set FDT[FIFO_DIS] bit since it isn't supported for AUTO_FE mode.

If it is NOT the last CC deleted from the CC list then perform the following stages -

6. Update the MCST_FIFO_CC_LAST in the FDT, which will prevent the deleted CC to be scanned.
7. Update the No_Iterations field in the FDT, if necessary.

Notice - There could be conditions where the receiver stopped receiving anymore cells and will not receive anymore cells to a specific FIFO, and therefore it doesn't clear the FIFOs WFT[FE] anymore, but the FIFO transmitters didn't transmitted all the cells yet, since they set WFT[FE] bit already. In this case the user should set WFT[FE]=0 (FDT[FIFO_EN] is already set in that condition by the RISC), so the transmitters of that FIFO will transmit the last cell it the multicast source list.

39.14.6 Multicast Receiver Event

In case when a source channel detects that not all of the Multicast members field in the COV area of the cell were cleared by the transmitter member group, and the MRCT[MCRIE] is set, an event indication is set in the interrupt queue entry. The information given in such an interrupt entry is the receiver channel code causing the event. Further info is required to determine which of the destination channels is overwritten by the receiver and the information is obtained in this way: In the MSP parameter table the entry MCE_BASE points to the Multicast Event Table structure which consists of up to 256 one word entries. Each of the source channels of the multicast is assigned with a group number MRCT[MCGID]. So each of the entries in this table corresponds to a source group by the MCE_BASE address + MCGID*4. Each entry in the table is a replication of the multicast Member field in the COV area which was overwritten by the source channel. The user can tell which of the destination channels was overwritten since the bit representing it's ID is set.

Table 39-29. Multicast Event Table

Address	Name	Width	Description
Offset+ 0x00	Multicast Member group 0	word	Multicast Member image for source group 0
Offset+ 0x04	Multicast Member group 1	word	Multicast Member image for source group 1

39.14.7 Multicast Cells Format

At initialization, each MRCT[Next_Receive_Cell_Ptr] and MTCT[MQPTR] should point to a free cell of the following format. All fields are given for informative purposes only.

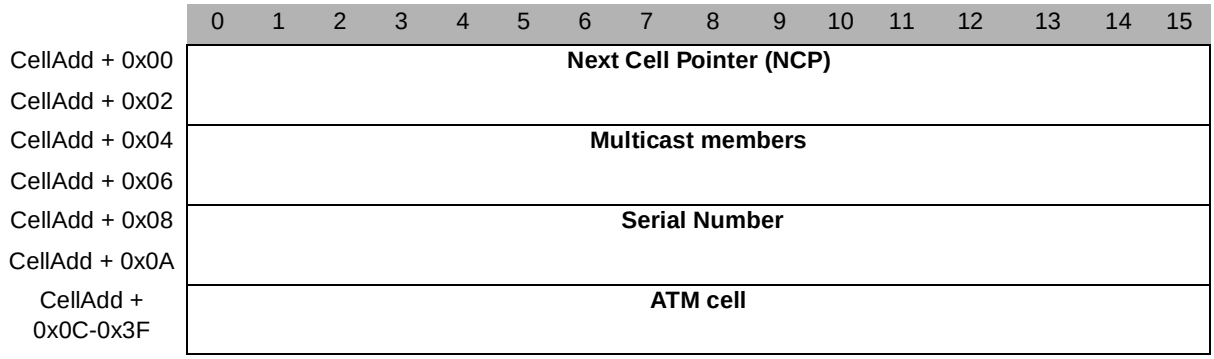

Figure 39-47. Multicast ATM Cell Format

The Serial Number (SN) is updated by the receiver for each incoming cell.

The Multicast Members field is a mask for 32 available destination channels used by the receiver to detect whether one or more of the destination connections stopped performing transmit operation.

The Multicast members and Serial Number fields should be cleared and are for RISC use only. The NCP field should be initialized to point to the next cell in the source link list.

It is preferred that the cells in the Multicast linked list would be ordered one after the other in the external memory. This in order to simplify the action of finding the cell in the linked list which lags the source pointer by at least one cell, as described in Section 39.14.5, “On-Line Modification of the Multicast Destination Group” for adding a destination member to the multicast group. In this case the only operation needed to be done for finding the MQPTR of the added MTCT, is to substitute 0x40 from MRCT[next_receive_cell_ptr], or in case that MRCT[next_receive_cell_ptr] points to the beginning of the linked list, MTCT[MQPTR] should be the address of the last cell in the linked list.

Table 39-30 describes Multicast RCT fields.

Table 39-30. Multicast RCT Field Descriptions

Offset	Bits	Name	Description
0x00	0		Reserved. Set to zero.
	1		Reserved. Set to zero.
	2	**GBL**	Global. Asserting GBL signal on memory bus, enables snooping of data buffers, BD interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	**BO**	Byte ordering—used for data buffers. 00, 01, 11 Reserved 10 Big endian
	5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.
	6	**DTB**	Data buffers bus (source linked list cells) 0 Cell buffers reside on the coherent system bus. 1 Cell buffers reside on the secondary bus.
	7	**BDB**	Interrupt queues and UPCT 0 Interrupt queues and UPCT reside on the coherent system bus. 1 Interrupt queues and UPCT reside on the secondary bus.
	8	**VPC**	Virtual Path Connection (used for OAM termination) 0 This channel is not a VP connection 1 This channel is a VP connection
	9-11	**-**	Reserved. Initialized to zero.
	11	**PPDE**	Partial Packet Discard (PPD) Enable. When a single cell is dropped by the policer, then all other cells associated with the current packet are dropped. The last cell in a packet will always be accepted. Only if the first cell is discarded then the Last cell will be discarded as well. Setting this bit implies frame based connection (AAL5). 0 PPD is disabled. 1 PPD is enabled. It is preferred from performance issues that PPDE will be disabled, even if working in frame mode, when the policer is disabled - since in this case no cells should be dropped.
	12-13	**UPCM**	UPC (Policing) Mode (See Section 39.11, "UPC Policer" for details) 00 UPC is disabled. 01 UPC is enabled. 10 Not valid for Multi-cast mode. 11 Not valid for Multi-cast mode.
	14–15	**INTQ**	Points to one of four interrupt queues available.

Table 39-30. Multicast RCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0-1	**RCTM**	RCT Mode 00 This RCT is used for a switched channel shaped by the APC. 32 bit QPTRL is placed in address 0x4 of RCT. 01 This RCT is used for a switched channel shaped by external FIFOs. 32 bit EFDP FIFO Descriptor Pointer to external memory is placed in address 0x4 of RCT. 10 This RCT is used for a switched channel shaped by internal FIFOs. 16 bit FDP FIFO Descriptor Pointer to internal multi-user RAM is placed in address 0x4 of RCT. 11 This RCT is an MRCT and is used for Multicast shaping. See Section 39.14, "Multicast."
	2	**FE_AUTO_ CLR**	For Multicast using WFT algorithm only. 0 Auto FE clear receive mechanism is disabled. 1 Auto FE clear receive mechanism is enabled.
	3	-	Reserved. Initialized to 0.
	4	-	Reserved. Initialized to 0.
0x02	5-12	**MCGID**	Multicast source Group ID - indicate one of 256 available m/c source groups. Upon an event (MCE) the status of the m/c members that caused this event will be replicated in MCE_BASE + MCGID*4 in multi-user RAM. Also for Multicast FIFO using auto FE mechanism, indicate the pointer to the Pointer Table for per MCGID WFT Pointer Tables location in FEPRP_BASE+ MCGID*2. see Section 39.14.3.4, "Auto FE mechanism for FIFO Multicast Mode"
	13-15	**AAL**	AAL type: 000 AAL0 Reassembly with no adaptation layer. 001 AAL1 ATM adaptation layer 1 protocol. 010 AAL5 ATM adaptation layer 5 protocol. 011 AAL3. 100 AAl2. 101 CES. 110 MSP-Multi ServIce Protocol - switched ATM cells.
0x04	—	**Receive Cell Serial Number**	Receive Cell Serial Number. is SN assigned for each received cell by the receiver. All destination group member should transmit the cells in the order of this numbering. Initialized by the user.
0x08	—	**Cell Time Stamp**	Whenever a cell is received, the PowerQUICC II Pro MSP timestamp timer is sampled and written to this field. See Section 20.3.9, "QUICC Engine Time-Stamp Control Register (CETSCR)."
0x0C	—	**QDCC**	Queue Dropped Cell Count. Cells dropped due to policer.
0x0E	—	**CLP1 Count**	CLP1 cells Count.
0x10	—	**CLP0 Count**	CLP0 cells count.
0x14		**Next Receive Cell Pointer**	A pointer to the next cell in the linked list queue. Initialized by the user.
0x18	—	**UPCPTR**	Pointer to external UPC Parameter Table (UPCT). Aligned to 32 byte addresses.
0x1A		**Multicast Members Mask**	Holds a mask where each bit represents a member of the destination channels of the Tx. For example 0x00000005 represents destination members #31 and # 29 as represented in the MTCT[MCIDN]

Table 39-30. Multicast RCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x1E	0	**MS**	Match Status. Valid only for CC in UDH mode. 0 Match was found. 1 Match was not found. Cell will be discarded without updating the SRCT in external memory. The CPU can use this mechanism when performing dynamic changes in the SRCT/MRCT, without the interfering of the QUICC Engine block.
	1	**NCCLPIE**	Non-Conforming CLP1 or CLP0 counters overflow interrupt enable
	2-7	**PMT**	Performance monitoring Table Index. One of 64 performance monitoring parameter tables is chosen fir this channel
	8	**SEGT**	Segment OAM termination (used for OAM termination) 0 Do not terminate segment OAM cells 1 Terminate segment OAM cells (OAM cells are sent to Raw Cell Queue)
	9	**ENDT**	End-to-end OAM termination (used for OAM termination) 0 Do not terminate end-to-end OAM cells 1 Terminate end-to-end OAM cells (OAM cells are sent to Raw Cell Queue)
	10-11	**-**	Reserved. Initialized to 0.
	12	**MCRIE**	Multicast receiver event Interrupt Enable
	13	**QDCCIE**	QDCC Counter overflow Interrupt Enable
	14	**CLPIE**	CLP0C Counter or CLP1C Counter overflow Interrupt Enable
	15	**PME**	Performance monitoring Enable 0 No performance monitoring o this channel 1 Performance monitoring is enabled on this channel

NOTE

For an active channel, the RISC uses a burst cycle to fetch the 32-byte RCT and writes back only the first 24 bytes. The user can alter the interrupt enable bits or the multicast members field on the fly.

39.14.9 MTCT- Multicast TCT

TCTM=11, AAL=110

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0x00	—	—	GBL	BO		CETM	DTB	BDB	AVCF	---	ATT			VCON	INTQ

Offset + 0x04	MQPTR															
Offset + 0x06																
Offset + 0x08	Transmit Serial Number															
Offset + 0x0A																
Offset + 0x0C	Rate Remainder								PCR Fraction							
Offset + 0x0E	PCR															
Offset + 0x10	CPL0 Count															
Offset + 0x12																
Offset + 0x14	CLP1 Count															
Offset + 0x16	APCLC															
Offset + 0x18	TVPI												TVCI			
Offset + 0x1A	TVCI												—	CVP	CVC	CGFC
Offset + 0x1C	Res		PMT													
Offset + 0x1E	INS_CELL_ Flag												MCETIE	STPT	CLPIE	PME

Figure 39-49. Multicast Transmit Connection Table (MTCT)

The RISC updates only entries 0x00-0x17 (24 bytes), and 1 byte located in 0x1e; other bytes are read by the RISC but are not updated by it. The CPU controlling the connection can change relevant bits from entries 0x18-0x1F (not including 0x1E) on the fly, and the RISC will act upon the new value, next time the TCT is used. The CPU shouldn’t update the byte in location 0x1E, after setting the INS_CELL_En bit - until the RISC reset this bit again.

Next Table (Table 39-31) describes general MTCT fields.

Table 39-31. MTCT Field Descriptions

Offset	Bits	Name	Description
0x0	0-1		Reserved. Initialize to zero.
	2	**GBL**	Global. Asserting GBL enables snooping of data buffers, BD, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	**BO**	Byte ordering. This field is used for data buffers. 00, 01, 11 Reserved. 10 Big endian.
	5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.
	6	**DTB**	Data buffers bus (Source linked list). If Insert cell mode is enabled and the cell resides in external memory, this bit should reflect the bus location of the cell to be transmitted. 0 Data buffers reside on the coherent system bus. 1 Data buffers reside on the secondary bus.
	7	**BDB**	Interrupt queues bus. If Insert cell mode is enabled and the CC>255 this bit should reflect the bus location of the Insert Cell pointers Table see Section 39.15.3, "Insert Cell Mode." 0 I reside on the coherent system bus. 1 reside on the secondary bus.
	8	**AVCF**	Auto VC off. APC Mode- 0 - The RISC doesn't remove this connection automatically, upon overwritten condition (when the serial number of the transmitter is smaller the actual serial number in the cell's COV). Instead this connection continues to transmit regularly by adopting the serial number of the COV, which is done by the RISC. 1 - The RISC remove this connection automatically by setting STPT, upon overwritten condition. FIFO Mode - 0 - The same as for APC mode. 1 - The RISC doesn't remove automatically the Transmit connection upon overwritten condition. It is the CPU's responsibility to remove this connection from the Channel code list structure of the corresponding FIFO.
	9	**-**	Reserved. Set to zero.

Table 39-31. MTCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x00	10-11	**ATT**	ATM traffic type 00 Peak cell-rate pacing. The host must initialize PCR and the PCR fraction. Other traffic parameters are not used. 01 Peak and sustain cell rate pacing (VBR traffic). The APC performs a continuous-state leaky bucket algorithm (GCRA) to pace the channel-sustain cell rate. The host must initialize PCR, PCR fraction, SCR, SCR fraction, and BT (burst tolerance). 10 Peak and minimum cell rate pacing (UBR+ traffic). The host must initialize PCR, PCR fraction, MCR, MCR fraction, and MDA. If Scalable APC is enabled, then the user should allocate an additional 4-6 bytes (depend on the alignment) for the APC scheduling table. 11 Reserved.
	12	**-**	Reserved. Set to zero.
	13	**VCON**	Virtual channel is on. Only valid for APC Mode scheduling. Should be set by the host before it issues an ATM TRANSMIT command. When the host sets TCT[STPS] (stop transmit), the RISC deactivates this channel and clears VCON when the channel is next encountered in the APC scheduling table. The host can issue another ATM TRANSMIT command only after the RISC clears VCON.
	14-15	**INTQ**	Points to one of four interrupt queues.
0x02	0-1	**TCTM**	TCT Mode 00 This is a STCT used as a leaf node for APC shaping 01 This is a HTCT used for a root node of hierarchical shaping 10 This is a FTCT used for Fast FIFO shaping 11 This is a MTCT used for Multicast shaping
	2	**---**	Reserved. Initialized to zero.
	3-7	**MCIDN**	m/c ID number is a number representing the destination channel number (0-31). The RISC upon transmitting a cell resets the corresponding bit in the Multicast Members field in the COV area of the cell. For example MCIDN = 7 will reset bit 7 in the COV.
	8	**---**	Should be initialized to zero.
	9	**ADDCH**	Set by the core on adding a MTCT to the source linked list, only when MRCT[Receive Cell Serial Number] is not equal to zero. See Section 39.14.5, “On-Line Modification of the Multicast Destination Group” for more information.
	10	**FIFO MODE**	Multicast mode used for scheduling the transmitter- 0 - APC like 1- FIFO WFQ
	13-15	**AAL**	AAL type: 000 AAL0 Reassembly with no adaptation layer. 001 AAL1 ATM adaptation layer 1 protocol. 010 AAL5 ATM adaptation layer 5 protocol. 011 AAL3. 100 AAl2. 101 CES. 110 MSP-Multi ServIce Protocol - switched ATM cells.
0x04		**MQPTR**	Multicast queue pointer (32 bits): Points to the next cell to be transmitted from the multicast source queue. Initialized by the user.
0x08		**Transmit Serial no.**	Transmit serial number. Should be initialized to zero.

Table 39-31. MTCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x0C	0–7	**Rate Remainder**	Rate remainder. Used by the APC to hold the rate remainder after adding the pace fraction to the additive channel rate. Initialize to 0. Valid only on APC mode operation.
	8–15	**PCR Fraction**	Peak cell rate fraction. Holds the peak cell rate fraction of this channel in units of 1/256 slot.Valid only on APC mode operation.
0x0E	—	**PCR**	Peak cell rate. Holds the peak cell rate (in units of APC slots) permitted for this channel according to the traffic contract. Valid only on APC mode operation.
0x10	—	**CLP0 Count**	CLP0 cell count. Initialize to 0.
0x14	—	**CLP1 Count**	CLP1 cell count. Initialize to 0.
0x16	—	**APCLC**	APC Linked Channel. Used by RISC. Initialize to zero.Valid only on APC mode operation.
0x18	0-11	**TVPI**	Transmit VPI. Replaces VPI of cell if CVP bit is set (including GFC bits if CGFC is set)
	12-15	**TVCI**	Most significant bits of Transmit VCI. Replaces VCI of cell if CVC bit is set
0x1A	0-11	**TVCI**	Least significant bits of Transmit VCI. Replaces VCI of cell if CVC bit is set
	12	**Reserved**	Reserved. Initialize to zero.
	13-15	**CVP/CVC/CGFC**	CVP/CVC/CGFC (address translation) 000 no translation 001 NOT valid 010 Change VCI Portion of ATM address 011 NOT valid 100 Change VPI Portion of ATM address (including GFC) 101 Change VPI Portion of ATM address (NOT including GFC) 110 Change VCI & VPI Portion of ATM address (including GFC) 111 Change VCI & VPI Portion of ATM address (NOT including GFC)
0x1C	0-1	**-**	Reserved. Set to zero
	2-7	**PMT**	Performance monitoring Table Index. One of 64 performance monitoring parameter tables is chosen for this channel
	8-15	**-**	Reserved. Set to zero

Table 39-31. MTCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x1E	0	**INS_CELL_ Flag**	Insert Cell Flag. Initialized to 0. Set by the RISC when insert cell host command is performed by the user, for inserting a cell to this connection. Reset by the RISC on completion of the inserted cell operation. See Section 39.15.3, "Insert Cell Mode." The CPU can only read this status bit in order to verify that the inserted cell was actually transmitted for this channel. Only after this bit was cleared another insert cell host command for this channel could be issued.
	1-11	**-**	Reserved. Set to zero
	12	**MCETIE**	MCET interrupt enabled.
	13	**STPT**	Stop transmit. Initialize to 0. When the host sets this bit, the RISC deactivates this channel and clears TCT[VCON] when the channel is next encountered in the APC scheduling table. This bit should not be used in switch mode (other than debug purposes). Host command Stop Rx should be used instead (so remaining cells are transmitted). The RISC reads 32 bytes of TCT, but writes back only 24 bytes. Therefore this bit is not altered by the RISC. Valid only for APC mode of operation.
	14	**CLPIE**	CLP0C Counter or CLP1C Counter overflow Interrupt Enable
	15	**PME**	Performance monitoring Enable 0 No performance monitoring on this channel 1 Performance monitoring is enabled on this channel

39.15 OAM Support

39.15.1 Receive Raw Cell Queue

Each UCC has a raw cell queue designated for OAM handling. This queue is managed by a designated ATM Channel per UCC (RCT) which is called the raw cell queue. The user should program this channel to operate in AAL0 mode. This channel's parameters are pointed by **OAM CH RCT PTR** which resides in parameter page of each UCC. In switch mode the receive raw cell queue is used for removing management cells from the regular cells flow to the host. When a management cell is sent to the receive raw cell queue, the RISC sets OAM in the RxBD. Cell Filtering

Cell filtering is done according to the programming in the cell's associated RCT which depends on the switch function (End Point, Segment Point, Transparent point).

As shown in Figure 39-50, the main cell stream of a certain PHY is divided to several cell streams (Several VPC's, VCC's or combination of both).

The filtering may be done at the F4 level (Filtering of cells from the VPC's cell stream) or at the F5 level (Filtering of cells from the VCC's cell stream).

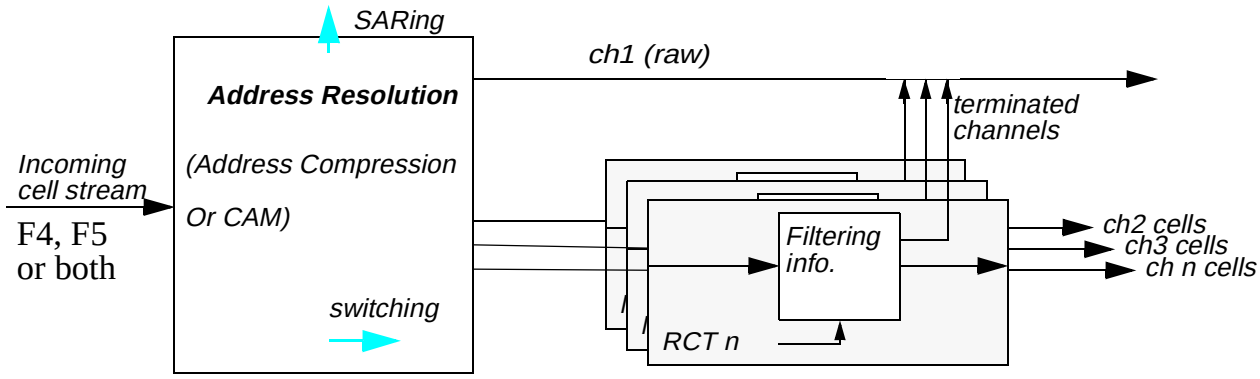

Figure 39-50. Management Cell Filtering

According to the cell's header and the required type of filtering, it will either be redirected to the raw cell queue (This action is called termination) or it will continue with the regular cell flow.

OAM cells are sent to the RAW Cell Queue if their associated RCT[SEGT], RCT[ENDT] and RCT[VPC] match the information extracted from the cell's header i.e whether it's an End Point OAM cell, Segment Point OAM cell and the switching level (F4 or F5).

Reserved VCI (6,7-15) are sent to the raw cell queue if the associated VCI bit in the VCI_Filtering entry in the parameter ram is set.

Following is a table that summarizes all the filtering options.

The first four entries are for VCC channels, the latter four are for VPC channels. Error cells are cells that should not have been received. The OAMERR bit is set in the extra header of those cells, and they are forwarded to the CPU.

Table 39-32. Cell Filtering Options

RCT[VPC]	RCT[SEGT]	RCT[ENDT]	F4 Segment (VCI=3)	F4 End-toEnd (VCI=4)	F5 Segment (PTI=100)	F5 End-toEnd (PTI=101)
0	0	0	Forward to CPU (OAMERR)	Forward to CPU (OAMERR)	Forward to Switch	Forward to Switch
0	0	1	Forward to CPU (OAMERR)	Forward to CPU (OAMERR)	Forward to CPU (OAMERR)	Forward to CPU
0	1	0	Forward to CPU (OAMERR)	Forward to CPU (OAMERR)	Forward to CPU	Forward to Switch
0	1	1	Forward to CPU (OAMERR)	Forward to CPU (OAMERR)	Forward to CPU	Forward to CPU
1	0	0	Forward to Switch	Forward to Switch	Forward to Switch	Forward to Switch

Table 39-32. Cell Filtering Options (continued)

RCT[VPC]	RCT[SEGT]	RCT[ENDT]	F4 Segment (VCI=3)	F4 End-toEnd (VCI=4)	F5 Segment (PTI=100)	F5 End-toEnd (PTI=101)
1	0	1	Forward to CPU (OAMERR)	Forward to CPU	Forward to Switch	Forward to Switch
1	1	0	Forward to CPU	Forward to Switch	Forward to Switch	Forward to Switch
1	1	1	Forward to CPU	Forward to CPU	Forward to Switch	Forward to Switch

1. Cells marked with OAMERR in the extra header are sent to the CPU. Those cells should not have been received in the first place

39.15.2 Performance monitoring (PM)

See Section 32.2.4, “Performance Monitoring.”

39.15.3 Insert Cell Mode

The user may require OAM cells to run in-band, i.e., shaped like the data stream they are part of. MSP features an “Insert Cell” mode, which enables the host to insert cells into APC or FIFO shaped channels on transmission.

An Insert Cell pointers Table was defined, see Figure 39-51. This Table contains one entry for each Channel Code in the system, and is located in internal RAM for the first 256 channels, or in external RAM, for channels codes which are bigger than or equal to 256. INT_INS_CELL_BASE and EXT_INS_CELL_BASE parameters were defined in the MSP Extended Parameter RAM. The user should always allocate at least one entry at INT_INS_CELL_BASE (associated with channel 0). This entry size should match the size as determined by the INS_CELL_Header_LOC parameter in the MSP Extended Page. Each Table entry consists of four bytes length pointer to the Insert Cell Template, and optionally another four bytes for the new cell header which will replace the existing cell header in the cell template. This could be useful for saving memory resources, and avoiding duplication of cells in memory when the difference between the Insert Cell templates of different VCs is limited to the cell header itself. The length of this entry is determined by the INS_CELL_Header_LOC parameter in the MSP Extended Page.

The Insert Cell pointer, or the cell template, should be aligned to 64 bytes, and could be an internal RAM address. Since there is a requirement for alignment of the cell address in memory, the 6LSB are available for usage. Setting the LSB to 1 implies [INS_CELL_LOC]=1 and therefore the cell address is on the external memory, if [INS_CELL_LOC] is cleared the cell address is in multi-user RAM. Setting the bit [CR10] in this entry means that CRC10 insertion is enabled. See Figure 39-52” for description. The size of the cell template is 52 bytes (HEC isn’t included), unless stated that a UDH mode is on, by the TUDC bit and TEHS field in the FPSMR register.

The user should prepare the cell including user-defined cell header (if exist) in a continuous manner so that the UDC comes first containing 12 bytes (no matter what is the number indicated in the FPSMR[TEHS] parameter), then the cell header containing 4 bytes (this header should be located even if INS_CELL_Header_LOC parameter is enabled), and the payload 48 bytes. If UDC is not enabled, then

the Cell header comes immediately at the beginning of the template. See Figure 39-51 for more details. Note that if the cell template is internal, then all the cell fields, i.e. UDH (if exist), header and payload, should be placed byte swapped (each 4 bytes should be swapped) to assure proper transmission. If the template is external, then the cell is located normally in Big Endian manner.

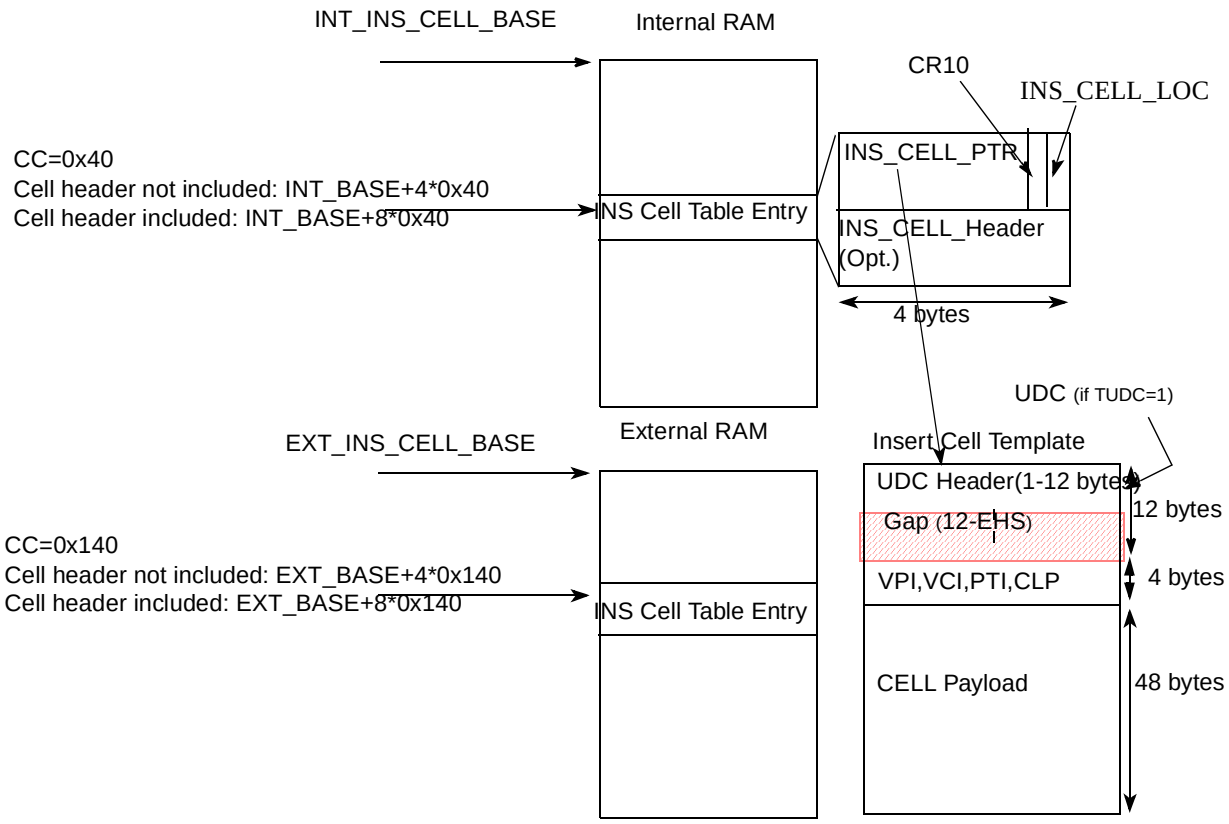

Figure 39-51. Insert Cell Table Description

The user inserts cell into a specific channel code using an host command, see Section 39.20.2, "MSP Insert Cell Command." The RISC set the INS_CELL_Flag bit in the corresponding xTCT(STCT, FTCT or MTCT), and also perform additional tasks in order to validate that the channel is valid in the APC table or in the FIFO. After transmitting the cell, the RISC clears this bit, so the user could resend another cell for this channel.

The user should monitor the INS_CELL_Flag bit after issuing the insert cell command, and only after it is cleared, a new insert cell command for this channel could be issued.

Notice that the xTCT should already be assigned to a specific SRCT or MRCT, as for normal MSP switch operation. The host command verifies that for STCT the channel will be rescheduled into the APC (since the AVCON/AVCOF mechanism), and for FTCT the channel would be entered into the FIFO list as there was a "dummy" receive operation.

Figure 39-52 shows the layout of the INS_CELL_PTR entry.

Field	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
00	Address (high)															
02	Address (Low)														**CR10**	**INS_CELL_LOC**
04	**Optional** Cell Header (VPI,VCI,PTI,CLP)															
06																

Figure 39-52. INS_CELL_PTR Entry

Table 39-33. INS_CELL_PTR Entry Description

Offset	Name	bits	Description
0x00	Address (High)	0-15	Inserted cell template address high.
0x02	Address (Low)	0-13	Inserted cell template address low.
	CR10	14	CRC-10 0 - CRC10 insertion is disabled. 1 - CRC10 insertion is enabled.
	INS_CELL_LOC	15	Inserted cell location 0 - Cell resides in multi-user RAM. Address high should be cleared. 1 - Cell resided in external memory.
0x04	Cell Header	Word	Cell header. Optional entry that depends on INS_CELL_Header_LOC parameter in the MSP Extended Page.

39.16 Global Mode Entry (GMODE)

See Global mode entry in Section 32.3.2.5, “Global Mode Entry (GMODE).”

39.17 ATM Parameter RAM Map

See more description in Table 32-18, “Sub-page0 Configuration Table.”

39.18 MSP Extended parameter RAM page

See description in Table , “Subpage1 Configuration Table”

39.18.1 FIFO Status Entry

FIFO Status Entry is shown in Figure 39-53.

Bit	0	1	2	3	4	5	6	7
Field	FS0	FS1	FS2	FS3	FS4	FS5	FS6	FS7

Figure 39-53. FIFO Status (FS) Entry

Table 39-34 describes the operation FIFO status bits.

Table 39-34. FIFO Status Entry

Bits	Name	Description
0-7	**FSi**	FIFO Status. Bit 7 for FIFO 7, bit 6 for FIFO6 ... bit 0 for FIFO0. For each FIFO, if its respective FS bit is set, the FIFO has cells queued in it; if the bit is reset, the FIFO is empty. If all bits in FS are reset, this HTCT has no cells in its lower hierarchy to be transmitted. Initialize to zero. The CPU does not access these bits during the operation of the MSP.

Each hierarchical connection has a FIFO Status entry associated with it. The location of this entry is located FSOff from FS_BASE in the multi-user RAM (FSOff is specified in the HTCT and in SRCT). The RISC updates the FS Status Entry.

39.18.2 FIFO Descriptor Pointers Table

The FIFO descriptor Pointers Table contains up to 128 entries used only for each PHY configured to FIFO mode (GMODE[MSP]=1 and Scheduler Parameter Table[AFM]=0). The FDT Pointer Table base address is pointed by the FDTP_BASE in the MSP parameter ram. The first entry is associated with PHY0, and the last entry with PHY 128. In this mode, the scheduling is done with WFQ. Each entry is 8 bytes long. A space of 1024 bytes is allocated for this table.

Only PHYs configured for FIFO mode (multicast or unicast) in the transmitter UCC side, have a valid entry in their respective location in this table.

Table 39-35 is described below:

Table 39-35. FIFO Descriptor Pointer Table

Address	Name	Width	Description
FDTP_BASE+ 0x00	FDTPTR0	Hword	Pointer to the first FIFO Descriptor Table entry (FDT) for PHY0.
FDTP_BASE+0x02	WFTMIN0	Hword	Used by RISC initialize to zero.
FDTP_BASE+0x04	res		
FDTP_BASE+0x06	APC_PARAM_PTR0		(APCP_BASE + 128*phy #0) This is the address of the Scheduler parameter table designated for FIFO mode to which this FDP correspond.
FDTP_BASE+ 0x00+8*i	FDTPTRi	Hword	Pointer to first FIFO Descriptor Table entry (FDT) for PHYi.

Table 39-35. FIFO Descriptor Pointer Table (continued)

Address	Name	Width	Description
FDTP_BASE+0x02+8*i	WFTMINi	Hword	Used by RISC initialize to zero.
FDTP_BASE+0x04+8*i	res		
FDTP_BASE+0x06+8*i	APC_PARAM_PTRi[1]		(APCP_BASE + 128*phy #i) This is the address of the Scheduler parameter table designated for FIFO mode to which this FDP correspond.
FDTP_BASE+ 0x3F8	FDTPTR127	Hword	Pointer to first FIFO Descriptor Table entry (FDT) for PHY128.
FDTP_BASE+0x3fa	WFTMIN127	Hword	Used by RISC initialize to zero.
FDTP_BASE+0x3fc	res		
FDTP_BASE+0x3fe	APC_PARAM_PTR127		(APCP_BASE + 128*phy #31) This is the address of the Scheduler parameter table designated for FIFO mode to which this FDP correspond.

1 "i" refers to PHY number

39.19 MSP Exceptions

The MSP interrupt handling involves two principal data structures, UCCEs (UCC event registers) and circular interrupt queues.

Four priority interrupt queues are available. By programming RCT[INTQ] and TCT[INTQ], the user determines which queue receives the interrupt.

After an interrupt request, the host reads UCCE. If UCCE[GINT*x*] = 1, at least one entry was added to one of the interrupt queues. After clearing GINT, the host starts processing the interrupt queue and clears this entry's valid bit. See Section 39.19.2, "Interrupt Queue Entry in MSP mode." The host follows this procedure until it reaches an entry with V = 0.

The host controls the number of interrupts send to the CPU by programming the interrupt queues counters. When an event is sent to an interrupt queue, a counter is decremented. When a counter reaches zero, an UCCE[GINT*x*] is set. The counter should be user-initialized to INT_ICNT.

39.19.1 Interrupt Queues

See Interrupt queues description in Section 32.3.13.2, "Interrupt Queues."

39.19.2 Interrupt Queue Entry in MSP mode

Figure 39-54 shows an interrupt queue entry.

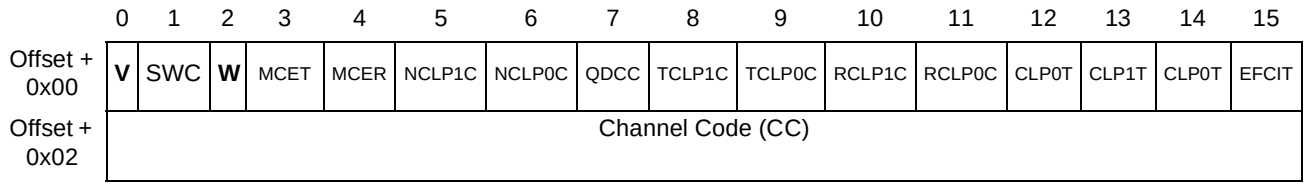

Figure 39-54. Interrupt Queue Entry

Table 39-36 describes interrupt queue entry fields if SWC=1.

Table 39-36. Interrupt Queue Entry Field Description

Offset	Bits	Name	Description
0x00	0	**V**	Valid interrupt entry 0 This interrupt queue entry is free and can be use by the RISC. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	SWC	0 This interrupt queue entry is associated with SAR interrupt. 1 This interrupt queue entry is associated with Switch interrupt.
	2	**W**	Wrap bit. When set, this is the last interrupt circular table entry. During initialization, the HOST must clear all W bits in the table except the last one, which must be set.
	3	MCET	Multicast Transmitter Error. Multicast destination Channel serial number does not match. The current cell has been overwritten by the receiver.
	4	MCER	Multicast Receive Error. Receive Channel has overwritten one or more Tx destinations channel cell. Also for FIFO Multicast mode, this bit together with EFCI bit indicates FIFO Disable interrupt.
	5	NCLP1C	NCLP1 Policing Counter Overflow
	6	NCLP0C	NCLP0 Policing Counter Overflow
	7	QDCC	Queue Dropped Cell Counter Overflow
	8	TCLP1C	Transmitter CLP1 Billing Counter Overflow
	9	TCLP0C	Transmitter CLP0 Billing Counter Overflow.
	10	RCLP1C	Receiver CLP1 Billing Counter Overflow
	11	RCLP0C	Receiver CLP0 Billing Counter Overflow.
	12	CLP01T	CLP01 Threshold violation. Bit is set when a cell is dropped due to Threshold violation.
	13	CLP1T	CLP1 threshold violation. Bit is set when a cell is dropped due to Threshold violation.
	14	CLP0T	CLP0 threshold violation. Bit is set when a cell is dropped due to Threshold violation.
	15	EFCI T	EFCI threshold violation. Bit is set when a the PTI bit in a cell was set due to crossing of this threshold. Also for FIFO Multicast mode, this bit together with MCER bit indicates FIFO Disable interrupt.

39.19.3 ATM Event Register (UCCE)/Mask Register (UCCM)

The UCCE register is the ATM controller event register when the UCC operates in ATM mode. When it recognizes an event, the ATM controller sets the corresponding UCCE bit. Interrupts generated by this register can be masked in UCCM. UCCE is memory-mapped and can be read at any time. Bits are cleared by writing ones to them; writing zeros has no effect. Unmasked bits must be cleared before the RISC clears the internal interrupt request.

UCCM is the ATM controller mask register. It is a 16-bit read/write register with the same bit format as UCCE. If an UCCM bit is set, the corresponding interrupt is enabled in UCCE. If it is cleared, the corresponding interrupt is masked. UCCM is cleared at reset.

Bit	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	—				FCPI	TIRU	GRLI	GBPB	GINT3	GINT2	GINT1	GINT0	INTO3	INTO2	INTO1	INTO0
Reset	0000_0000_0000_0000															
R/W	R/W															
Address	0x11310 (UCCE1), 0x11330 (UCCE2), 0x11350 (UCCE3)/ 0x11314 (UCCM1), 0x11334 (UCCM2), 0x11354 (UCCM3)															

Figure 39-55. ATM Event Register (UCCE)/UCC Mask Register (UCCM)

Table 39-37 describes UCCE fields.

Table 39-37. UCCE/UCCM Field Descriptions

Bit	Name	Description
0–3	—	Reserved, should be cleared.
4	FCPI	Free Cell Pool Interrupt. An interrupt related to the free cell pool has occurred.
5	TIRU	Transmit internal rate underrun. A transmit internal rate counter expired and a cell was not sent because the transmit FIFO was empty. TIRU may be set only when using transmit internal rate mode.
6	GRLI	SAR events
7	GBPB	SAR events
8–11	GINT*x*	Global interrupt. Set when an event is sent to the corresponding interrupt queue.
12–15	INTO*x*	Interrupt queue overflow. Set when an overflow condition occurs in the corresponding interrupt queue. This occurs when the RISC attempts to overwrite a valid interrupt entry.

39.20 MSP Host Commands

39.20.1 MSP FCP Commands

See Section 20.3.1, “QUICC Engine Command Register (CECR) for CECR programming description CECR to MSP host commands.

Before issuing the FCP (GET/PUT) command, the user should initialize COMM_INFO fields in the subpage0 configuration parameter RAM as described in Figure 39-56.

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0x12	—					FCPN	—									BIB
0x14	FCP_ADDRESS															
0x16																

Figure 39-56. COMM_INFO Field

Table 39-38 describes COMM_INFO fields

Table 39-38. COMM_INFO Field Descriptions

Offset*	Bit	Name	Description
0x12	0–4	-	n/a
	5	FCPN	Free Cell Pool number. Used only for Free Cell Pool Host commands. 0 - Free Cell Pool 1 1 - Free Cell Pool 2 * This FCP value must be the same as the FCP value in the TCT or RCT that related to the host command.
	6–14	—	n/a
	15	BIB	Interrupt queues and UPCT bus 0 reside on the coherent system bus. 1 reside on the secondary bus. *This Field must be the same as the BDB field in The RCT /TCT that related to the Host command.
0x14 - 0x16	0–31	FCP_ADDRESS	FCP address - The 32 bits word of the returned cell pointer during CP_GET command or the 32 bits word address given by the host to be returned to the selected FCP.

Note: *Offset from Global ATM Parameters Table pointer (See Table 32-18)

Table specifies the commands supported by the MSP:

Table 39-39. Command Code Description

Command Code value	Command Name	Description
0x00	**Start TX**	This command turns a passive channel into an active channel by scheduling it into the APC table. This command should only be used for VCs that are SARed. This command should not be used during normal operation of a switched VC (SRCT-STCT) with automatic scheduling where the transmitter is automatically activated by the switch when a cell for a given VC is received. This command is still applicable to other APC modes: - Unicast mode (SRCT-STCT) with non-auto scheduling. - Hierarchical mode (HTCT). - Multicast mode (MRCT-MTCT).
Performed by the CPU	**Stop TX**	Deactivated channel, by not rescheduling the channel in the APC. Performed by the RISC.U by setting STPT bit in TCT.
Performed by the CPU	**Stop RX**	Performed by the CPU by resetting the Match-Successful (MS) bit in the address look-up table (either in the CAM or in the address compression table) of the receive channel. This command is useful in case there is a need to deactivate one receive channel, out of many channels aggregated into one transmit channel. The transmitter sends the remaining cells, and (assuming the APC is used) once they are all transmitted, the APC does not reschedule them (either because the STPT bit in the TCT is set by the CPU, or because the AVCF bit has been set at initialization). If there is no aggregation of multiple receive channels into one transmit channel, issuing a Stop RX command eventually results in halting switching of cells from channel-code from both the receive and the transmit This method also ensures that no cells with the transmit channel code remain in the memory.
0x01	**Insert Cell**	Insert Cell command. The insert cell command set the corresponding INS_CELL_Flag in the xTCT. This command also make sure that the corresponding xTCT will be valid in the APC table or in the FIFO, depending on the mode selected. For STCT mode which is using AVCON/AVCOFF mechanism, the activation of a channel in the APC is done by checking the TL=0, QCC=0 field in the STCT. For fifo mode, the FTCT is entered into the FIFO as there was a “dummy” receive operation of the SRCT that is normally used to be switched to this specific FTCT. The user should monitor the INS_CELL_Flag bit after issuing the insert cell command, and only after it is cleared, a new insert cell command for this channel could be issued.
0x02	**CP_GET**	Cell Pool GET command fetches a cell pointer out of the pool (The Pool number determined by COMM_INFO[FCPN] bit) and return it’s 32 bit address in COMM_INFO[FCP_ADDRESS_H] and COMM_INFO[FCP_ADDRESS_L] fields. The User will use the returned address to configure the relevant parameters according to the MSP mode of operation.
0x03	**CP_PUT**	Cell Pool PUT command puts the cell pointer which it’s specified in the COMM_INFO[FCP_ADDRESS_H] and COMM_INFO[FCP_ADDRESS_L back to the specified Pool (The Pool number determined by COMM_INFO[FCPN] bit). The user will use this command to return a cell to a Pool after the ATM channel is deactivated.

NOTE: Entries in boldface must be initialized by the user.

39.20.2 MSP Insert Cell Command

The Insert cell command is issued just like UCC ATM transmit command, see Section 39.20.1, “MSP FCP Commands,” with the CECR[SCB[page]] field set to the page in which the desired xTCT (the xTCT that belongs to the inserted cell) resides in.

39.20.2.1 Insert Cell in STCT Mode

The COMM_INFO fields for STCT mode should be initialized in the parameter RAM as described in Figure 39-57.

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0x12	-						GCRA Sched_ AVCON	AVCON						MSP MODE		
0x14	Insert Cell Channel Code															
0x16	TAPTR/ GCRA Scheduler PHY Parameter Table ptr															

Figure 39-57. COMM_INFO Field for STCT Mode

Table 39-40 describes COMM_INFO fields for STCT

Table 39-40. COMM_INFO Field Descriptions for STCT Mode

Offset	Bit	Name	Description
0x12	0–5	-	n/a
	6	GCRA Sched_AVCON	DRR APC AVCON. Valid only if AVCON bit is set. Indicates which type of APC is used to activate the channel. 0 - Traditional APC. 1 - GCRA Scheduler.
	7	AVCON	Auto VC ON (should be copied from the corresponding SRCT). If set the STCT is scheduled into the APC if STCT[QCC]=0 and STCT[TL]=0.
	13-15	MSP Mode	MSP Mode 000 - STCT 001 - Hierarchical FIFO 010 - WFQ FIFO 011 - MCST APC 100 - MCST FIFO (Non auto FE) 101 - MCST FIFO Auto FE mode 110 - res 111 - res
0x14	—	InsertCell Channel Code	Transmitter channel code of the insert cell.

Table 39-40. COMM_INFO Field Descriptions for STCT Mode (continued)

Offset	Bit	Name	Description
0x16	0-15	**TAPTR**	Valid only if AVCON mode is enabled. **Traditional APC mode:** TAPTR: Transmitter APC Pointer. This entry is the pointer to the APC priority Table entry in multi-user RAM. This is used by the RISC to automatically add a connection to the APC (if it was previously removed since its queue was empty). **GCRA Scheduler mode:** 14 most significant bits of the pointer to the GCRA Scheduler PHY Parameter Table.
	0-13	**GCRA Scheduler PHY Parameter Table ptr**	
	14-15	**PRI**	GCRA Scheduler Priority.

NOTE: Entries in boldface must be initialized by the user.

39.20.2.2 Insert Cell in Hierarchical and WFQ FIFO Modes

The COMM_INFO fields for Hierarchical and WFQ FIFO modes should be initialized in the parameter RAM as described in Figure 39-58.

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0x12	**-**													**MSP MODE**		
0x14	**RCT CC**															
0x16	**SRCT_TMP**															

Figure 39-58. COMM_INFO Field for FTCT/HTCT Mode

Notice that the user should allocate additional 8 bytes in Ram, see INS_CELL_RCELL_TMP parameter in Section 39.18, “MSP Extended parameter RAM page.” This parameter should be defined in the same page as CECR[SCB[page]] host command field indicates. Also notice that for both Hierarchical and WFQ FIFO modes the INS_CELL_Flag bit is set in the FTCT.

NOTE

The insert cell command for Hierarchical mode is valid for both modes of operations: HTCT AVCON/AVCF mode and Non HTCT AVCON/AVCF mode.

Table 39-41 describes COMM_INFO fields for STCT

Table 39-41. COMM_INFO Field Descriptions for STCT Mode

Offset	Bit	Name	Description
0x12	0-12	-	res.
	13-15	**MSP Mode**	MSP Mode 000 - STCT 001 - Hierarchical FIFO 010 - WFQ FIFO 011 - MCST APC 100 - MCST FIFO (Non auto FE) 101 - MCST FIFO Auto FE mode 110 - res 111 - res
0x14	—	**RCT CC**	RCT Channel Code. Consist the Receiver Channel code that is normally switched to the FTCT in which we want to insert the cell.
0x16	-	**SRCT_TMP**	SRCT temporary pointer. Allocates 32 bytes in RAM (should be 32 bytes aligned). This area should be Initialized to 0.

NOTE: Entries in boldface must be initialized by the user.

39.20.2.3 Insert Cell in MCST Auto FE Mode

The COMM_INFO fields for STCT mode should be initialized in the parameter RAM as described in Figure 39-59.

Offset	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Chapter 40
L2 Ethernet Switch

40.1 Overview

The L2 Ethernet switch in the QUICC Engine block offers up to eight connection ports of 10/100 Mbps with MII/RMII Ethernet external ports and one CPU internal port. In addition, the switch also provides VLAN functionality, IGMP snooping, store-and-forward switching operation, and packet-error filtering.

Each port in the switch supports 4 priority levels; the priority is determined either by the VLAN tag priority or the IP TOS field in the frame header. In this way, quality of service (QoS) is provided for different types of traffic, such as voice, video, and data.

The L2 microcode-based Ethernet switch in the QUICC Engine block runs on top of the UCC when configured in Ethernet mode. It is possible to configure any number of UCCs (up to eight) as switch ports. Figure 40-1 depicts an example of a 8-port switch with eight UCCs dedicated to eight external switch ports and the ninth port as the CPU interface.

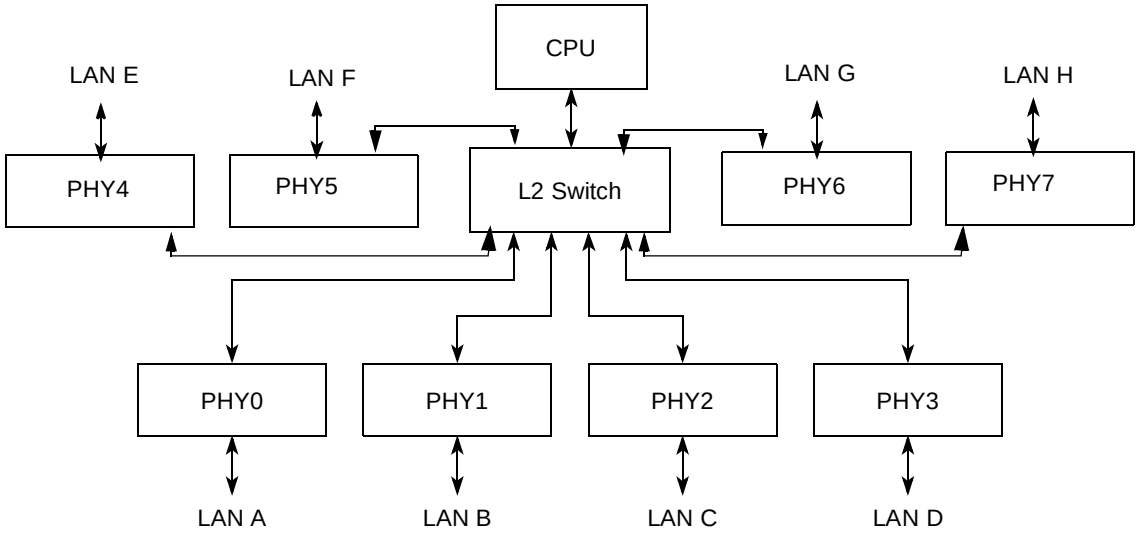

Figure 40-1. 8-Port Switch System

40.2 Features

The L2 switch supports the following features:

- L2 switch Ethernet controller
  - — Supports up to eight 10/100 Mbps full-/half-duplex Ethernet ports and one CPU internal port
  - — Independent MII/RMII interface for each port
  - — Serial management interface MDC/MDIO
- Internal and external memory
  - — External memory used as a packet storage buffer for up to 256 packets
  - — Multi-user RAM used for control structure and as a temporary packet storage buffer
  - — Size of multi-user RAM is programmable
  - — Internal address learning table (ADLT)
    - – Programmable table size
    - – Up to 2048 addresses using up to 16 Kbytes of multi-user RAM
    - – Self-learning mechanism
    - – Supports aging function
  - — Supports unicast/multicast/broadcast transmission
- VLAN
  - — Supports programmable number of virtual LANS (typically 64)
  - — Dynamic VLAN membership (per port or per VLAN ID)
  - — Tag insertion and extraction
  - — Supports tag-based priority (up to four priorities)
  - — Supports double VLAN tagging
- Flow control
  - — Supports flow control via IEEE 802.3 Pause packets for full duplex in case buffer is almost full
  - — Supports back pressure (collision mode) function for half duplex in case buffer is almost full
- Supports standard packet length for basic and VLAN modes. Programmable minimum and maximum frame length.
  - — Supports jumbo frames up to 9 Kbytes
- Statistical counters (RMON)
- Supports Ethernet II & 802.2 SNAP frames
- IGMP snooping
- QoS determined per port, tagged frame priority, IPv4’s type of service (TOS), IPv6’s traffic class (TC), or default priority
- Recognizes IEEE802.1D/802.1W/802.1S spanning tree protocol (BPDU packets) and forwards them to CPU
- Supports input port mirroring (for good frames)

40.3 Functional Overview

The following sections provide a functional overview of the L2 Ethernet switch in the QUICC Engine block.

40.3.1 Ethernet Ports

The L2 switch supports up to eight 10/100 BaseT Ethernet ports. These ports may be configured as half- or full-duplex. Each port includes a MAC, which is compliant with the IEEE 802.3 standard.

40.3.2 Frame Filtering

The L2 switch makes filtering decisions for each incoming packet based on its frame routing table, VLAN mapping, port state, and the system configuration. The switch may either forward the frame, if forwarding criteria are met, or discard it. All parameters are user-programmable. See Section 40.5, “Filtering Database,” for more details.

Incoming frames are discarded for the following situations:

- If an error such as a FCS error or short/long frame error is found in the incoming frame.
- If the destination port number is the same as the port on which the packet was received, unless the user enables this feature as described in Section 40.5.5, “Forwarding Frame Back to the Source Port.”
- If the source or destination port is disabled. (The port state can be changed according to the spanning tree protocol.)
- If the input buffer of the port is full. It is recommended that flow control be used to reduce the chance of packet loss.

40.3.3 Frame Forwarding

The switch forwards an incoming frame between its ports according to its destination address (DA). The switch uses a hash algorithm to learn the MAC address (source address, SA) and can learn up to 2K MAC addresses. The ADLT is stored in the internal multi-user RAM; the size of the table is programmable by the user. See Section 40.5.1, “Address Learning Table,” for more information.

The address lookup engine attempts to match the destination address with the addresses stored in the ADLT.

A unicast frame is forwarded to a destination port. If the destination port does not belong to the VLANs specified at the source port, the frame is discarded.

A multicast frame is forwarded to several destination ports according to the VLAN mapping and port state. See Section 40.5.3, “VLAN Destination Table (VDT),” for more details.

Frames with an unknown unicast or multicast destination are forwarded to all ports according to the default VLAN group.

40.3.4 Illegal Frames

The switch discards all the following illegal frames:

- Frames with a length smaller than the programmable minimum (typically 64 bytes),
- Frames with a length larger than the programmable maximum.
- Frames with a FCS error.
- Frame with line errors.

All of these frames are transmitted to the CPU in Error Debug mode.

40.3.5 FCS Checking

The FCS of received frames is checked for correctness. When a frame is transmitted, a new FCS is appended to account for any insertion or removal of a VLAN tag.

40.3.6 Address Aging

The address aging function supports the ability to automatically clear outdated entries in the ADLT. An aging timer is used to determine the aging time period. A learned source address (SA) is cleared if it is not updated by the address learning process during this aging time period. For security purposes, it is possible to disable the aging function on an entry basis.

40.3.7 IGMP Snooping

The L2 switch supports IGMP snooping. Without IGMP snooping, multicast traffic is forwarded to all ports, similar to broadcast traffic. With IGMP snooping, the multicast traffic of a group is only forwarded to ports that are members of that group. The IGMP snooping feature provides a significant reduction in multicast traffic through the switch.

40.3.8 Spanning Tree Protocol (BPDU Packets)

The switch recognizes bridge protocol data unit (BPDU) packets and sends them to the CPU for processing. The purpose of these packets is to provide path redundancy while preventing undesirable loops in the network. As a result of receiving BPDU packets, the CPU can disable ports to receive and transmit regular frame and/or BPDU packets.

40.3.9 Basic and Tag Modes

The L2 switch has the following two programmable modes of operation:

- Basic mode, which is used in a single LAN environment.
- Tagged mode, which is used for full VLAN support.

The switch supports a programmable number (typically 64) of different VLAN identifiers (VIDs) out of possible 4096 identifiers.

Each port of the switch can be assigned to one or multiple VIDs. Frames from the source port are forwarded to destination ports within the same VLAN domain. A broadcast/multicast frame is forwarded to all ports within the VIDs of the source port except the source port itself. A unicast frame is forwarded to the destination port only if the destination port is in the same VLAN as the source port. Otherwise, the frame is treated as a frame with an unknown DA. In basic mode, all ports belong to one undefined VID.

40.3.10 Flow Control

The L2 switch can operate at two different modes, half- and full duplex.

A pause frame is sent on a source port if that port exceeds a user-defined threshold value on the number of buffers currently used by that source port. Pause frames are transmitted on all ports if a user-defined global buffer usage threshold value is exceeded.

Back pressure is supported for half-duplex operation. When buffers of the switch are almost full, the switch transmits a JAM signal through the relevant ports. The remote station defers transmission after sensing the JAM signal.

In full-duplex mode, the switch transmits and receives frames in accordance to the 802.3x. In this mode, the transmission channel and the receiving channel operate independently. When buffers of the switch are almost full, the switch transmits a PAUSE frame with the maximum delay value. It also sends a new pause packet (with a pause period of 0x0000) to the transmitter to start sending new packets.

The transmission of a PAUSE frame reduces the chance of a packet loss.

40.3.11 Internal/External Memory

The L2 switch uses internal/external memory allocations for control structures (BDs, configuration parameters), packet buffering, the ADLT, and the VLAN table. The features of the internal/external memory allocations are listed as follows:

- The switch supports up to 256 packet buffers. The frame size is programmable. Jumbo frames are supported.
- The switch provides an on-chip ADLT with up to 2K entries for frame destination look-up.
- The switch provides an on-chip VID table and supports a programmable number (typically 64) of different VIDs out of a possible 4096 identifiers.

The overall multi-user RAM internal memory usage is programmable. See Section 40.9.1, “Internal Memory,” for details.

40.3.12 MII

The UCCs support the IEEE 802.3 media-independent interface (MII).

40.3.13 RMII

The UCCs provide a reduced media-independent interface (RMII) to the Ethernet MAC. The RMII interface is designed based on the standards and specifications that are documented in *Reduced MII Interface*, at AMD Inc., Broadcom Corp., National Semiconductor Corp., and Texas Instruments Inc.

The purpose of RMII is to provide a low-cost alternative to the IEEE802.3u MII interface (MII). Architecturally, the RMII is an additional reconciliation layer on either side of the MII. However, it can be implemented in the absence of a MII.

40.4 SWITCH Components

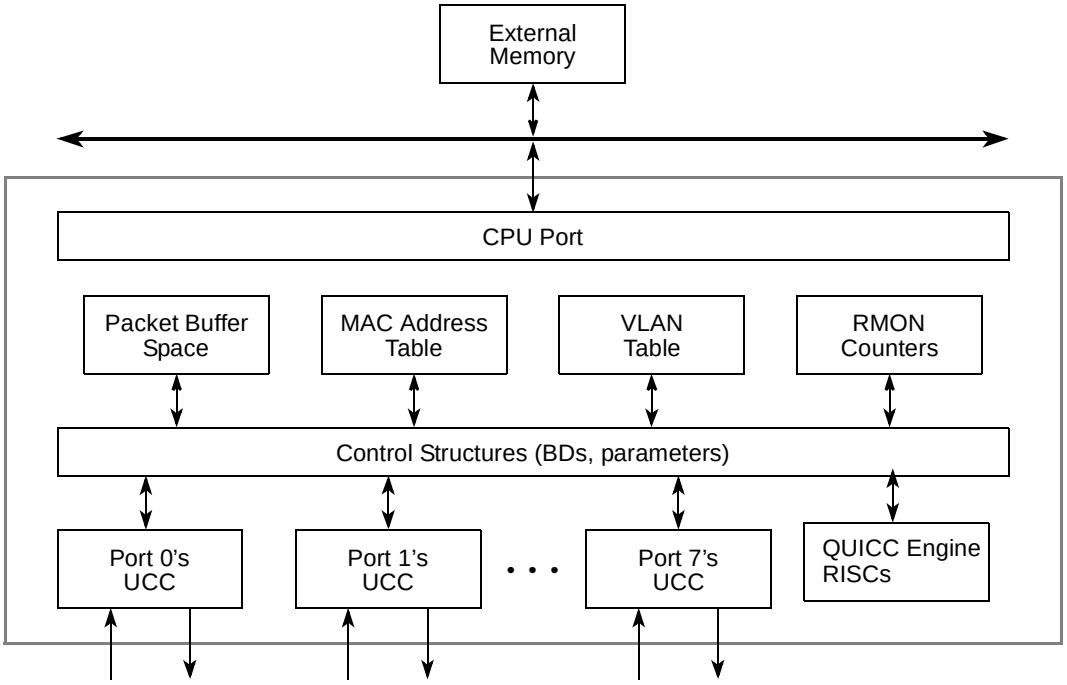

Figure 40-2. QUICC Engine Switch Components

40.4.1 Ingress Rule

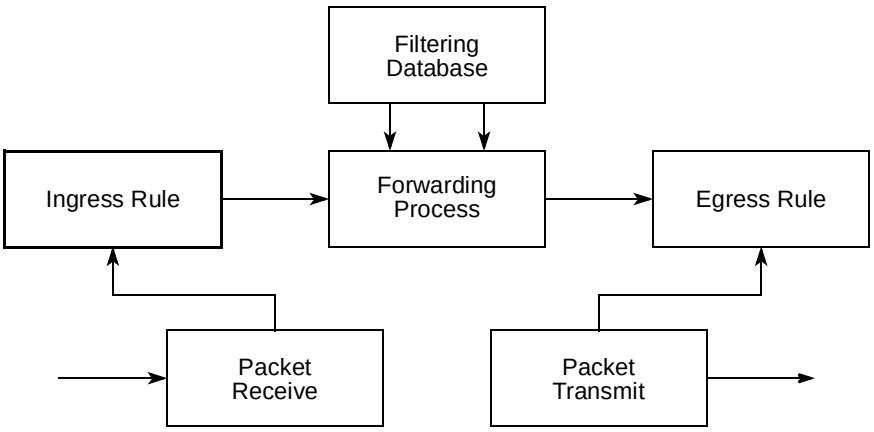

Figure 40-3. Switch Processing Flow

The purpose of the ingress rule is to define which frames are legal frames that can pass through the switch, and which are illegal and have to be either dropped or sent to the CPU for debugging.

The ingress rule is affected by the switch operation mode, e.g. basic or tag mode, and by the arriving frame, specifically the data or management frame.

Each port is capable of passing data or management (IGMP, BPDU, and flow control packets) tagged or untagged frames.

Figure 40-4 shows the Ethernet II / 802.3 / 802.2 SNAP frame formats.

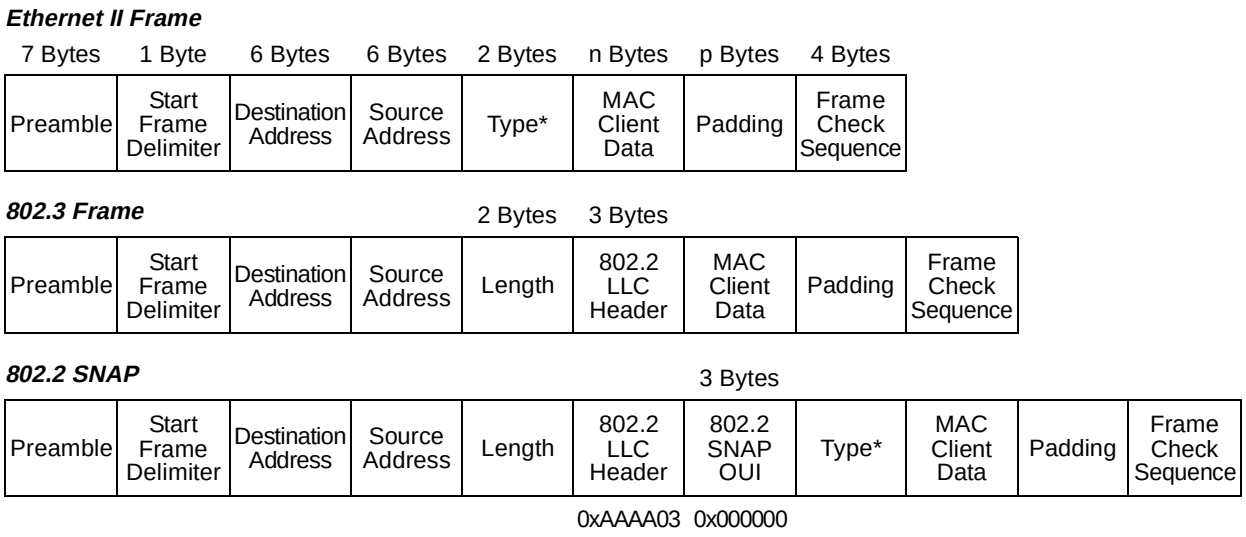

Figure 40-4. Ethernet II/802.3/802.2 SNAP Frame Formats

Figure 40-5 shows the basic and tag frame formats.

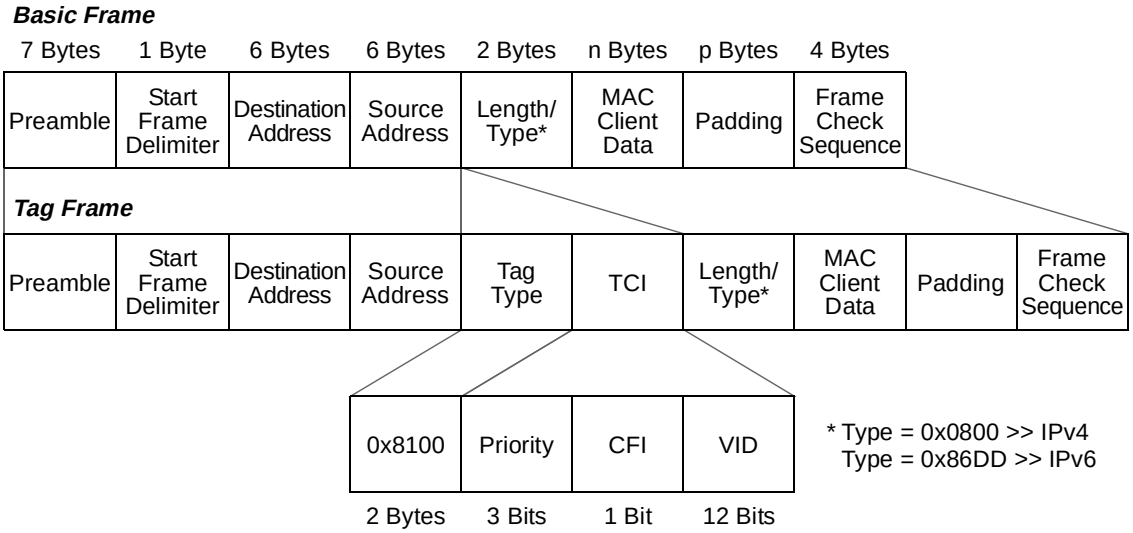

Figure 40-5. Basic/Tag Frame Formats

The L2 switch supports standard and jumbo frames with programmable length. See the MFLR field in Section 40.12.2, "Switch PRAM," for more details. Up to four priorities are supported out of a possible eight. The switch uses a priority table for mapping the original priority bits [2–0] to two priority bits. Section 40.13.3, "Priority Mapping Table (PMT)," provides more details.

40.4.2 IPv4 & IPv6 Frames (IP Multicast Support)

The L2 switch supports the IPv4 & IPv6 frame formats. It treats these frames as regular tagged/untagged frames with no priority, tag priority, or IP priority. IP priority includes a 6-bit priority field (TOS in IPv4 and TC in IPv6). The switch uses an IP priority mapping table to map the original priority bits [5–0] to two priority bits. See Section 40.13.4, "IP Priority Mapping Table (IPMT)," for more details. Table 40-1 shows the IPv4 & IPv6 header format.

Table 40-1. IPv4 & IPv6 Headers

Ver	IH	TOS	Total Length
Identification		Flags	Fragment
TTL		Protocol	Header Checksum
Source Address			
Destination Address			
Options			Padding

Ver	TC	Flow Label	
Payload Length		N Header	Hop Limit
Source Address			
Destination Address			

Field's name kept from IPv4 to IPv6
Fields not kept from/in IPv6
Name and position changed in IPv6
New field in IPv6

If IGMP snooping is enabled in the port, the switch assumes the header formats and can use them for multicast filtering. See Section 40.4.5, “IGMP Snooping” for more information.

40.4.3 Illegal Frames

The L2 switch either discards all illegal frames or sends them to the CPU for debugging. See the DM fields in Section 40.13.1, “Switch Parameters (SWPAR),” for details. Some examples of illegal frames are bad FCSs and short or long frames, smaller or larger than the programmable min/max frame lengths.

40.4.3.1 Tag Mode Ingress Rule

When an untagged frame is received on a port, the ingress process may drop the frame or add a default VID to it. See Section 40.7.2, “Tag Mode Switching,” for more information.

When a tagged frame is received on a port, the ingress process may deliver or drop the frame depending on the ingress VLAN destination table.

40.4.3.2 Management Frame

When an IGMP or BPDU frame arrives, the ingress process delivers it to the CPU for processing.

40.4.4 Default Tag

In tag mode, the L2 switch may add or replace the original tag with a default tag. Each port has its own default tag.

The default tag is used in the following situations:

- An untagged frame arrives
- A tagged frame arrives, and its VID is equal to zero
- A frame is in forced default tag mode

When a tag is inserted into an untagged frame, four bytes comprising the default tag are inserted immediately following the source address field. Refer to Figure 40-5 for the basic/tag frame format.

- The first byte is always 0x81.
- The second byte is always 0x00.
- The next three bits are the priority bits. They are copied from the default priority entry unless the frame is already tagged in which case its original priority bits remain.
- The next bit is always set to zero.
- The next twelve bits are the VID bits. These bits are copied from the default VID entry.

40.4.5 IGMP Snooping

The IGMP protocol is designed to specify membership of multicast groups. Using IGMP group memberships, the L2 switch can avoid flooding the network with multicast traffic by forwarding multicast packets only to specific ports according to which multicast group the packets are destined.

The L2 switch supports IGMP snooping. IGMP allows a host to inform the router that it wishes to receive packets addressed to a specific multicast group. These packets are always set to highest priority.

As the name implies, the switch snoops on the IGMP transmissions between the host and the router to keep track of multicast groups and member ports. A packet received on any of the eight ports is identified as an IGMP packet under all of the following situations:

- DA is multicast or broadcast.
- The type is IP (0x800 for IPv4 or 0x86DD for IPv6). See Figure 40-5 for the basic/tag frame format.
- {Protocol == IGMP (0x02)} / {Payload type (Next header) == 0x02}. See Table 40-1 for the IPv4 & IPv6 headers.

The switch-identified IGMP packet is delivered to the CPU for processing. The user can define more ports as destinations for these packets. See Section 40.13.1, "Switch Parameters (SWPAR)," for more information. However, these ports, including the CPU port, have to be members of the frame VID.

The CPU processes the IGMP frame and updates the GDA field details in the ADLT. See Section 40.5.1.4, "Group Destination Address (GDA)," for more information. This is done by using the command register; see Section 40.11.1, "Command Register," for details. The GDA field represents the actual port group for each multicast address.

40.4.6 Spanning Tree Protocol (STP)

The spanning tree protocol is a link-management protocol that provides path redundancy while preventing undesirable loops in the network. The IEEE 802.1D/802.1W/802.1S (STP/Rapid STP/Multiple STP), spanning tree is supported by the L2 switch using the CPU that runs this algorithm.

The example in Figure 40-6 shows a loop between three switches. When the spanning tree runs, one of the paths will be blocked automatically.

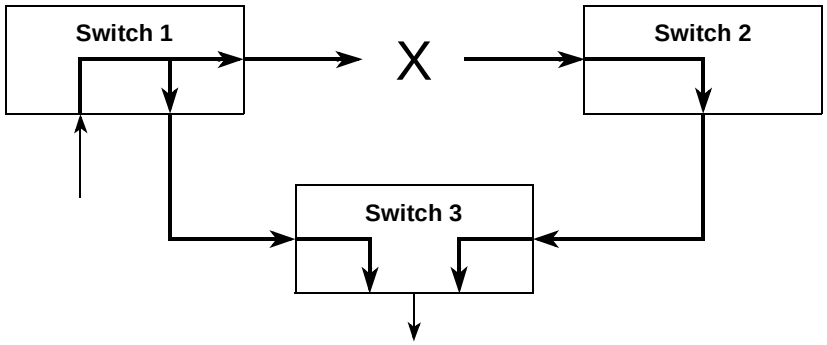

Figure 40-6. Example of Spanning Tree Preventing a Loop

The L2 switch supports the spanning tree protocol, which is recognized by the BPDU frames. It delivers these spanning tree frames to the CPU for processing and can change the state of the port (in case of STP/RSTP) or remove/add the port from/to any VLAN group (in case of MSTP). These packets are always set to highest priority.

A packet is recognized as spanning tree (BPDU frame) when the DA lies between 01-80-C2-00-00-00 and 01-80-C2-00-00-FF (with the exception of flow control pause packets, which use 01-80-C2-00-00-01).

The BPDU frame is delivered only to the CPU even though it is a multicast frame.

The BPDU indication, along with its source port, is supplied to the CPU by the Rx CPU buffer descriptor (RCBD). See Section 40.8.11.1, "Rx CPU BDs (RCBD)," for details.

As a result of these frames, the CPU may change the port's state. See Section 40.5.4, "Destination Port State Vector (DPSV)," and the PS field in Section 40.13.2, "Port Parameters (PPAR)," for more information.

40.4.6.1 Port State

The spanning tree protocol allows each port to work in one of the following states:

1. Forwarding — Regular operation (default mode). The port is open to all types of frames (incoming and outgoing). The ADLT is updated for any new good frame.
2. Disabled — The port is closed to all frames. The ADLT is not updated.
3. Blocking/Listening — The port is open (incoming and outgoing) only to BPDU frames. All other frames are dropped, and the ADLT is not updated.
4. Learning — The port is open (incoming and outgoing) only for BPDU frames. All other frames are dropped, but the ADLT is updated for new good frames.

NOTE

All of these states are relevant if spanning tree mode is enabled. If spanning tree mode is disabled, the L2 switch refers to the frames as regular multicast frames. See Section 40.13.1, "Switch Parameters (SWPAR)," for details.

40.4.7 Flow Control Packet

The switch recognizes the flow control packet (DA equal to 01-80-C2-00-00-01) and discards the packet after it is processed by the MAC control sublayer of the port. In Flow Control debug mode, the packet is sent to the CPU. See Section 40.3.10, "Flow Control," for more information.

40.4.8 Quality of Service (QoS)

The L2 switch supports up to four priority queues per port. The ingress rule can determine different priorities for each frame.

The following are the priority frame options:

- Error frames (in Error Debug mode), are always set to lowest priority.
- For a tagged frame with priority bits, the switch uses the priority table to map the original priority bits [2–0] to two priority bits. See Section 40.13.3, "Priority Mapping Table (PMT)," for details.
- An untagged frame gets a default priority per its source port. Each port has three default priority bits, and the switch treats them as if they have original frame priority. See Section 40.13.1, "Switch Parameters (SWPAR)," for more information.

- Unknown unicast destination addresses are always set to lowest priority.
- IGMP snooping and BPDU packets are always set to highest priority.
- The IPv4 and IPv6 packets have six priority bits (TOS[2–7] or TC[2–7]). The switch and the IP priority table map these six bits to two priority bits. See Section 40.13.4, “IP Priority Mapping Table (IPMT),” for more information.

NOTE

If the incoming frame is either tagged or is an IP frame, the user can choose which priority (IP or tag) needs to be used.

The lowest priority level is mapped from LOWEST_PR in Switch PRAM.

The highest priority level is mapped from the HIGHEST_PR in Switch PRAM.

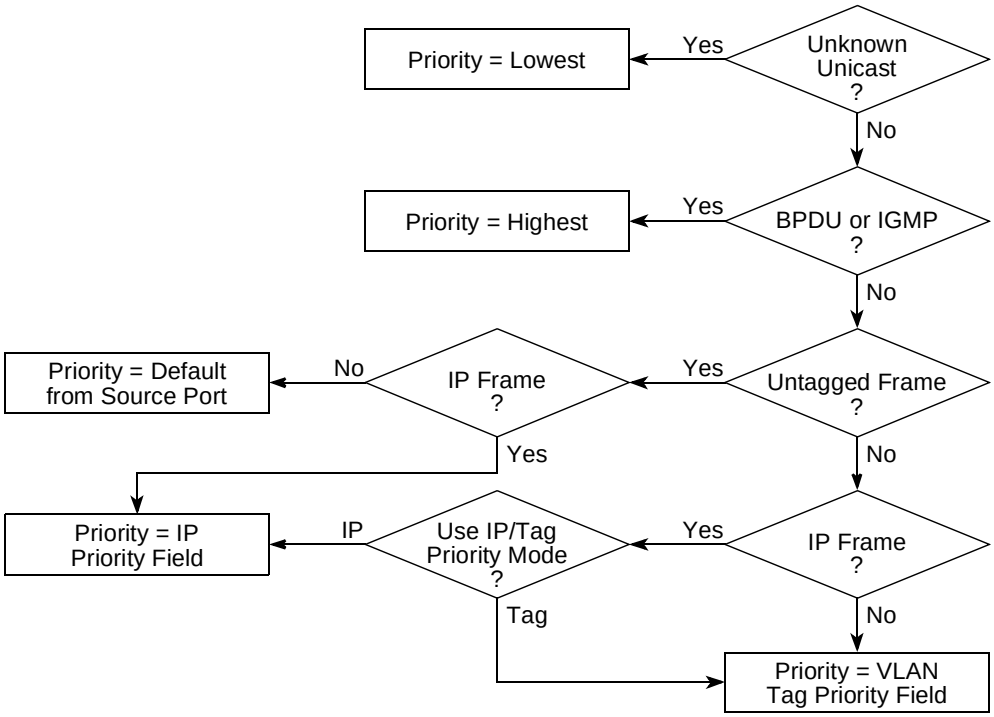

Figure 40-7. QoS Priority in Switch

40.4.9 Broadcast Storm Control

A broadcast storm occurs when message that has been broadcast across a network results in even more responses, and each response results in still more responses in a snowball effect. Errors in the network configuration can cause a storm.

In case of broadcast storm, the switch can block any port from receiving broadcast frames. The CPU can poll the RMON counters at intervals and if the rate of the broadcast traffic crosses a set threshold, disable the port receiving the broadcast. See BCD field in Section 40.13.2, “Port Parameters (PPAR).”

40.5 Filtering Database

The switch filtering database is an integral part of the switch. It is used by the switch to determine if a packet should be forwarded and which port it should be forwarded through.

The switch can apply multiple filtering databases when forwarding frames, with database choices programmed as part of the operating mode. The switch operation modes are as follows:

- Basic or tag mode. See Section 40.13.1, “Switch Parameters (SWPAR),” for information.
- IGMP snooping. See Section 40.13.2, “Port Parameters (PPAR),” for information.
- Spanning tree protocol. See Section 40.13.2, “Port Parameters (PPAR),” for information.

The switch filtering databases are as follows:

- Address learning table (ADLT) with Group destination address (GDA)
- Port designation table (PDT)
- VLAN destination table (VDT)
- Port state vector (PSV)

40.5.1 Address Learning Table

The address learning table (ADLT) learns the MAC source address of all arriving frames. Up to 2048 MAC addresses can be stored in the ADLT. See Table 40-13 for the internal memory usage for the ADLT. A minimum of four entries is required, and the number of entries must be a multiple of four. Each entry in the table is 64 bits long and contains a 48-bit MAC address and some control and status bits necessary to maintain the table. The table entries are updated in the following two ways:

- Automatic learning of unicast addresses performed by the switch
- CPU-initiated learning. The CPU updates the table by issuing a command in the CECR register. This mechanism is used for multicast and special unicast addresses that the CPU needs to add to the table.

If the destination address is found in the ADLT, the frame is forwarded to the port specified in the ADLT (GDA field).

For multicast traffic, the group destination address (GDA) is used for multicast grouping. The GDA field is updated by the CPU using the QUICC Engine RISC command register. See Section 40.11.1, “Command Register,” for details.

Figure 40-8 displays the ADLT entry format.

ADLT Entry Format

Figure 40-8. ADLT Entry Format

Table 40-2 shows the address learning table bit descriptions.

Table 40-2. Address Learning Table Bit Descriptions

Field	Bits	Description
MAC Addr	0–47	MAC Address 48 bits of MAC address (Bit 40 is the multicast bit)
GDA0–8	48–56	Group Destination Address. This field is used for unicast and multicast frames. For unicast frame, this field indicates the destination port. (Only one bit is set). For multicast frame It indicates which of the ports is associated with this address. 0 Do not forward to port 0–8 1 Forward frame to port 0–8 if other criteria are met. Bit 48 corresponds to port 0, 49 to port 1...bit 56 to port 8 (CPU). This field is used in either Tag mode or Basic mode.
Reserved	57–61	Reserved. Set to 0.
Status {A,V}	62–63	Status {A,V} 00 Invalid entry (reset value) 01 Valid entry + Aging bit is zero 10 Valid entry + Locked entry 11 Valid entry + Aging bit is set

Table 40-3 maps the port number to peripheral numbers.

Table 40-3. Mapping of Port Numbers to Peripheral Numbers

Port Number	Peripheral
0	UCC1
1	UCC2
2	UCC3
3	UCC4
4	UCC5
5	UCC6
6	UCC7
7	UCC8
8	CPU

40.5.1.1 Automatic Update of ADLT Entries

The hash-based lookup provides four buckets for each entry in the ADLT table. There are two modes of operation for updating the ADLT entries.

In the first mode, the switch fills in the four buckets with the first four addresses encountered in the SA field of the incoming packets. Any additional conflicts in the buckets are ignored, and no updates occur.

In the second mode, any conflicts beyond the first four are resolved by flushing the oldest entry in the four buckets. This mode is programmed in the HCM field in Section 40.13.1, "Switch Parameters (SWPAR)."

In both of these options, the older entry might also be removed by the aging mechanism.

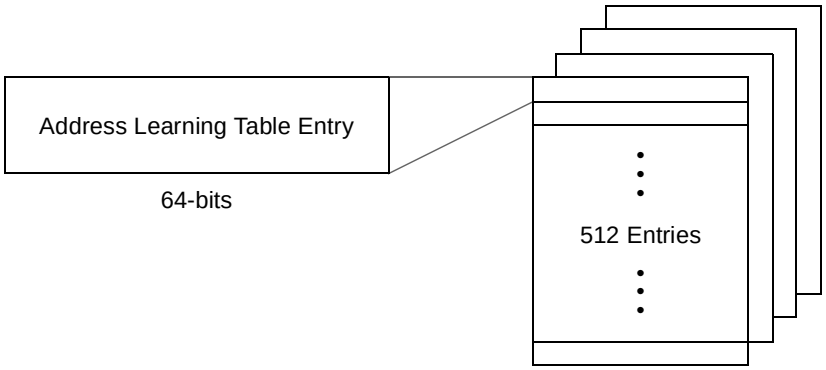

Figure 40-9. ADLT Memory

40.5.1.2 Address Aging

The purpose of the address aging mechanism is to remove unused/old entries from the ADLT and make room for new active ones. Address aging is performed by the QUICC Engine RISC (automatic aging) or by the CPU (command aging). This mechanism is provided in addition to the ADLT update mechanism.

When a new frame arrives and the switch updates the ADLT, it sets the aging bit of the relevant entry. In any aging cycle, the RISC scans 16 ADLT entries, resets all the aging bits that equal to 1 and resets the status bits of every entry containing an aging bit equal to 0 (thus, removes the entry).

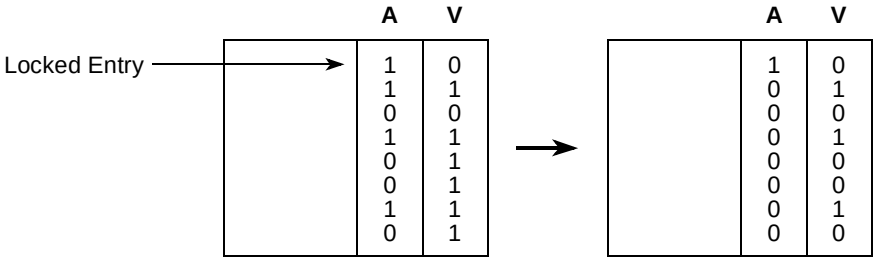

Figure 40-10. Address Aging Mechanism

The user has to determine the aging period (AP) in seconds. The ADLT entry life period, after the receipt of the last packet for this entry, is between one and two aging period seconds. For example, if the user sets the aging period to 100 seconds, the entry life period is between 100 and 200 seconds.

Before enabling the aging mechanism (See Aging Enable command, Section 40.11.3, “Switch Commands”), the CETSCR must be initialized. The CETSCR defines the time unit that is common to Time Stamps in the QUICC Engine block. Before enabling the aging, its Parameter field must be programmed.

Table 40-4. Aging Parameter Table

Offset [1]	Name	Width	Description	User Writes
0xC8	ATU	Word	Aging Time Unit. ATU = (AP * 16 * TSF)/(Total number of ADLT entries) TSF[2] = Time Stamp frequency = (QUICC Engine frequency) / (CETPS+2)	UD (User Defined)

1 Offset from Switch PRAM.
2 See CETSCR in the QUICC Engine Control chapter

Example for using AP, TSF:

AP = 100 sec

QUICC Engine frequency = 400MHz

CETPS = 998

TSF = 400MHz/1000=400KHz

Total number of ADLT entries = 2048Entries

ATU = (100*16*400,000)/2048 = 312500

40.5.1.3 Locked Entry

The CPU may lock entries in the ADLT so that the aging function does not affect them. This is accomplished by writing a command to the CECR register; refer to Section 40.11.1, “Command Register.” See Table 40-2 for the ADLT bit description.

40.5.1.4 Group Destination Address (GDA)

The Group Destination Address (GDA[0–8]) is used for unicast and multicast addresses. For unicast addresses, only one bit is set in this field and is typically updated automatically by the switch learning process. For multicast addresses, the table entry and this field are updated by the CPU. This update is application-dependent and typically occurs as a result of IGMP packet processing. IGMP packets are forwarded to the CPU by the L2 switch if the IGMP snooping feature is enabled. See Section 40.3.7, “IGMP Snooping,” for more information.

40.5.2 Port Designation Table (PDT)

The Port Designation Table (PDT) is used in tagged and untagged mode. It includes nine entries, one for each source port and one for the CPU. Each entry of the PDT contains one bit per destination port. It creates internal multicast groups for each source port.

In untagged mode it is used as a default table. Every untagged multicast frame or unicast frame whose destination address is not found in the ADLT is forwarded to the relevant ports specified by this table.

The PDT is also used in tagged mode for security problems or when the user is forced to work with it instead of the Filtering VLAN Destination Table. See Section 40.5.3.1, “Security Problems,” and Section 40.13.2, “Port Parameters (PPAR),” for more information.

NOTE

When the PDT is unused in tagged mode, the user should program the table to all ones, except the port’s own bit. See Section 40.5.5, “Forwarding Frame Back to the Source Port,” for details.

Figure 40-11 displays the entry format for the PDT.

PDT Entry Format

Offset [1]	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Table 40-5 provides a description of the PDT bits.

Table 40-5. PDT Bits Description

Field	Bits	Description
–	0–6	Reserved
Destination Port Enable	7–15	Indicates which destination port is associated with this source port (SP). 1 This port is a member of this SP group. 0 This port is not a member of this SP group. Note: Port 8 = CPU

40.5.3 VLAN Destination Table (VDT)

The VLAN Destination Table (VDT) contains programmable number of entries (typically 64). Each entry contains a 12-bit VLAN VID and one bit per source and destination port.

The VDT determines which port(s) is/are a member in each VID and is updated by the CPU using the command register. See Section 40.11.1, “Command Register,” for more information.

The source ports field (bits 12–20) is used to check if the incoming tagged frame VID is associated with this port. See Section 40.5.3.1, “Security Problems,” for more information.

Every tagged multicast frame or unicast frame whose destination address is not found in the ADLT is forwarded to the relevant ports according to the destination ports field in the VDT.

The entry format for the VDT is shown in Figure 40-12.

VDT Entry Format

Offset [1]	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
OFFSET + 0	VLAN VID												SP0	SP1	SP2	SP3

= Reserved

1 Offset from VDT_BASE

Figure 40-12. VDT Entry Format

Table 40-6 provides descriptions of the VDT bits.

Table 40-6. VDT Bits Description

Field	Bits	Description
VID	0–11	VLAN VID
Source Port En	12–20	Indicates which of the source ports are associated with this VLAN ID. 0 This source port is not a member of this VID. 1 This source port is a member of this VID. Note: Port 8 = CPU
Destination Port En	21–29	Indicates which of the destination ports are associated with this VLAN ID. 0 This destination port is not a member of this VID. 1 This destination port is a member of this VID. Note: Port 8 = CPU
–	30	Reserved
Valid	31	0 Invalid entry (reset value) 1 Valid entry

40.5.3.1 Security Problems

- If the current frame's VID is not contained in the VDT, the frame can be dropped or forwarded to the relevant ports as specified by the PDT. This is determined by the security mode in the port parameter table. See the DPT field in Section 40.13.2, "Port Parameters (PPAR)," for details.
- If, according to VDT, the current source port is not a member of its frame's VLAN, the frame is dropped.
- In Tag mode—when an untagged frame is received and NDUT bit is cleared in PPAR, the frame is dropped.

NOTE

If a security problem is found, the frame can be sent to the CPU. See the Security Debug mode field in Section 40.13.1, "Switch Parameters (SWPAR)," for details. An interrupt can then be asserted, and the CPU can update the VDT table using the command register.

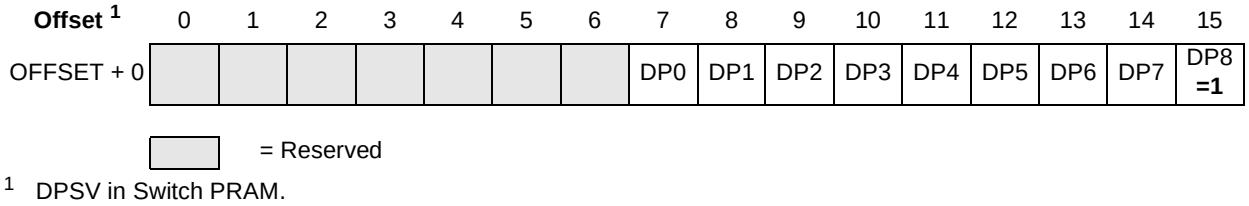
40.5.3.2 1Q Trunk

A port, designated as a 1Q trunk port, is able to receive and transmit all VIDs. In this case, there is no checking of the associated source ports in the VDT. See Section 40.13.2, “Port Parameters (PPAR),” for details.

40.5.4 Destination Port State Vector (DPSV)

The DPSV entry is updated by the CPU according to the spanning tree protocol. See Section 40.11.1, “Command Register,” for more information. It includes nine bits, one per destination port, and can prohibit the switch from forwarding packets to one or more disabled ports.

DPSV Entry Format



1 DPSV in Switch PRAM.

Figure 40-13. DPSV Entry Format

Table 40-7 provides description of the DPSV bits.

Table 40-7. DPSV Bits Description

Field	Bits	Description
–	0–6	Reserved
Destination Port En	7–15	Indicates which of the destination ports is disabled according to the spanning tree protocol. 0 This port is disabled. 1 This port is enabled.

40.5.5 Forwarding Frame Back to the Source Port

In general, the switch does not forward the frame to its source port. If the user insists on sending the frame to its source port, it can be done for each port by setting the port’s own bit in the PDT. This feature is enabled in both basic and tag modes.

40.5.6 Debug Modes

The switch supports the following debug modes:

- Error—the frame is sent to the CPU if an error is found in the incoming frame.
- Flow control—flow control packets are sent to the CPU.
- Security—the frame is sent to the CPU if a security problem is found in the incoming frame. See Section 40.5.3.1, “Security Problems,” for details.
- Miss—the frame is sent to the CPU if no destination ports are found.

These debug modes are optional modes. The user can choose to work with none, any, or all of the debug modes. See Section 40.13.1, “Switch Parameters (SWPAR),” for more information.

40.6 Egress Rule

The egress process decides if the outgoing frame is sent tagged or untagged.

In tag mode, the switch stores only tagged frames in memory. The egress process decides if the tag is removed before the frame leaves the switch.

The user can define each port as a 1D trunk. See Section 40.13.2, “Port Parameters (PPAR),” for more information. A 1D trunk is a connection from the switch that passes only untagged traffic. In this case, the switch has to remove the tag before the frame leaves that port, and the new FCS calculation replaces the old one.

40.7 Switch Processing

The L2 switch supports two processing modes—basic mode and tag mode.

All ports work in the same mode. The processing mode is set to basic mode as a default.

Basic mode is used for a single LAN environment and supports grouping based on a multicast destination address and internal port groups. See Section 40.3.7, “IGMP Snooping,” and Section 40.5.2, “Port Designation Table (PDT),” for details.

Tag mode is suitable for full VLAN and supports grouping based on a multicast destination address and VID groups. See Section 40.5.3, “VLAN Destination Table (VDT),” for more information.

In these two modes, switch processing involves the following three tasks:

- Ingress process
- Forwarding process
- Egress process

40.7.1 Basic Mode Switching

In basic mode, the L2 switch only stores standard frames (untagged frames) in memory.

The switch determines the destination ports for each received frame based on the following:

- Internal port grouping with the PDT. See Section 40.5.2, “Port Designation Table (PDT),” for details.
- Destination address as a consequence of learning or IGMP snooping packets (GDA field in the ADLT)
- Port state as a consequence of the spanning tree protocol. See the DPSV field in Section 40.5.4, “Destination Port State Vector (DPSV),” and the PS field in Section 40.13.2, “Port Parameters (PPAR),” for details

Each port is capable of passing data or management (IGMP, BPDU, and flow control packets) tagged or untagged frames.

Each port has its own ingress/egress rule based on the port parameters.

- If an error frame is found, the packet is dropped or sent only to the CPU (error debug mode), and the source address is not learned. The switch includes error counters for each port.
- When an IGMP or BPDU frame is received, the frame is sent to the CPU for processing.
- In flow control packet, the frame is dropped after being processed by the MAC of the port. The packet is sent to the CPU in Flow-Control debug mode.

40.7.1.1 Ingress Rules

Usually when a tagged frame is received, the tag is removed, and the L2 switch can consider the frame's priority. See Section 40.13.3, "Priority Mapping Table (PMT)," for more information.

However, in transparent mode (see TRA in Section 40.13.2, "Port Parameters (PPAR)") the frame is kept as is. (Note - this mode is global for all ports).

40.7.1.2 Forwarding Process

If the DA is found in the ADLT, the destination ports (DPs) are determined by GDA, PDT, and DPSV. If there are no DPs, the frame is dropped.

If the DA is not found in the ADLT, the DPs are determined by PDT and DPSV. If there are no DPs, the frame is dropped.

Figure 40-14 shows the flow chart for basic mode.

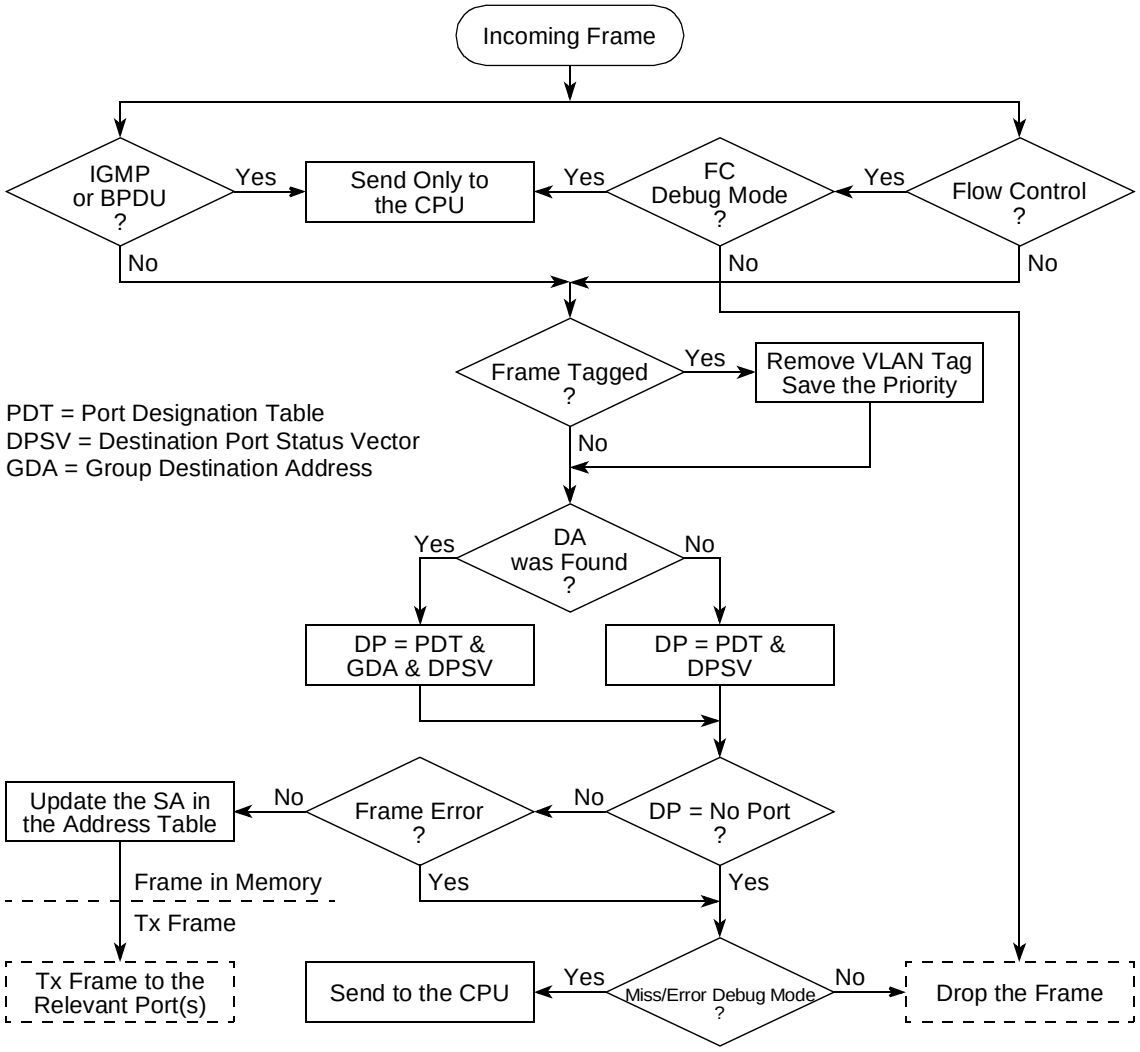


Figure 40-14. Basic Mode Flow Chart

40.7.2 Tag Mode Switching

In tag mode, the L2 switch only stores tagged frames in memory.

The switch determines the destination ports for each received frame based on the following:

- Internal ports grouping with the PDT. See Section 40.5.2, “Port Designation Table (PDT),” for details.
- VLAN grouping with the VDT. See Section 40.5.3, “VLAN Destination Table (VDT),” for details.
- Destination address as a consequence of learning or IGMP snooping packets (GDA field in the ADLT)
- Port state as a consequence of the spanning tree protocol. See the DPSV field in Section 40.5.4, “Destination Port State Vector (DPSV),” and the PS field in Section 40.13.2, “Port Parameters (PPAR),” for details.

Each port is capable of passing data or management (IGMP, BPDU, and flow control packets) tagged or untagged frames.

Each port has its own ingress/egress rule based on the port parameters.

- If an error frame is found, the packet is dropped or sent only to the CPU (error debug mode), and the source address is not learned. The switch includes error counters for each port.
- When an IGMP or BPDU frame is received, the frame is sent to the CPU for processing.
- In flow control packet, the frame is dropped after being processed by the MAC of the port. The packet is sent to the CPU in Flow-Control debug mode.

40.7.2.1 Ingress Rules

The following occurs when an untagged frame is received from any external port:

- Usually the frame is dropped or the default source port VID is added to the frame, depending on the NDUT field in Section 40.13.2, “Port Parameters (PPAR).”
- In Transparent mode (see TRA in Section 40.13.2, “Port Parameters (PPAR)”) - frame is kept as is. (Note - this mode is global for all ports).

The following occurs when a tagged frame is received:

- The tag is extracted and changed by the default VID if forced default tag mode is enabled.
- If the VID is equal to zero, it is overwritten by the default VID.
- If the VID is not contained in the VDT, the frame is either dropped or allowed to exit according the PDT.
- If the source port (SP) is not a member of the VLAN, the frame is dropped.

40.7.2.1.1 Ingress Double VLAN Tagging Rules

Double VLAN Tagging places an Extra (Service) Tag before a frame’s regular tag (additional 4 bytes).

The following occurs when RET field in Section 40.13.2, “Port Parameters (PPAR),” is set:

- The Extra Tag is removed from a received frame, and only then the port’s Ingress rules apply. Extra Tag is removed only if it exists.
- The priority and the VID used by the forwarding process are those of the inner tag.

Typically a port that has RET bit set, also has AET bit set.

40.7.2.2 Forwarding Process

The forwarding process occurs in unicast or multicast address as follows:

- If the DA is found in the ADLT, the DPs (Destination Ports) are determined according to GDA, DPSV, and PDT or VDT, depending on the DPT field in Section 40.13.2, “Port Parameters (PPAR).” If there is no DP, the frame is dropped.
- If the DA is not found in the ADLT, the DPs are determined according to DPSV and VDT or PDT. If there is no DP, the frame is dropped.

40.7.2.3 Egress Rules

When an untagged frame is received, the frame is dropped, or the default destination port VID is added to the frame (or kept as is in transparent mode).

The Egress process decides if the outgoing frames are sent tagged or untagged. The egress process refers to the 1D field in Section “Port Parameters (PPAR)”. If the value is untagged (1D trunk), the tag is removed before leaving the egress port.

40.7.2.3.1 Egress Double VLAN Tagging Rules

Typically a port that has RET bit set, also has AET bit set.

The following occurs when AET field in Section 40.13.2, “Port Parameters (PPAR),” is set:

- All frames are transmitted with Extra (Service) Tag placed after the frame‘s source address.

Figure 40-15 shows the flow chart for tag mode (Double VLAN Tagging is not shown).

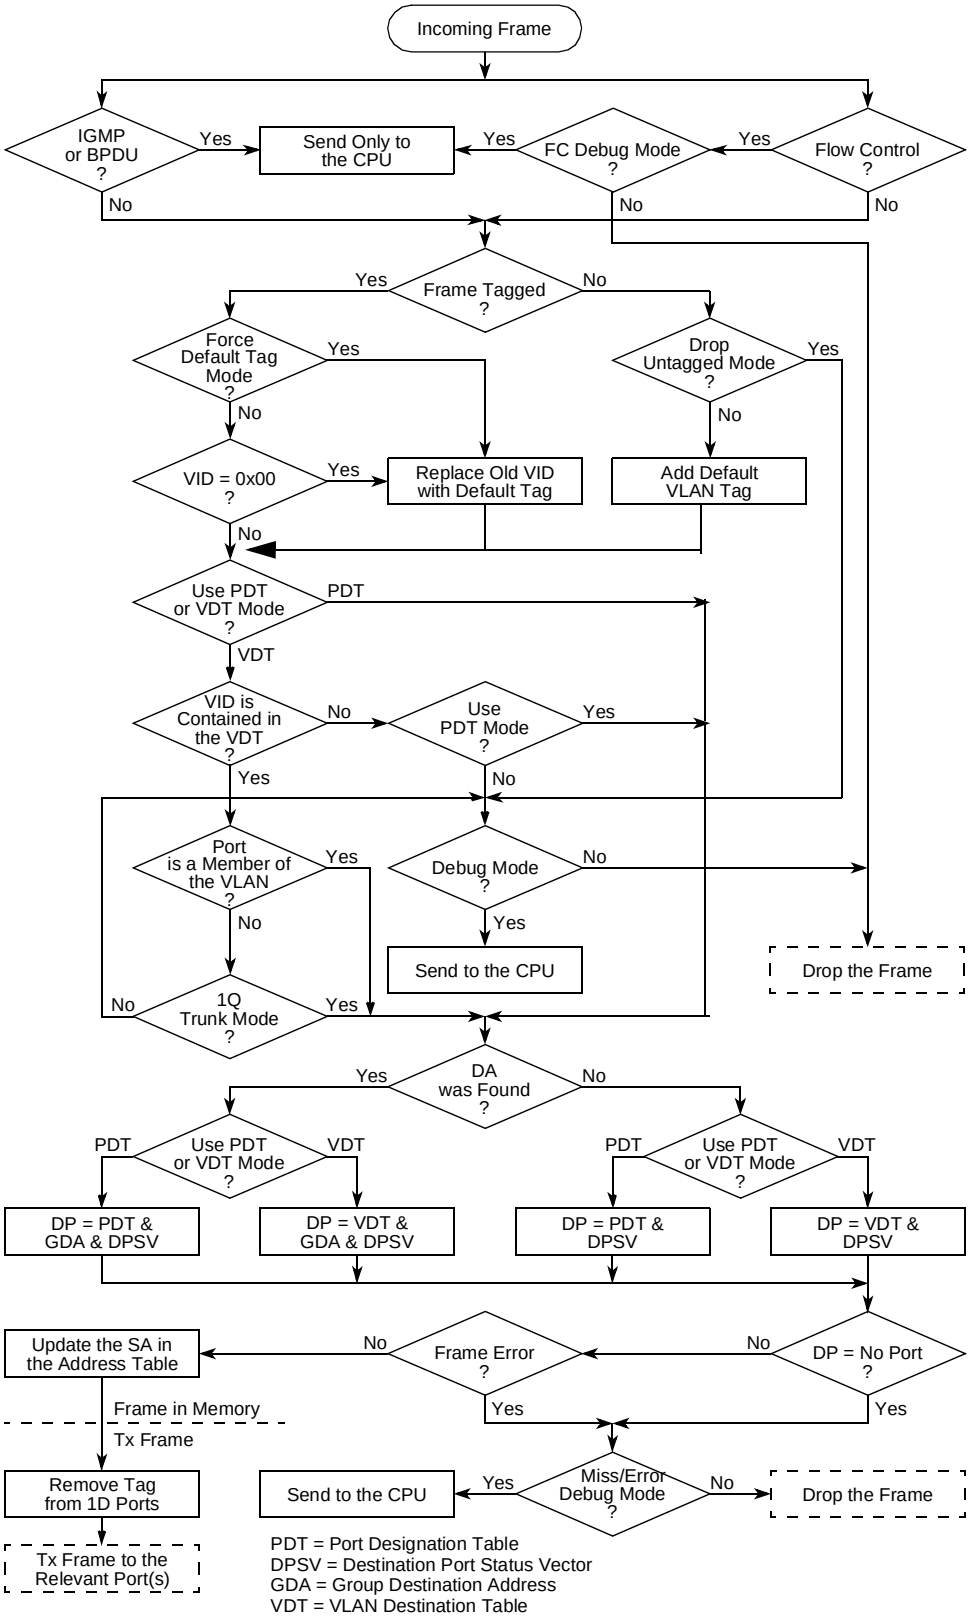

Figure 40-15. Flow Chart for TAG Mode

40.8 Switch Data Flow

The switch stores most of the packets in the external memory, up to 256 packets with a programmable maximum and minimum size.

Internal memory is used in for most of the control structure.

Each port has four priority transmit queues that limit the maximum number of packets that can be separately stored in memory for each port. The size of these transmit queues is programmable and can be smaller or even equal to the total possible packets in memory (256 packets), enabling it to support bursts of traffic.

The switch includes a frame counter for each port and one global counter for all of the ports. If one of the transmit queues is full, the next frame that arrives is dropped. If the number of frames in memory is equal to a threshold number (see Section 40.8.3, “Flow Control,” for details), the switch sends a pause packet (in full-duplex mode) or back pressure is activated (in half-duplex mode) to reduce or stop traffic. If memory is full, the next incoming frame is dropped.

40.8.1 Priority Queueing

The switch supports up to four priority queues per port or the CPU. The user can choose to use four or less priority queues for any port separately. In the case of an untagged frame without priority bits, the user can determine a default priority. See Section 40.13.2, “Port Parameters (PPAR),” for more information. Unknown unicast destination addresses are always set to lowest priority.

Every priority queue has its own size. The user must determine the size of all queues. The size of each queue varies from minimum of zero (unused queue) to maximum of 256 entries. See Section 40.8.2, “Transmit Queue Parameter Table,” for more information.

Figure 40-16 shows the transmit queue.

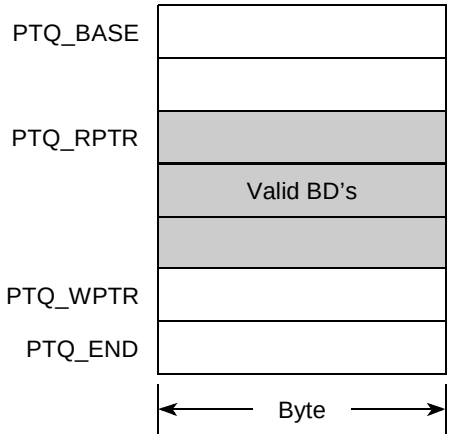

Figure 40-16. Transmit Queue

This mechanism prevents blocking between the ports. The main idea is to prevent a situation where one or several ports consume more and more buffers (packets placed in memory) as these ports may eventually become blocked entirely (all ports are blocked).

If one queue is full, the next received packet at this queue is dropped, and an interrupt is asserted.

Note that if a multicast or broadcast frame needs to be forwarded to multiple ports, and one or several of these queues are full, the frame is not dropped and is forwarded only to the queues, which are not full.

The L2 switch selects the next priority queue for transmit packets by using fixed priority, weighted round robin priority polling or a combination of them. See Section 40.8.7, "Transmission Data Structure," for more information.

40.8.2 Transmit Queue Parameter Table

Table 40-8 shows transmit queue parameters found in multi-user RAM. The TQ_BASE entry in the PRAM points to the start address of this table.

Table 40-8. Transmit Queue Parameter Table (per port)

Offset [1]	Name	Width	Description	User Writes
0x00	PTQ0_BASE	Word	Priority TQueue 0 Base pointer	User Defined Bit[31] = 0

[1] Offset from TQ_BASE in Port/CPU PRAM.

40.8.3 Flow Control

The purpose of flow control is to reduce the chance of dropping packets when memory is full.

Each port can operate at either half- or full-duplex mode and have flow control or back pressure enabled or disabled.

The switch uses flow control (either in full- or half-duplex) based on the port packets group limit or based on the global packets limit.

The limit value per port and the global limit for all ports are programmable. See Section 40.12.2, “Switch PRAM,” and Section 40.13.2, “Port Parameters (PPAR),” for more information on GFrame_Hlimit and PFrame_Hlimit, respectively. Therefore, there is one Rx counter per port and one global Rx counter for all receive ports. To enable burst traffic, it is recommend to set the per port packets limit to a higher number than its relative part (256/ports_number) in the memory buffers.

If the number of packets in memory that are allocated to the same source port is equal to the high port threshold number, the switch sends pause packets (in full-duplex mode) or back pressure is activated (in half-duplex mode) on this specific port to stop the traffic. When the number of packets in memory is equal to the low port threshold number, the flow control mechanism is stopped.

If the number of global frames in memory is equal to a high global threshold number, the switch sends pause packets (in full-duplex mode) or back pressure is activated (in half-duplex mode) on all the ports to reduce or stop traffic. When the number of packets in memory is equal to the low global threshold number, the flow control mechanism is stopped.

40.8.3.1 Full-Duplex Flow Control

The L2 switch supports IEEE 802.3x flow control on any full-duplex port.

When the switch sends pause packets their pause period is equal to 0xFFFF. When the number of frames in memory is equal to the low threshold, the switch sends new pause packet with pause period equal to 0x0000.

40.8.3.2 Half-Duplex Flow Control (Back Pressure)

Back pressure is used for flow control in half-duplex mode. Whenever the switch uses a flow control mechanism, the MAC of the port starts sending a JAM signal through the port. After sensing the JAM signal, the remote station defers transmission.

40.8.3.3 Receiving Pause Frame

If a port receives a pause frame with a non-zero delay, it delays transmission for the period of time specified in the received pause packet after the ongoing frame transmission is finished. If UPSMR[FTFE] bit is set and a Flow Control pause frame is received, the UCC sends the current frame till completion, and then flushes the frames in the transmit FIFO. No transmission occurs till the specified delay has elapsed.

40.8.4 Empty BD List

The empty BD list is a memory space located in the multi-user RAM. It points to the next buffer descriptor (BD) that is empty and ready for use. See Section 40.8.8, “Internal BDs,” for details.

The list is separated into two lists. The first list includes the first M BDs, and the second list includes the rest of BDs. The first M BDs point to M frames, the first 64 bytes of which are allocated in internal memory; the rest of the frames are in external memory. The last BDs point to frames that are all allocated in external memory.

The larger the value of M, the higher the performance (if internal memory is available). However, for applications where the internal memory space is not sufficient, M can be set to a small value.

For short frames (up to 128 bytes) when a new frame arrives, the switch first looks for an empty BD in the first list (high priority list). If the first list does not include any empty BD, it moves to the second one. For larger frames, it is the opposite way.

Every list has two pointers, RPTR and WPTR. The receiver follows the RPTR and reads the next empty BD. When the BD is empty again (its associated frame was transmitted), the transmitter returns the new empty BD to the list by writing after the WPTR. The valid empty BDs are located in the space between RPTR and WPTR. See Section 40.12.2, “Switch PRAM,” for more information on FEL/SEL_BASE and FEL/SEL_END.

M is equal to (FEL_END - FEL_BASE + 1).

It is required that (FEL_END - FEL_BASE + 1) + (SEL_END - SEL_BASE + 1) <= 256.

The first list is initialized with values of 0 up to (M-1) (using INIT_CPU command).

The second list is initialized with values of M up to 255 (or less) (using INIT_CPU command)

Figure 40-17 displays the two empty BD lists.

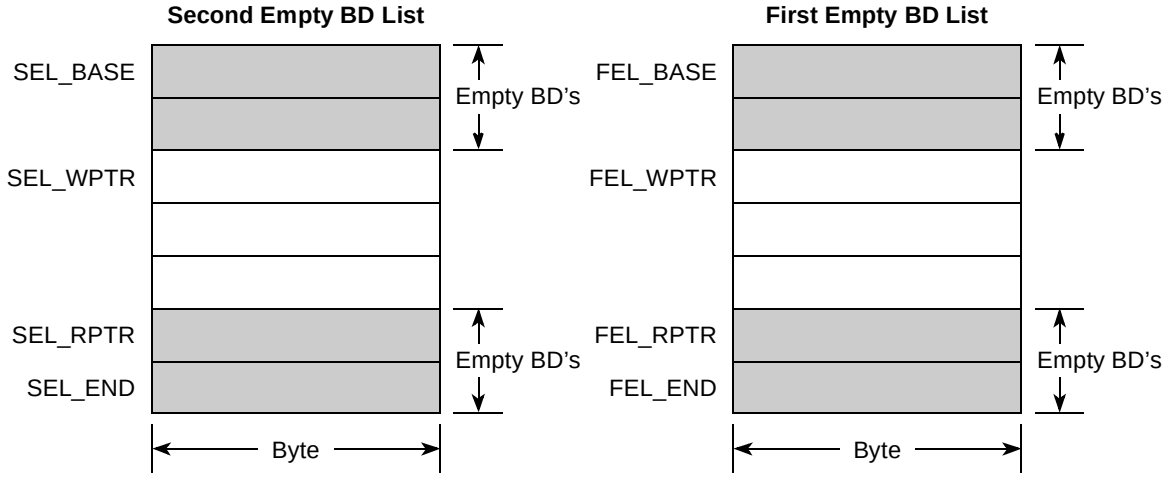

Figure 40-17. Empty BD Lists

40.8.5 BD Pointers Table

The BD pointers table includes a 32-bit frame pointer for each internal BD. See Section 40.8.8, “Internal BDs,” for more information. These pointers are used to point to the external buffer location of each frame. The table is prepared during initialization by the CPU.

The minimum spacing between two consecutive BD frame pointers has to be equal to the maximum frame length allowed. See MFLR field in Section 40.12.2, “Switch PRAM,” for more information. Also the pointers should be 8 bytes aligned.

When a new empty BD is chosen, the first 64 bytes of the new frame are stored in internal or external memory, and the rest of the frame (or all of the frame) is forwarded to external memory based on the BD pointer.

If the current frame also needs to be delivered to the CPU, all the frame is forwarded to external memory, including the first 64 bytes.

Figure 40-18 shows the BDs pointers table.

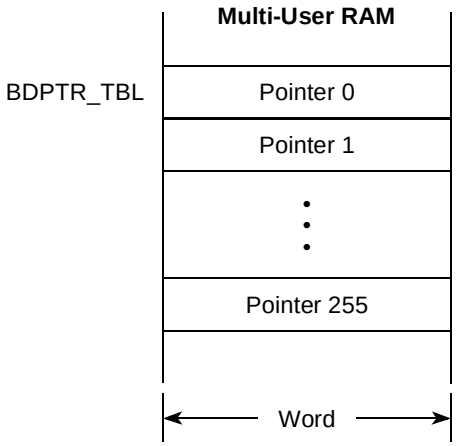

Figure 40-18. BDs Pointers Table

40.8.6 Reception Data Structure

The receiver can receive unicast, multicast or broadcast frames. When the receiver gets the first bytes of a frame, the L2 switch performs address recognition on the frame. Since Ethernet receive frame data is not written to memory until the internal address recognition algorithm completes, bus usage is not wasted on frames with empty destination ports.

If a destination port is found, the switch fetches the next empty BD and its pointer, and starts transferring the incoming frame to the BD associated data buffer. Each BD represents a full frame.

During reception, the switch checks for frames that are too short or too long. When the frame has been received, the received FCS field is checked but not written to the data buffer. The data length is written to the relevant BD in the frame length field. If an error is found (FCS error, frame is too short etc.), the BD associated with the frame is reused.

When the receive frame is completed, the BD number is written to the relevant transmit priority queue (TQ) buffer(s).

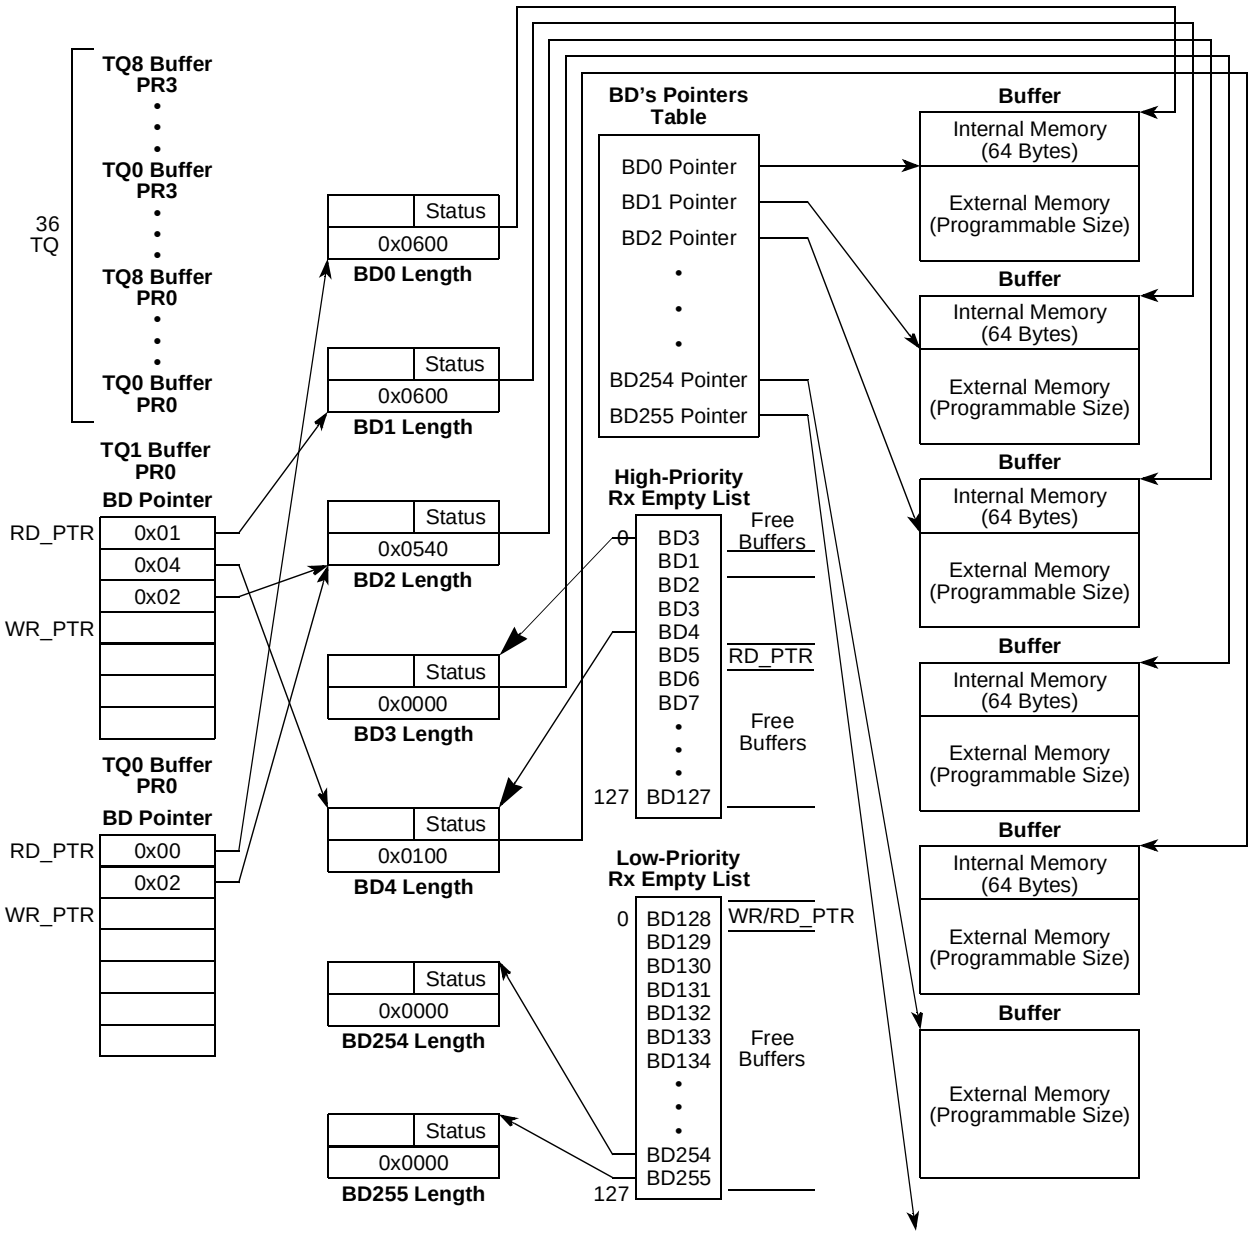

Figure 40-19. Data Structure (Without CPU Traffic)—M =128

40.8.7 Transmission Data Structure

The arbitration between TQs (with valid BDs) uses the fixed priority, weighted round robin mechanisms or a combination of them between the highest and lowest priority queues. This is determined by the PPW field in Section 40.13.2, "Port Parameters (PPAR)."

- Fixed priority mechanism—The TQ's polling always starts at TQ0. TQ0 is given the highest priority and so on down to the last TQ.

  This method can cause the lower priority TQs to starve when all frames are transmitted from the highest priority TQ.

- Weighted round robin mechanism—This mechanism gives variable priority to all TQs. All TQs have a chance to be used, preventing lower priority TQs from starving. An example for allocation may be: 16 frames from TQ0, eight from TQ1, four from TQ2, and two from TQ3.
- Fixed highest priority for TQ0 & weighted round robin for 3 lower priority queues - this allows shorter latency for TQ0.

  When a TQ is chosen, the transmitter reads the BD number from the table, and transmits a frame that is associated with this BD.

  When the end of the current buffer is reached, the transmitter releases the current BD and its pointer and writes its number back to the BD empty list.

40.8.8 Internal BDs

The L2 switch uses up to 256 BDs to report information about the received frames. These BDs are used for all external ports including the CPU and are kept in multi-user RAM.

Each BD points to a data buffer in external memory, the location of which is determined by the BD's frame pointer table. See Section 40.8.5, "BD Pointers Table," for details.

The internal BDs are located in the multi-user RAM as shown in Figure 40-20.

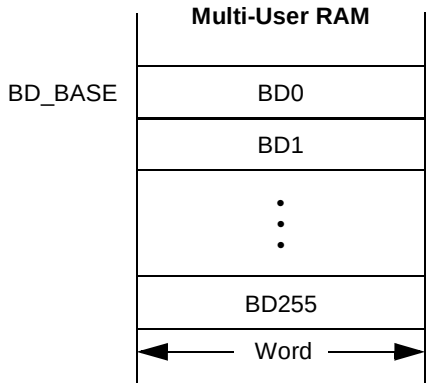

Figure 40-20. Internal BDs in Multi-User RAM

40.8.9 Packet Forwarding to the CPU

When a packet is forwarded to the CPU, the frame is stored in external memory, and the special external CPU RxBD (RCBD) is used to report information about the received frame. See Section 40.8.11.1, "Rx CPU BDs (RCBD)," for details.

If the received frame is a multicast or broadcast frame, meaning it has to be forwarded to a few external ports and to the CPU, all the frame (including the first 64 bytes) is stored in external memory.

When the whole frame is received, the switch generates a maskable interrupt, indicating that a frame was received and is in external memory. The external RCBD now points to the frame and represents it for the CPU.

A frame is forwarded to the CPU in the following scenarios:

1. The switch works in debug mode. See Section 40.5.6, “Debug Modes.”
2. It is a packet that one of the destination ports points to the CPU.
3. It is a BPDU frame.
4. It is an IGMP frame.

Frames forwarded to the CPU map to four priority levels of TQs and RCBD priority levels. See TQ_BASE and RCBD in Section 40.12.4, “CPU PRAM,” for more information.

40.8.10 Packet Forwarding from the CPU

Packets can be forwarded from the CPU to one or more external ports. The trigger for this forwarding is the CPU Tx command. See Section 40.11.1, “Command Register,” for information.

The frame length and the buffer pointer can be found in the relevant TCBD (Tx CPU BD). There are 2 types of TCBDs.

The first type is implicit (EXP=0) - the destination ports and the frame priority are determined according to the ingress rules.

The second type is explicit (EXP=1) - the destination ports and the frame priority are determined according to the bits on the TCBD itself (ingress rules are not applied).

(There is no limitation of using only one type; TCBDs may have any type).

See Section 40.8.11.2, “Tx CPU BDs (TCBD),” for information on TCBDs.

40.8.11 External CPU BDs

40.8.11.1 Rx CPU BDs (RCBD)

The L2 switch uses the Rx CPU BD (RCBD) for packet transfers to the CPU. The RCBDs are kept in external memory.

The CPU can use up to four priority RCBD tables. Each RCBD table is associated with a suitable priority transmit queue.

Each BD has 32-bit frame pointer that points to the location of the frame data buffer in external memory. The minimum spacing between two consecutive RCBD frame pointers has to be equal to the maximum frame length allowed. Every buffer stores one full frame.

Figure 40-21 shows the switch external RCBD format.

Rx CPU BUFFER DESCRIPTOR

Offset [1]	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
OFFSET + 0	E	M	W	VSP	Frame Type			SP				NO	LE	CR	OV	CL
OFFSET + 2	Frame Data Length															
OFFSET + 4	Rx Frame Buffer Pointer															
OFFSET + 6																

= Reserved

1 Offset from RCBD_PRx_BPTR in CPU PRAM - 8 bytes aligned.

Figure 40-21. External Rx CPU BD Format

Table 40-9 describes the external Rx CPU BD fields.

Table 40-9. External Rx CPU BD Format

Offset	Bits	Field	Description
0x00	0	**E**	Empty 0 The buffer associated with this RCBD is full. 1 The buffer associated with this RCBD is empty.
	1	M	Miss. Destination port was not found.
	2	**W**	Wrap (final BD in table) 0 Not the last BD in the RCBD table 1 Last BD in the RCBD table
	3	VSP	VLAN Security Problem.
	4–6	FT	Frame Type. 000 Unicast address 001 Multicast address 010 Broadcast address 011 IGMP frame. 100 Flow Control packet 101 BPDU frame. 11x Reserved
	7–10	SP	Source Port (Port 0 to Port 8) SP=0x0 - Port0 SP =0x8 - CPU
	11	NO	Rx nonoctet aligned frame
	12	LE	Rx frame length error. Long/short frame.
	13	CR	Rx FCS error. This frame contains a FCS error.
	14	OV	Overrun. A receiver overrun occurred during frame reception.
	15	CL	Collision. This frame is closed because a collision occurred during frame reception.
0x02	0–15	Data Length	Frame Data Length The data length is the number of octets the receiver writes into this BD data buffer (Not including four FCS bytes).
0x04–0x06	0–31	FBP	Rx Frame Buffer Pointer (32 bits) - 8 bytes aligned.

NOTE

At least one BD from each priority RCBD table must be prepared before beginning reception.

40.8.11.2 Tx CPU BDs (TCBD)

The switch uses the Tx CPU BD (TCBD) for packet transfers from the CPU. The TCBDs are kept in external memory.

Each BD has a 32-bit frame pointer that points to the location of the frame data buffer in external memory. Every buffer stores one full frame.

There are 2 types of TCBDs.

The first type is implicit (EXP=0) - the destination ports and the frame priority are determined according to the ingress rules.

The second type is explicit (EXP=1) - the destination ports and the frame priority are determined according to the TCBD itself (ingress rules are not applied, works like in transparent mode).

There is no limitation of using only one type; TCBDs may have any type.

NOTE

For any type, the frame data length must be in the range of MFLR and MINFLR.

Figure 40-22 shows the external Tx CPU BD format for the implicit type.

Tx CPU BUFFER DESCRIPTOR EXP=0

Offset [1]	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

0x04 – 0x06	0:31	FBP	Tx Frame Buffer Pointer (32 bits) - 8 bytes aligned.

40.9 Internal and External Memory

The switch has internal/external memories for control structure, packet buffering, the ADLT, and the VLAN table. In the maximum configuration up to 375 Kbytes (2.4 Mbytes for jumbo frames) of external memory are used. The multi-user RAM internal memory space is programmable.

Internal memory is used for Ethernet address recognition (ADLT), VLAN tables, control structure, and as for partial (high-priority) data buffering. External memory is used at most for data buffering and control structure (buffer descriptors for packets forwarded to or from the CPU).

40.9.1 Internal Memory

Parameter RAMs (PRAM)

- Up to ten PRAMs are used, 256 bytes for each PRAM
  - — Switch PRAM
  - — Ports PRAM (up to eight ports)
  - — CPU PRAM

Data Buffering

- The L2 switch supports up to 256 packet buffers. Internal memory can store the first 64 bytes of M packets.

Control Structure

- The control structure includes up to 256 local BDs, 36 transmit queues (4 TQs per port and CPU), and 2 empty BD tables.

Address Recognition

- The switch provides an on-chip ADLT with up to 2K entries for frame destination look-up.
- The switch provides an on-chip VID table and supports programmable number (typically 64) of different VIDs out of a possible 4096.

In the maximum configuration, eight external ports and 256-packet buffer, 38 Kbytes of internal multi-user RAM are used.

Table 40-12 provides the maximum size in internal memory for data buffering, control structures, address recognition, and PRAMs.

Table 40-12. Internal Memory Maximum Size (for 8 External Ports + CPU port)

Memory Area		Tables (for 256 Packets)	Size (in Bytes)
Data buffering		64 bytes * M packets	64*M
Control structures	BDs	4 bytes * 256 BDs	1024
	TQ	256 bytes * 32 TQ	8192 (worst case)
	CPU TQ	256 bytes * 4 TQ	1024 (worst case)
	Empty BD Tables	128 bytes * 2 tables	256
	Pointers Table	4 bytes * 256 BDs	1024
Address recognition	ADLT	8 bytes * 2048 entries	up to 16384
	VDT	4 bytes * 64 VIDs	256
PRAMs		256 bytes * Switch	256
		256 bytes * 8 ports	2048
		256 bytes * CPU	256
		Total	up to 30K + 64*M

40.9.1.1 Programmable Internal Memory

The overall multi-user RAM internal memory usage is programmable.

1) Table 40-13 specifies memory usage at a few configurations of ADLT size.

Table 40-13. Internal Memory Usage for ADLT

Address Table Entries	Internal Memory Usage	ADLT_MASK in Switch PRAM
128	1 Kbytes	ADLT_MASK = 1F
256	2 Kbytes	ADLT_MASK = 3F
512	4 Kbytes	ADLT_MASK = 7F
1024	8 Kbytes	ADLT_MASK = FF
2048	16 Kbytes	ADLT_MASK = 1FF

2) Table 40-14 specifies the multi-user RAM memory for one, two, three, and four queues (for at most 256 packet buffers).

Each port has four priority transmit queues; these queues limit the maximum number of packets that can be stored in memory for each port separately. The size of these transmit queues is programmable and can be smaller than or even equal to the total number of possible packets in memory (256 packets), enabling it to support bursts of traffic. So either limiting the number of priority queues or their size (256 is worst case) reduces the internal memory usage significantly.

Table 40-14. TQ Internal Memory Usage in Worst Case

Number of Priority Queues	Internal Memory Usage (per port)	Internal Memory Usage (8 Ports + CPU)
1	Up to 256 bytes	Up to 2.25 Kbytes
2	Up to 512 bytes	Up to 4.5 Kbytes
3	Up to 768 bytes	Up to 6.75 Kbytes
4	Up to 1024 bytes	Up to 9 Kbytes

3) Internal memory can store the first 64 bytes of M packets. Thus when setting the value of M, one can take into account the internal memory space limitations.

40.9.2 External Memory

Data Buffering

- The L2 switch stores most of the received packet data in external memory for up to 256 packets. The frame size is programmable.
  - — Jumbo frames are supported (up to 9 Kbytes).

Control Structure

- The control structure includes external Rx and Tx CPU BDs (RCBDs and TCBDs) for packets that are forwarded to/from the CPU.

At the maximum configuration of 256 packet buffers 375 Kbytes of external memory are used (2.4 Mbytes for jumbo frames).

40.9.3 RMON Counters

The switch can automatically gather network statistics required for Remote Monitoring (RMON).

32-bit counters per port (including the CPU), are used to provide the network management with up-to-date and historical network component data. The CPU can read, or clear these counters.

The following RMON groups are supported:

- Statistics (group 1)
- History (group 2)
- Alarm (group 3)
- Event (group 9)

The switch supports the statistics group; all other groups can be supported by the CPU.

Statistics

This statistics group contains information about the number of unicast, multicast or broadcast frames, frame rate and distribution, or the number of faulty frames classified according to error types.

The statistics group contains the following information about network load and quality:

- Packets
- Octets
- Broadcasts
- Collisions
- Dropped packets
- Fragments
- FCS alignment errors
- Undersize/oversize packets
- Multicasts
- Jabbers
- 64-octet packets
- 65- to 127-octet packets
- 128- to 255-octet packets
- 256- to 511-octet packets
- 512- to 1023-octet packets
- 1024- to 1518-octet packets

40.9.3.1 Receive RMON

The receive RMON statistics and their corresponding counters in the PRAM are described in Table 40-15.

Table 40-15. Rx RMON Counters

Offset [1]	Name	Width	Description	User Writes
0x00	RX_Byte_Cnt	Word	The total number of octets of data (including those in bad packets) received on the network (excluding framing bits but including FCS octets).	0x0000_0000
0x04	RX_64	Word	The total number of packets (including bad packets) received that were 64 octets long (excluding framing bits but including FCS octets).	0x0000_0000
0x08	RX_L64	Word	The total number of packets received that were less than 64 octets long (excluding framing bits but including FCS octets) with valid FCS.	0x0000_0000
0x0C	RX_L64CRCE	Word	The total number of packets received that were less than 64 octets long (excluding framing bits but including FCS octets) with invalid FCS.	0x0000_0000
0x10	RX_65T127	Word	The total number of packets (including bad packets) received that were between 65 and 127 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000
0x14	RX_128T255	Word	The total number of packets (including bad packets) received that were between 128 and 255 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000

Table 40-15. Rx RMON Counters (continued)

Offset [1]	Name	Width	Description	User Writes
0x18	RX_256T511	Word	The total number of packets (including bad packets) received that were between 256 and 511 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000
0x1C	RX_512T1023	Word	The total number of packets (including bad packets) received that were between 512 and 1023 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000
0x20	RX_1024T1522	Word	The total number of packets (including bad packets) received that were between 1024 and 1522 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000
0x24	RX_Jabber	Word	The total number of packets received that were longer than 1522 octets (excluding framing bits but including FCS octets) and had a valid FCS	0x0000_0000
0x28	RX_JabberErr	Word	The total number of packets received that were longer than 1522 octets (excluding framing bits but including FCS octets) and had an invalid FCS	0x0000_0000
0x2C	RX_BC	Word	The total number of broadcast packets (including bad packets) received.	0x0000_0000
0x30	RX_UC	Word	The total number of unicast packets (including bad packets) received.	0x0000_0000
0x34	RX_MC	Word	The total number of multicast packets received (including bad packets).	0x0000_0000
0x38	RX_FC	Word	The total number of flow control packets received.	0x0000_0000

1 Offset from Rx_RMON_BPTR in Port PRAM / RxfromCPU_RMON_BPTR in CPU PRAM

40.9.3.2 Transmit RMON

The transmit RMON statistics and their corresponding counters in the PRAM are described in Table 40-16.

Table 40-16. Tx RMON Counters

Offset [1]	Name	Width	Description	User Writes
0x00	TX_Byte_Cnt	Word	The total number of octets of data transmitted on the network (excluding framing bits but including FCS octets).	0x0000_0000
0x04	TX_64	Word	The total number of packets transmitted that were 64 octets long (excluding framing bits but including FCS octets).	0x0000_0000
0x08	TX_L64	Word	The total number of packets transmitted that were less than 64 octets long (excluding framing bits but including FCS octets).	0x0000_0000
0x0C	TX_65T127	Word	The total number of packets transmitted that were between 65 and 127 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000
0x10	TX_128T255	Word	The total number of packets transmitted that were between 128 and 255 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000

Table 40-16. Tx RMON Counters (continued)

Offset [1]	Name	Width	Description	User Writes
0x14	TX_256T511	Word	The total number of packets transmitted that were between 256 and 511 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000
0x18	TX_512T1023	Word	The total number of packets transmitted that were between 512 and 1023 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000
0x1C	TX_1024T1522	Word	The total number of packets transmitted that were between 1024 and 1522 octets long inclusive (excluding framing bits but including FCS octets).	0x0000_0000
0x20	TX_Jabber	Word	The total number of packets transmitted that were longer than 1522 octets (excluding framing bits but including FCS octets).	0x0000_0000
0x24	TX_BC	Word	The total number of broadcast packets transmitted.	0x0000_0000
0x28	TX_UC	Word	The total number of unicast packets transmitted.	0x0000_0000
0x2C	TX_MC	Word	The total number of multicast packets transmitted.	0x0000_0000
0x30	TX_FC	Word	The total number of flow control packets transmitted by switch request	0x0000_0000

1 Offset from Tx_RMON_BPTR in Port PRAM / TxtoCPU_RMON_BPTR in CPU PRAM

40.9.4 Error Counters

The switch supports 32-bit error counters per port. The CPU can read, or clear these counters.

40.9.4.1 Receive Counters

The receive error statistics and their corresponding counters in the PRAM are described in Table 40-17.

Table 40-17. Rx Error Counters

Offset [1]	Name	Width	Description	User Writes
0x9C	SECEC	Word	Security Error Counter. See Section 40.5.3.1, “Security Problems” for details.	0x0000_0000
0xA0	MISSC	Word	Miss Counter. Destination port was not found.	0x0000_0000
0xA4	MFLEC	Word	MEM Full Counter. Packet was dropped due to full memory.	0x0000_0000
0xA8	CRCEC	Word	Receive FCS Error Counter	0x0000_0000
0xAC	ALEC	Word	Receive Alignment Error Counter. Rx nonoctet aligned frame arrived.	0x0000_0000
0xB0	OREC	Word	Receive Overrun Error Counter. A receiver overrun occurred during frame reception.	0x0000_0000
0xB4	COLC	Word	Receive Collision Counter. This frame was closed because a collision occurred during frame reception.	0x0000_0000

1 Offset from Port PRAM.

40.9.4.2 Transmit Counters

The transmit error statistics and their corresponding counters in the PRAM are shown in Table 40-18.

Table 40-18. Tx Error Counters

Offset [1]	Name	Width	Description	User Writes
0xDC	TxDFT_Cnt	Word	Transmit Defer Counter. Deferring while trying to transmit the frame.	0x0000_0000
0xE0	TxCRS_Cnt	Word	Transmit Carrier Sense Counter. Carrier sense lost during frame transmission.	0x0000_0000
0xE4	TxUN_Cnt	Word	Transmit Underrun Counter. Transmitter underrun condition while sending the frame.	0x0000_0000-
0xE8	TxLC_Cnt	Word	Transmit Late Collision Counter.	0x0000_0000
0xEC	TxRL_Cnt	Word	Transmit Retransmission limit Counter. The transmitter failed to successfully send a massage due to maximum allowed repeated collisions number.	0x0000_0000
0xF0	TxCL_Cnt	Word	The best estimate of the total number of collisions on this Ethernet segment.	0x0000_0000
0xF4	TxEXD_Cnt	Word	Transmit Excessive Defer Counter.	0x0000_0000

1 Offset from Port PRAM.

40.10 Switch Exceptions

40.10.1 Switch Event Register (SWE)/Mask Register (SWM)

The SWE, shown in Figure 40-24, is used as an Ethernet switch event register. This register is used for switch interaction with the CPU. It generates interrupt events recognized by the switch. On recognition of the event, the switch sets the corresponding SWE bit. Interrupts generated by this register can be masked in the Ethernet switch mask register (SWM). The proper EXT bit in CRIMR should also be set in order to generate an interrupt.

The SWM has the same bit format as the SWE. Setting a SWM bit enables and clearing a bit masks the corresponding interrupt in the SWE.

The SWE can be read at any time. Bits are cleared by writing ones; writing zeros does not affect bit values. Unmasked SWE bits must be cleared before the QUICC Engine block clears the internal interrupt request.

SWITCH EVENT REGISTER / SWITCH MASK REGISTER

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	BSY	HC	CTQF	RXF0	RXF1	RXF2	RXF3	MF	TQF0	TQF1	TQF2	TQF3	TQF4	TQF5	TQF6	TQF7
Reset	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Figure 40-24. Switch Event /Mask Register

Table 40-19 provides field descriptions for the switch event/mask register.

Table 40-19. Switch Event /Mask Register Field Descriptions

Bits	Field	Description
0	BSY	Busy condition. Set when a frame for CPU is received and discarded due to a lack of empty RCBDs.
1	HC	Hashing conflict occurred. (Set when frame arrives from the CPU) - when this occurs clear the whole ADLT and select new preset_crc value
2	CTQF	CPU Transmit queue(s) is full. A failure to write new frame to one (or more) CPU transmit queues occurred due to full transmit queue(s).
3	RXF0	Rx Frame Priority0. Set when a complete frame is forwarded to the CPU with priority 0.
4	RXF1	Rx Frame Priority1. Set when a complete frame is forwarded to the CPU with priority 1.
5	RXF2	Rx Frame Priority2. Set when a complete frame is forwarded to the CPU with priority 2.
6	RXF3	Rx Frame Priority3. Set when a complete frame is forwarded to the CPU with priority 3.
7	MF	Memory is full. No room for new frames. The current incoming frame was dropped. (Set when the frame has arrived from the CPU)
8	TQF0	Port0 Transmit queue(s) is full. The CPU failed to write new frame to one (or more) Port0 transmit queues due to full transmit queue(s).
9	TQF1	Port1 Transmit queue(s) is full. The CPU failed to write new frame to one (or more) Port1 transmit queues due to full transmit queue(s).
10	TQF2	Port2 Transmit queue(s) is full. The CPU failed to write new frame to one (or more) Port2 transmit queues due to full transmit queue(s).
11	TQF3	Port3 Transmit queue(s) is full. The CPU failed to write new frame to one (or more) Port3 transmit queues due to full transmit queue(s).
12	TQF4	Port4 Transmit queue(s) is full. The CPU failed to write new frame to one (or more) Port4 transmit queues due to full transmit queue(s).
13	TQF5	Port5 Transmit queue(s) is full. The CPU failed to write new frame to one (or more) Port5 transmit queues due to full transmit queue(s).
14	TQF6	Port6 Transmit queue(s) is full. The CPU failed to write new frame to one (or more) Port6 transmit queues due to full transmit queue(s).
15	TQF7	Port7 Transmit queue(s) is full. The CPU failed to write new frame to one (or more) Port7 transmit queues due to full transmit queue(s).

40.10.1.1 SWE and SWM Address

The SWE and SWM addresses are determined by the MSNUM (SMSNUM) field in the switch parameter RAM. There are 4 possible options for the SMSNUM.

Table 40-20 maps switch MSNUM (SMSNUM) to the SWE and SWM address.

Table 40-20. Mapping of SMSNUM to SWE and SWM addresses

SMSNUM	SWE Internal Address	SWM Internal Address	External Request
0xf8	CE_BASE + 0x160 (CEEXE1)	CE_BASE + 0x164 (CEEXM1)	EXT1
0xf9	CE_BASE + 0x168 (CEEXE2)	CE_BASE + 0x16c (CEEXM2)	EXT2
0x3c	CE_BASE + 0x170 (CEEXE3)	CE_BASE + 0x174 (CEEXM3)	EXT3
0x3d	CE_BASE + 0x178 (CEEXE4)	CE_BASE + 0x17c (CEEXM4)	EXT4

NOTE

SWE/SWM refers to one of CEEXEx/CEEXMx registers that would otherwise be used by external requests. External requests registers not referred to by the SMSNUM are not used by the L2 switch.

40.10.2 Port Event Register (UCCE)/Mask Register (UCCM)

The UCCE, shown in Figure 40-25, is used as an Ethernet port event register when the UCC functions as an Ethernet switch port. It generates interrupt events recognized by the switch port. On recognition of the event, the port sets the corresponding UCCE bit. Interrupts generated by this register can be masked in the Ethernet port mask register (UCCM). The proper bit in CIMR should also be set in order to generate an interrupt.

The UCCM has the same bit format as the UCCE. Setting a UCCM bit enables and clearing a bit masks the corresponding interrupt in the UCCE.

The UCCE can be read at any time. Bits are cleared by writing ones; writing zeros does not affect bit values. Unmasked UCCE bits must be cleared before the QUICC Engine block clears the internal interrupt request.

PORT EVENT REGISTER / PORT MASK REGISTER

	3	16	17	18	19	22	23	24	25	26	27	28	29	30	31
Field	CBPR	GRA	HC	CTQF	TXE	GFC	MF	TQF0	TQF1	TQF2	TQF3	TQF4	TQF5	TQF6	TQF7
Reset	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Figure 40-25. Port Event /Mask Register

Table 40-21 provides field descriptions for the port event/mask register.

Table 40-21. Port Event /Mask Register Field Descriptions

Bits	Field	Description
3	CBPR	In half-duplex mode Change Back Pressure 0 - No change in back pressure state 1 - The UCC transmitter has entered the back pressure state; OR the UCC has exited the back pressure state. OR In full duplex mode Change Pause 0 - No change in PAUSE state. 1 - The UCC transmitter has entered the PAUSE state (i.e. it has received a PAUSE frame and its transmitter is currently not transmitting on the line); OR the UCC has exited a PAUSE state (i.e. either the MAC parameter time has expired, or a PAUSE frame with MAC parameter zero has been received). The status of the UCC transmitter is reflected in the UCCS Register.
16	GRA	Graceful stop complete. A graceful stop, initiated by the graceful stop transmit command, is complete. When the command is issued, GRA is set as soon the transmitter finishes sending a frame in progress. If no frame is in progress, GRA is set immediately.
17	HC	Hashing conflict occurred. (Set when frame arrives from the current port) - when this occurs clear the whole ADLT and select new preset_crc value
18	CTQF	CPU Transmit queue(s) is full. The port failed to write new frame to one (or more) CPU transmit queues due to full CPU transmit queue(s).

Table 40-21. Port Event /Mask Register Field Descriptions (continued)

Bits	Field	Description
19	TXE	TX Error. A severe Tx error occurred on the transmitter channel: late collision or underrun or excessive defer or retransmission limit reached.
0-2,4-15, 20-21	-	Reserved, should be cleared.
22	GFC	Global Flow Control event. Stop CPU transmission.
23	MF	Memory is full. No room for new frames. The current incoming frame was dropped.
24	TQF0	Port0 Transmit queue(s) is full. The port failed to write new frame to one (or more) Port0 transmit queues due to full transmit queue(s).
25	TQF1	Port1 Transmit queue(s) is full. The port failed to write new frame to one (or more) Port1 transmit queues due to full transmit queue(s).
26	TQF2	Port2 Transmit queue(s) is full. The port failed to write new frame to one (or more) Port2 transmit queues due to full transmit queue(s).
27	TQF3	Port3 Transmit queue(s) is full. The port failed to write new frame to one (or more) Port3 transmit queues due to full transmit queue(s).
28	TQF4	Port4 Transmit queue(s) is full. The port failed to write new frame to one (or more) Port4 transmit queues due to full transmit queue(s).
29	TQF5	Port5 Transmit queue(s) is full. The port failed to write new frame to one (or more) Port5 transmit queues due to full transmit queue(s).
30	TQF6	Port6 Transmit queue(s) is full. The port failed to write new frame to one (or more) Port6 transmit queues due to full transmit queue(s).
31	TQF7	Port7 Transmit queue(s) is full. The port failed to write new frame to one (or more) Port7 transmit queues due to full transmit queue(s).

40.10.3 Port Status Register (UCCS)

The UCCS contains the real time status of the port transmitter.

PORT STATUS REGISTER

	0	1	2	3	4	5	6	7
Field	-	-	-	-	-	-	-	BPR
Reset	0	0	0	0	0	0	0	0

Figure 40-26. Port Status Register

Table 40-22 provides field descriptions for the port status register (read only).

Table 40-22. Port Status Register Field Descriptions

Bits	Name	Description
0-6	-	Reserved
7	BPR	Back Pressure (in half-duplex mode) 0 - UCC is not in back pressure state 1 - The UCC Transmitter is in back pressure state OR Pause State (in full duplex mode) 0 - The UCC is not in PAUSE state. 1 - The UCC transmitter is in PAUSE state and is not transmitting on the line.

40.11 Switch/Ports Commands

40.11.1 Command Register

The transmit and receive commands described in the following sections are issued to the CECR.

The CPU should set CECR[FLG] when it issues a command and the QUICC Engine block clears FLG after completing the command, thus indicating to the core that it is ready for the next command. Subsequent commands to the CECR can be given only after FLG is clear.

40.11.2 Ports Commands

The QUICC Engine port command opcodes are shown in Table 40-23

Table 40-23. Ports Command Descriptions

Command	Opcode	Description
init Tx and Rx params	000000	See in CECR description (MCN=0x0d)
init Rx params	000001	See in CECR description (MCN=0x0d)
init Tx params	000010	See in CECR description (MCN=0x0d)
graceful stop Tx	000101	See in CECR description (MCN=0x0d)
restart Tx	000110	See in CECR description (MCN=0x0d)
SWITCH COMMAND	000111	Switch commands. See Section 40.11.3, “Switch Commands”

40.11.3 Switch Commands

Before issuing the command, the user should initialize the Switch command opcode (SWCO) and COMM_INFO1/2 (if needed) fields in the Switch PRAM.

For specific switch commands (SWCO=0x04/05/06/07), the core should set the SBC field (in CECR) to the desired UCC.

For general switch commands (SWCO!=0x04/05/06/07), the core can set the SBC field (in CECR) to any UCC which is a switch port.

The QUICC Engine switch command opcodes are shown in Table 40-24

Table 40-24. Switch Command Descriptions

Switch Command	Switch Command Opcode (SWCO)	COMM_ INFO1	COMM_ INFO2	Description
Update VDT Entry	0x00	VDT Entry	-	This command adds/updates one VID entry to/in the VLAN Destination Table.
VDT lookup	0x01	{VID, 20'h0}	-	This command returns the SP[0:8] and DP[0:8] of a VID in the VDT. Value is returned on COMM_INFO1[12:29] (if not found, value is 0).
Update ADLT Entry	0x02	ADLT Entry (first 32bits)	ADLT Entry (last 32bits)	This command adds/updates one entry to/in the ADLT. This command can be useful to create multicast groups as a result of IGMP snooping control packets or to create locked entries.
ADLT lookup	0x03	MAC address (first 32bits)	{last 16bit of MAC address, 0x0000}	This command returns the GDA[0:8] of a MAC address in the ADLT. Value is returned on COMM_INFO2[16:24] (if not found, value is 0).
Disabled_ Port	0x04	-	-	The port is closed for all types of frames. The ADLT is not updated.
Forwarding _Port	0x05	-	-	Regular operation (default mode)
Blocking/ Listening_ Port	0x06	-	-	The port is open (incoming and outgoing) only for BPDU frames. All other frames are dropped and the ADLT is not updated.
Learning_ Port	0x07	-	-	The port is open (incoming and outgoing) only for BPDU frames. All other frames are dropped, but the ADLT is updated for new good frames
Reset_ ADLT	0x08	-	-	This command resets the ADLT. May be used when hash conflict interrupt is asserted. During the reset period input frames are treated as frames with unknown destination addresses.
Reset_VDT	0x09	-	-	This command resets the VDT.
CPU Tx Command	0x0A	-	-	This command is used as a trigger for forwarding packet from the CPU to the switch (TCBD). The CPU uses this command when it has a full packet for the switch in external memory.
Aging Enable	0x0B	-	-	Enable the Aging mechanism. The aging routine will be done automatically by the QUICC Engine block. See Section 40.3.6, "Address Aging"
INIT_CPU	0x0C	-	-	Init parameters of CPU PRAM and some switch PRAM parameters.

40.12 Parameter RAM

40.12.1 Parameter RAM Map

The switch parameter RAM is used to configure the L2 switch. The QUICC Engine block also uses the PRAM to store operational and temporary values used during the switch activities. The switch parameter RAM is divided to 3 memory spaces. The first area (Port PRAM) serves the UCC (one space per each port), the second is dedicated for the CPU (CPU PRAM), and the last is the switch PRAM that serves all the ports and includes the basic switch operation modes.

40.12.2 Switch PRAM

The switch PRAM is mapped as shown in Table 40-25. It occupies 256 bytes. Addresses not mapped within it are reserved for QUICC Engine block internal usage.

Table 40-25. Switch PRAM Configuration

Offset	Name	Width	Description	User Writes
0x00	SWPAR	Word	Switch Parameters Register. See in Section 40.13, "Switch Tables" for more information.	UD
0x04	VDT_BASE	Word	VLAN Destination Table Base pointer	UD
0x08	VDT_MASK	Half word	This field fixes the VDT size (VDT size must be a power of 2) VDT_END = VDT_BASE + (VDT_MASK + 1)* 4 or VDT_MASK = (VDT SIZE / 4) - 1	UD
0x0A	ADLT_MASK	Half word	This field fixes the ADLT size (ADLT size must be a power of 2) ADLT_END = ADLT_BASE + (ADLT_MASK +1)* 32 or ADLT_MASK = (ADLT SIZE / 32) - 1	UD
0x0C	ADLT_BASE	Word	Address Learning Table Base pointer	UD 8 byte aligned
0x11	LOWEST_PR	Byte	Mapping of lowest priority (possible values 0:3)	UD
0x12	HIGHEST_PR	Byte	Mapping of highest priority (possible values 0:3)	UD
0x14	Internal_DBufferPTR	Word	The Base pointer for the internal data buffer (for the first M high priority BDs). This pointer points to the base buffer of BD# 0.	UD
0x18	PMT	Half word	Priority Mapping Table. See in Section 40.13, "Switch Tables" for more information.	UD
0x20	DPSV	Half word	Destination Port Status Vector. The port is open or closed for transmitting data. The value of this vector is determined by the CPU according to spanning tree (BPDU) packets. DPSV[0–6] Reserved, should be cleared. DPSV[7–15] [P0,P1,...,P7,**1**]	UD
0x22	IGDP	Half word	IGMP Destination Ports. IGMP packets are delivered to these ports: IGDP[0:6] = Reserved, should be cleared. IGDP[7:15] = [P0,P1,...,P7,CPU] Note: In case of tag mode, all these destination ports also have to be a members of the IGMP packet's VID.	UD
0x24	GFrame_Cnt	Byte	Global Frame Counter. The current number of frames in the memory.	0x00
0x25	GFrame_Hlimit	Byte	High Global Threshold. If the number of frames in memory is equal to this value, the switch starts to send pause packets to all ports.	UD
0x26	GFrame_Llimit	Byte	Low Global Threshold. If the number of frames in memory is equal to this value, the switch stops the flow control mechanism.	UD
0x27	SMSNUM	Byte	Switch MSNUM (for CPU routine)	UD
0x28	FC	Byte	FC vector [P0,P1,.....,P7]	

Table 40-25. Switch PRAM Configuration (continued)

Offset	Name	Width	Description	User Writes
0x2B	SWCO	Byte	Switch Command Opcode. See Section 40.11.3, “Switch Commands”	UD
0x2C	HConflict_cnt	Word	Hash Conflict counter	
0x34	Preset_CRC	Word	Preset value of CRC	0xFFFFFFFF
0x38	BD_BASE	Word	BDs Base pointer	UD
0x3C	BDPTR_TBL	Word	BDs Pointer Table. BDs external data pointer	UD
0x50	FEL_BASE	Word	First Empty List Base pointer (although its word aligned, bit[31] indicating full must be initialized with 1)	UD word aligned Bit[31] = 1
0x54	FEL_END	Word	First Empty List End pointer. Byte per entry.	UD
0x58	FEL_WPTR	Word	First Empty List Write pointer	{FEL_BASE [0:30]<<1}
0x5C	FEL_RPTR	Word	First Empty List Read pointer	{FEL_BASE [0:30]<<1}
0x60	SEL_BASE	Word	Second Empty List Base pointer (although its word aligned, bit[31] indicating full must be initialized with 1)	UD word aligned Bit[31] = 1
0x64	SEL_END	Word	Second Empty List End pointer. Byte per entry	UD
0x68	SEL_WPTR	Word	Second Empty List Write pointer	{SEL_BASE [0:30]<<1}
0x6C	SEL_RPTR	Word	Second Empty List Read pointer	{SEL_BASE [0:30]<<1}
0x70	IPMT	Word	IP Priority Mapping Table. PR[0:15] See Section 40.13, “Switch Tables” for more information.	UD
0x74	IPMT	Word	IP Priority Mapping Table. PR[16:31]	UD
0x78	IPMT	Word	IP Priority Mapping Table. PR[32:47]	UD
0x7C	IPMT	Word	IP Priority Mapping Table. PR[48:63]	UD
0xBC	MFLR	Half word	Maximum frame length allowed (not including four FCS bytes) Typically 1514 in basic mode or 1518 in tag mode. Jumbo frames are also supported.	UD
0xBE	MINFLR	Half word	Minimum Frame Length allowed, not including FCS (typically 60 decimal).	UD
0xC4	Next_Entry	word	The next aging entry	ADLT_BASE
0xC8	ATU	word	Aging Time Unit. See Section 40.3.6, “Address Aging”	UD
0xD0	COMM_INFO1	Word	This field is used for command information. First 32 bits.See Section 40.11.3, “Switch Commands”	UD
0xD4	COMM_INFO2	Word	This field is used for command information. Second 32 bits. See Section 40.11.3, “Switch Commands”	UD
0xDC	EXRAM_PORT0	Word	Port0 PRAM base pointer.	0x0000_8400

Table 40-25. Switch PRAM Configuration (continued)

Offset	Name	Width	Description	User Writes
0xE0	EXRAM_PORT1	Word	Port1 PRAM base pointer.	0x0000_8500
0xE4	EXRAM_PORT2	Word	Port2 PRAM base pointer.	0x0000_8600
0xE8	EXRAM_PORT3	Word	Port3 PRAM base pointer.	0x0000_9000
0xEC	EXRAM_PORT4	Word	Port4 PRAM base pointer.	0x0000_8000
0xF0	EXRAM_PORT5	Word	Port5 PRAM base pointer.	0x0000_8100
0xF4	EXRAM_PORT6	Word	Port6 PRAM base pointer.	0x0000_8200
0xF8	EXRAM_PORT7	Word	Port7 PRAM base pointer.	0x0000_8300
0xFC	EXRAM_CPU	Word	Port8 (CPU) PRAM base pointer	UD

40.12.3 Port (UCC) PRAM

Each UCC PRAM area begins at the same offset from each UCC base area.

The UCC PRAM is mapped as shown in Table 40-26.

Table 40-26. Port PRAM Configuration

Offset	Name	Width	Description	User Writes
0x00	PPAR	Word	Port Parameters Table. See Section 40.13, “Switch Tables” for more information.	UD
0x04	RISC ALLOCATION	Byte	Risc allocated for the UCC 0x01 - RISC1 0x02 - RISC2	UD
0x05	RXIDLE	Byte	Internal variable	
0x08	RSTATE	Word	bus mode and Rx internal state	BUSMode,24’h0
0x0C	TSTATE	Word	bus mode and Tx internal state	BUSMode,24’h0
0x18	SWPRAM	Word	Switch PRAM Base pointer	UD
0x1C	DTTE	Byte	Internal variable. Initialize to value = 0x10	0x10
0x1D	DMFF	Byte	Internal variable. Initialize to value = 0xFF	0xFF
0x1E	DTTL	Byte	Internal variable. Initialize to value = 0x40	0x40
0x34	Port_Mirror	Half Word	a bit set for one of the ports makes it a mirror of the source port. [7’b0,P0,P1,.....,P7,CPU]	UD
0x80	PDT	Half word	Port Designation Table PDT[0–6] Reserved, should be cleared. PDT[7–15] [P0,P1,...,P7,CPU]	UD PDT[0–6]=0
0x90	Type_or_Len	Half Word	Internal variable. Initialize to value = 0x0600	0x0600
0x92	DTag	Half word	Default Tag = [PR(3bits),CFI(1bit),VID(12bits)] In tag mode, the switch may add or replace the original tag with the default tag. Each port has its own default tag (VID and priority).	UD
0x94	PFrame_Cnt	Byte	Port Frame Counter.The number of the frames (that arrived from this port) in the memory.	0x00

Table 40-26. Port PRAM Configuration (continued)

Offset	Name	Width	Description	User Writes
0x95	PFrame_Hlimit	Byte	High Port Threshold. If the number of frames from this source port in memory is equal to this value, the switch starts to send pause packets to this SP.	UD
0x96	PFrame_Llimit	Byte	Low Port Threshold. The switch stops the Flow Control mechanism when the number of frames (from this SP) in memory is equal to this value.	UD
0x98	Extra Tag TYPE	Half Word	Extra (Service) Tag Type (distinct from 0x8100)	UD
0x9a	Extra Tag ID	Half word	Extra (Service) Tag ID	UD
0x9C	SECEC	Word	Security Error Counter. See Section 40.5.3.1, “Security Problems”	
0xA0	MISSC	Word	Miss Counter. Destination port was not found.	
0xA4	MFLEC	Word	MEM Full Counter. Packet dropped due to full memory.	
0xA8	CRCEC	Word	Receive FCS Error Counter.	
0xAC	ALEC	Word	Receive Alignment Error Counter.	
0xB0	OREC	Word	Receive Overrun Error Counter.	
0xB4	COLC	Word	Receive Collision Counter (a collision occurred during frame reception)	
0xC0	TQ_BASE	Word	TQ Table Base pointer	UD 8 byte aligned
0xC4	TQ0_MAX_CNT	Byte	TQ0 Weighted Priority. Maximum continuous frames from TQ0.	UD
0xC5	TQ1_MAX_CNT	Byte	TQ1 Weighted Priority. Maximum continuous frames from TQ1.	UD
0xC6	TQ2_MAX_CNT	Byte	TQ2 Weighted Priority. Maximum continuous frames from TQ2.	UD
0xC7	TQ3_MAX_CNT	Byte	TQ3 Weighted Priority. Maximum continuous frames from TQ3.	UD
0xDC	TxDFT_Cnt	Word	Transmit Defer Counter. Deferring while trying to transmit the frame.	
0xE0	TxCRS_Cnt	Word	Transmit Carrier Sense Counter. Carrier sense lost during frame transmission.	
0xE4	TxUN_Cnt	Word	Transmit Under Run Counter. Transmitter underrun condition while sending the frame.	
0xE8	TxLC_Cnt	Word	Transmit Late Collision Counter.	
0xEC	TxRL_Cnt	Word	Transmit Retransmission limit Counter. The transmitter failed to successfully send a massage due to maximum allowed repeated collisions number.	
0xF0	TxCL_Cnt	Word	The best estimate of the total number of collisions on this Ethernet segment.	
0xF4	TxEXD_Cnt	Word	Transmit Excessive Defer Counter.	
0xF8	Rx_RMON_BPTR	Word	Receive RMON Base pointer.	UD
0xFC	Tx_RMON_BPTR	Word	Transmit RMON Base pointer	UD

40.12.4 CPU PRAM

The CPU PRAM is mapped as shown in Table 40-27

Table 40-27. CPU PRAM Configuration

Offset	Name	Width	Description	User Writes
0x00	PPAR	Word	CPU Parameters Table. See Section 40.13, "Switch Tables" for more information.	UD
0x08	RSTATE	Word	bus mode and Rx internal state	BUSMode,24'h0
0x0C	TSTATE	Word	bus mode and Tx internal state	BUSMode,24'h0
0x30	Rx_TEMP_PTR	Word	Receive TEMP internal pointer (64 bytes buffer) for use with TCBDs	UD
0x34	Port_Mirror	Half Word	a bit set for one of the ports makes it a mirror of the source port. [7'b0,P0,P1,.....,P7,1'b0]	UD
0x40	RCBD_PR0_BPTR	Word	RCBD Priority0 Base Pointer	UD
0x48	RCBD_PR1_BPTR	Word	RCBD Priority1 Base Pointer	UD
0x50	RCBD_PR2_BPTR	Word	RCBD Priority2 Base Pointer	UD
0x58	RCBD_PR3_BPTR	Word	RCBD Priority3 Base Pointer	UD
0x80	PDT	Half word	Port Designation Table PDT[0–6] = PDT[15] = 0 PDT[7–14] = [P0,P1,...,P7]	UD PDT[0:6] = 0 PDT[15] = 0
0x90	Type_or_Len	Half Word	Internal variable. Initialize to value = 0x0600	0x0600
0x92	DTag	Half word	Default Tag = [PR(3bits),CFI(1bit),VID(12bits)] In tag mode, the switch may add or replace the original tag with the default tag. Each port has its own default tag (VID and priority).	UD
0x94	PFrame_Cnt	Byte	Port (CPU) Frame Counter. The number of the frames (that arrived from this port) in the memory.	0x00
0x98	Extra Tag TYPE	Half Word	Extra (Service) Tag Type (distinct from 0x8100)	UD
0x9a	Extra Tag ID	Half word	Extra (Service) Tag ID	UD
0x9C	SECEC	Word	Security Error Counter. See Section 40.5.3.1, "Security Problems."	
0xA0	MISSC	Word	Miss Counter. Destination port was not found.	
0xA4	MFLEC	Word	MEM Full Counter. Packet was dropped due to full memory.	
0xB0	TCBD_BPTR	Word	TCBD Base Pointer in external memory.	UD
0xB4	TCBD_CPTR	Word	TCBD Current Pointer	TCBD_BPTR
0xC0	TQ_BASE	Word	CPU TQ Table Base pointer.	UD 8 byte aligned
0xC4	TQ0_MAX_CNT	Byte	CPU TQ0 Weighted Priority. Maximum continuous frames from TQ0.	UD
0xC5	TQ1_MAX_CNT	Byte	CPU TQ1 Weighted Priority. Maximum continuous frames from TQ1.	UD
0xC6	TQ2_MAX_CNT	Byte	CPU TQ2 Weighted Priority. Maximum continuous frames from TQ2.	UD
0xC7	TQ3_MAX_CNT	Byte	CPU TQ3 Weighted Priority. Maximum continuous frames from TQ3.	UD
0xF8	RxfromCPU_ RMON_BPTR	Word	Receive from CPU RMON Base pointer	UD
0xFC	TxtoCPU_ RMON_BPTR	Word	Transmit to CPU RMON Base pointer	UD

40.13 Switch Tables

40.13.1 Switch Parameters (SWPAR)

SWITCH PARAMETERS

Figure 40-28. Port Parameters

Table 40-29. Port Parameters Table Entry

Bits	Field	Description
0–1	DPT	Destination Port Table selection. (Security Mode) 00 Use VDT (Only in tag mode). Discard the incoming frame if its VID not contained in the VDT. 01 Use VDT (Only in tag mode); Use PDT for the incoming frame if its VID is not contained in the VDT. 10 Use PDT (basic or tag mode) 11 Reserved
2	1Q	1Q Trunk. A port designated as a 1Q trunk port is enable to receive and transmit all VIDs (no checking of the associated source ports in VDT) - (only in Tag mode). 0 Normal port 1 1Q trunk
3	1D	1D Trunk. 1D trunk is a connection from the switch that passes only untagged traffic - (only in Tag mode). 0 Normal port 1 1D trunk Note: If the CPU is the source port, this field should be cleared.
4–5	PS	Port State. Each port can work in a different state as a consequence of the spanning tree protocol. 00 Disabled —The port is closed for any types of frames. The ADLT and the RMON counters are not updated. 01 Forwarding —Regular operation (default mode) 10 Blocking/Listening —The port is open (incoming and outgoing) only for BPDU frames. All other frames are dropped and the ADLT and the RMON counters are not updated. 11 Learning—The port is open (incoming and outgoing) only for BPDU frames. All other frames are dropped, but the ADLT is updated for any new good frame. Note: It is recommend to activate these modes by using switch command. See Section 40.11.3, “Switch Commands” Note: for the CPU source port, this field is set to 01 (Forwarding) by the firmware.
6	NDUT	Drop Untagged Frames - (only in Tag mode) 0 Drop untagged frames 1 Add default tag (VID + priority) to untagged frames
7	FDT	Force Default Tag (VID) - (only in Tag mode) 0 Do not force default tag 1 Force default tag
8	IGE	IGMP Enable. The switch can support IGMP snooping per port. 0 IGMP disable. IGMP packet is parsed as a normal frame. 1 IGMP enable
9	STE	Spanning Tree Enable. The switch can support spanning tree packets per port. 0 Spanning tree disable. BPDU packet is parsed as a normal frame. 1 Spanning tree enable

Table 40-29. Port Parameters Table Entry (continued)

Bits	Field	Description
10	AET	Add Extra (Service) Tag - (only in Tag mode) 1 - all frames are transmitted with Extra tag - used for double-tagging.
11	BCD	Broadcast Disable. The switch can drop all Broadcast frames in case of Broadcast storm. 0 Normal operation. 1 The port is closed for Broadcast traffic. The ADLT is updated for any new good frame. Note: If the CPU is the source port, this field should be 0.
12–13	IPP	IP Packets Priority 00 Use IP fields for priority mapping (for tagged and untagged frames) 01 Use IP fields for priority mapping only in case of untagged frame and tag priority in case of tagged frames. 10 Ignore IP priority (IPv4 & IPv6 priority fields). 11 Force default priority.
14-15	PPW[0:1]	Port Priority Weight. The switch uses fixed priority and/or Weighted Round Robin mechanism between the highest and the lowest priority queues: 00 Fixed priority. Polling always starts at TQ# 0. 01 Reserved. 10 Use a X0, X1, X2, X3 weighted priority. See the TQx_MAX_CNT field in Section 40.12.3, “Port (UCC) PRAM and Section 40.12.4, “CPU PRAM” for details. X0 = Max_TQ0_cnt X1 = Max_TQ1_cnt X2 = Max_TQ2_cnt X3 = Max_TQ3_cnt 11 Fixed priority and WRR - Polling always starts at TQ# 0, WRR for other queues. Use a X1, X2, X3 weighted priority. X1 = Max_TQ1_cnt X2 = Max_TQ2_cnt X3 = Max_TQ3_cnt
16	RET	Remove Extra (Service) Tag - (only in Tag mode) - used for double-tagging 1 - when a frame is received with 2 tags, the first tag is ommitted. When a frame is received with one tag, it is ommitted.
17	TRA	0 - no transparent mode 1 - Transparent mode - frame kept as is (no addition/removal of tag) (if TRA=1, bits RET,AET,FDT,1D should be cleared)
18-31	Reserved	Must be cleared

40.13.5 Bus Mode Register

This register was named ‘FCR’ in MPC82xx.

Figure 40-31 shows the format of the bus mode registers, which reside at TSTATE[0–7] and RSTATE[0–7] in Port/CPU PRAM.

Bits	0	1	2	3	4	5	6	7
Field	—		GBL	BO		CETM	DTB	BDB

Figure 40-31. Bus Mode Register (BMR)

BMR fields are described in Table 40-32.

Table 40-32. BMR Field Descriptions

Bits	Name	Description
0-1	—	Reserved, must be programmed to 0
2	GBL	Global. Indicates whether the memory operation should be snooped. 0 Snooping on the Coherent System Bus (CSB) is disabled. 1 Snooping on the Coherent System Bus (CSB) is enabled. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 24.1.8.2, “Serial DMA Mode Register (SDMR).”
3–4	BO	Byte ordering. Used to select the byte ordering of the buffer. 00, 01, 11 Reserved. 10 Big-endian byte ordering. As data is sent onto the serial line from the data buffer, the MSB of the buffer word contains data to be sent earlier than the LSB of the same buffer word.
5	CETM	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.
6	DTB	Indicates on what bus the data is located. 0 On the coherent system bus (CSB) 1 On the QUICC Engine secondary bus.
7	BDB	Indicates on what bus the BDs are located. 0 On the coherent system bus (CSB). 1 On the QUICC Engine secondary bus.

40.14 L2 Switch Initialization

The following fields should be programmed as described below when using the L2 switch:

1. PT in UEMPR should have a realistic value - its recommended not using the max value.
2. SCOV=0x01 in UESCR.
3. URMODE = UTMODE = 1 in GUEMR - fast protocol.
4. MODE = 0xC in GUMR.
5. CRE=1, PAD/CRC=0 in MACCFG2 register.
6. TERCE = 1, FTFE = 1 in UPSMR.

When programming the switch it is advised to do the following steps:

1) configure the I/O ports

2) configure the UCCs registers except for ENR,ENT bits in GUMR

3) initialize all the user-defined fields in the switch, ports and CPU PRAMs

4) execute init Tx and Rx commands for every switch port

5) execute INIT_CPU command

6) enable the UCCs by setting ENR,ENT bits in GUMR.

40.15 L2 Switch Port Removal

When removing a port from the L2 switch, it is advised to do the following steps:

1) execute Disabled_Port switch host command

2) check that RXIDLE in Port PRAM is equal to 0x00

3) check that all 4 TQs of the port are empty; i.e. check that

((PTQxWPTR==PTQxRPTR)&&~PTQx_BASE[31]) == 1 for x=0:3.

4) Reset ENR,ENT in UCC GUMR.

Chapter 41
E2AAL2 Microcode

This implementation of the ATM adaptation layer type 2 (AAL2) is compliant with the ITU-T recommendations I.363.2 and I.366.1. This section describes the functionality and data structures of AAL2 CPS, CPS switching, and SSSAR and is meant to be used as a supplement to the ATM controller chapter, see Chapter 32, "ATM Controller AAL0, AAL1, and AAL5."

41.1 Introduction

AAL2 enables the multiplexing of voice and data channels over a single ATM VC. The channels consist of packets transported within individual ATM cells (see Figure 41-1). Packet lengths are allowed to vary in order to accommodate bandwidth fluctuations of the individual channels. Each packet has a channel identifier (CID) so that each AAL2 user (channel) is uniquely identified by the triplet VP | VC | CID.

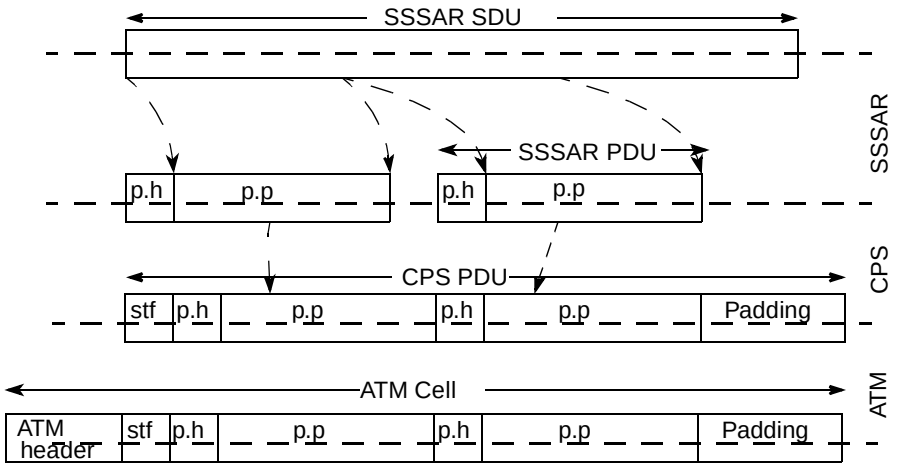

Figure 41-1. AAL2 Data Units

AAL2 is subdivided into two sublayers (see Figure 41-2): the common part sublayer (CPS) and the service-specific convergence sublayer (SSCS). In the CPS sublayer, variable length packets coming from multiple users are assembled into CPS-PDUs belonging to a single ATM VCC. The SSCS sublayer handles the mapping of user data to the CPS sublayer. The SSCS segments large data frames into smaller CPS packets and also provides different services to the user, such as transmission error detection. The SSCS sublayer is further divided into three service-specific layers: the service-specific segmentation and reassembly sublayer (SSSAR), the service-specific transmission error detection sublayer (SSTED), and the service-specific assured data transfer sublayer (SSADT).

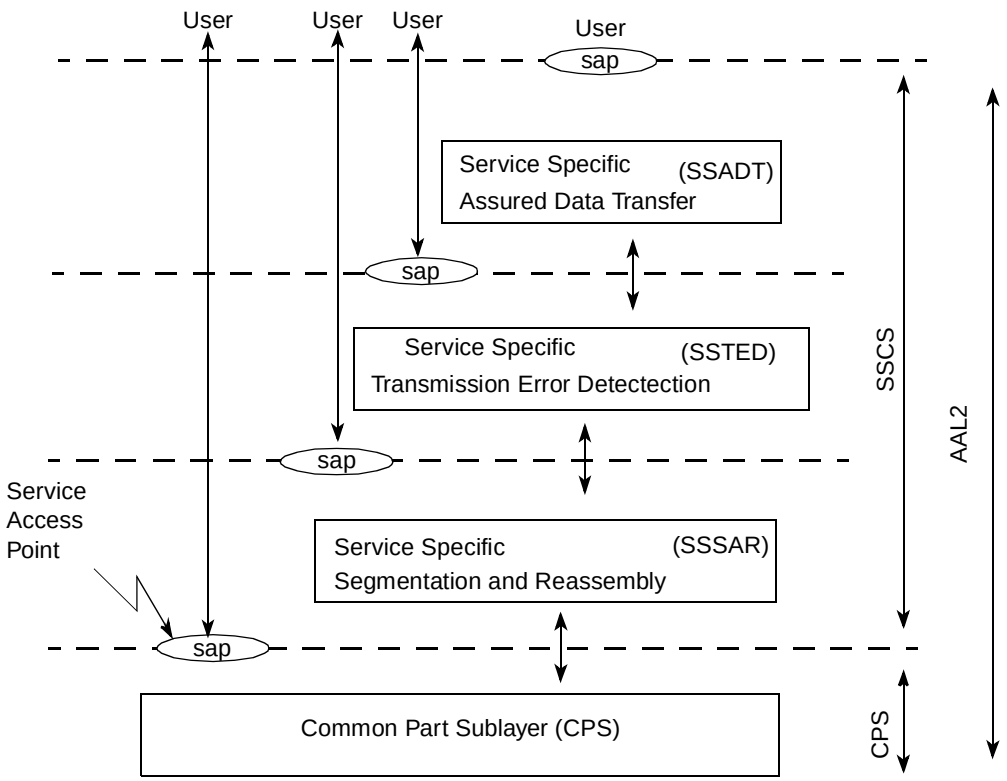

Figure 41-2. AAL2 Sublayer Structure

The AAL2 microcode implements the CPS and SSSAR sublayers. (The SSADT and SSTED sublayers are not implemented.) As shown in Figure 41-2, the user can access the CPS sublayer directly or through the SSSAR sublayer. The SSSAR sublayer is used mainly for transferring large data frames.

The AAL2 microcode also enables switching from one PHY | VP | VC | CID combination to another; an example is shown in Figure 41-3.

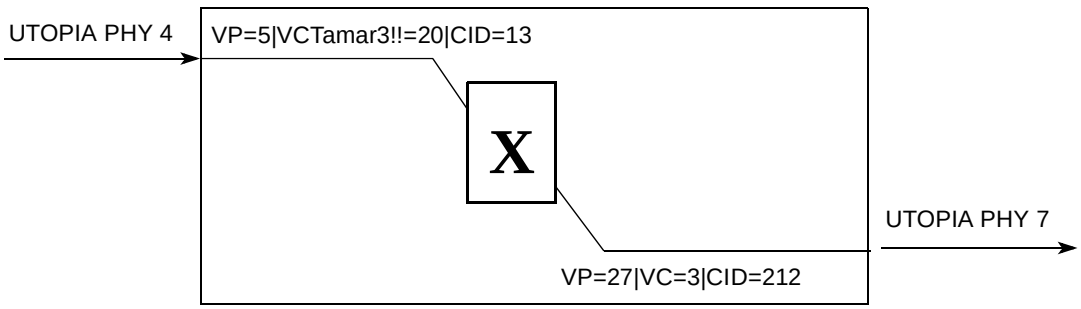

Figure 41-3. AAL2 Switching Example

41.2 Features

- Fully complies with ITU-T I.363.2 and ITU-T I.366.1 specifications.
- Supports up to 256 internal channels of AAL2
- Supports CBR, VBR, UBR+ and GBR traffic types.
  - PCR pacing
  - VBR pacing
  - UBR+ pacing
  - GBR pacing
- Priority mechanism for transmitting per VC. This allows for flexibility in prioritization of the Tx Queues.
- CNT_CU support.
- NoSTF mode support.
- Support for partially filled cells.
- User-defined cells (as described in the UDC section of the ATM controller chapter, see Section 32.2.16, "User-Defined Cells (UDC)."
- Interrupt indications include the ATM channel number, the CID, and the event type. The events reported are TX buffer not ready, TX buffer transmitted, RX buffer not ready, RX buffer, RX SSSAR frame, and RX AAL2 error events.
- Support CID MASKING - allows CID screening on a per channel basis. The packets with CID outside the mask are discarded.
- CPS switching
  - Switching from a receive PHY_1 | VP_1 | VC_1 | CID_1 combination to another transmit PHY_2 | VP_2 | VC_2 | CID_2 combination.
  - Receive one or multiple VP | VC | CIDs directly to a specific TX queue to enable switching.
  - When statistics mode is Enabled - for each switched queue, record a counter for discarded packets, due to unavailable Buffer Descriptors.
  - When statistics mode is Disabled - for each switched queue, a counter for the total number of packets in the queue is available.
  - Record counters for number of transmitted/received packets per CID.
  - Record counters for number of transmitted/received ATM AAL2 cells per VC.
  - The switch operation is independent of CPS/SSSAR traffic.
  - Partial packet discard support for SSSAR traffic.
  - Partial Packet Received Storage (PPRS) Mode.
  - Weighted Fair Queueing (WFQ) mode.
  - WFQ Thresholds interrupts.
  - WFQ APC Enhancements.
- CPS Receiver
  - Segmentation of CPS PDU directly to external memory queues.

  - A separate queue for every VP | VC | CID or a common queue for multiple VP | VC | CID combinations.
  - Sequence number (SN) protection check for CPS-PDU.
  - CRC5 (HEC) check to detect errors in the CPS-PH of the CPS-Packet
  - OSF (offset field) of the STF (start of frame) check (a valid value is less than 48)
  - An SDU length limit parameter (Max_SDU_Deliver_Length) per ATM VC.
  - Odd parity check for the STF octet of the CPS-PDU.
  - Record counters for number of received packets per CID.
  - Record counters for number of received ATM AAL2 cells per VC.
- CPS Transmitter
  - Reassemble CPS PDU directly from external memory.
  - Perform CPS-PDU padding as needed.
  - Insert Sequence Number bit of the CPS-PDU.
  - Parity bit is calculated to provide odd parity over the STF octet.
  - Calculation of CRC-5 on the first 19 bits of the CPS-PH.
  - UUI field in the CPS-Packet header is programmed according to the value of the CPS_UUI parameter (per packet).
  - A free running counter (per TX Queue) is decremented for each packet sent.
  - Record counters for number of transmitted packets per CID.
  - Record counters for number of transmitted ATM AAL2 cells per VC.
- SSSAR Receiver
  - Reassemble CPS packets from the same CID into a SSSAR SDU.
  - A separate queue for every PHY | VP | VC | CID.
  - Perform all the above mentioned CPS receiver functions.
  - The UUI field is stored for the host into the RxBD after receiving the whole SSSAR frame.
  - A Ras_Timer mode is provided. When the Ras_Timer expires the buffer is closed with a timer expired error. The next packet received starts a new SSSAR SDU in a new buffer.
  - The SDU length is checked. If the frame exceeds the length limit (SSSAR_Max_SDU_Length), the receiver discards the rest of the packets from the current frame, closes the buffer and reports a Max_SDU violation error in the BD. The next packet received starts a new SSSAR SDU in a new buffer.
  - Partial Packet Discard. If no buffer is available when a packet arrives, the receiver enters a frame hunt state and discards each incoming packet from the current frame.
  - Record counters for number of received frames per CID.
  - Record counters for number of received ATM AAL2 cells per VC.
- SSSAR Transmitter
  - Segmentation of SSSAR SDUs from SSSAR TX queue into CPS packets.
  - An SSSAR TX queue may contain several CIDs.
  - Performs all the above mentioned CPS transmitter functions.

— A programmable segment length (Seg_Len) is copied from the SSSAR SDU into the CPS packet payload, except for when at the end of the frame or buffer.
— UUI mode available. The UUI value of the last packet in the SSSAR frame defaults to 26. When UUI mode is enabled, the SSSAR UUI is copied from the byte following the last byte of the frame.
— Record counters for number of transmitted frames per CID.
— Record counters for number of transmitted ATM AAL2 cells per VC.

41.3 AAL2 Transmitter

The following sections describe the AAL2 transmitter.

41.3.1 Transmitter Overview

A transmitter cycle starts when the APC schedules an ATM channel number for transmission. The TCT is fetched and the AAL type of the channel is checked. For AAL2 cells, the transmitter first handles uncompleted packets from the previous cell of the current CID (partial and split cases) by filling the beginning of the cell with the remainder of the last packet.

Then, the transmitter performs the priority mechanism (see Section 41.3.2, “Transmit Priority Mechanism”) in order to fill the cell with new packets. The priority mechanism determines the order in which the TX queues are serviced. The transmitter continues to search for ready packets in the TX Queues until either the cell is successfully filled with packets, or no more packets are ready but the cell is not yet completed. In the first case the cell is simply sent. In the latter case, the optional CNT_CU (described in Section 41.3.5.1, “AAL2 Transmit Connection Tables”) is examined. If the CNT_CU has expired, meaning that the same channel was scheduled CNT_CU plus one iterations and still the cell is uncompleted, the uncompleted cell is padded with zeros and sent; otherwise, the cell is temporarily stored in external memory for the RISC to attempt to complete it the next time the channel is scheduled.

The TX queues are the data structures that store the CPS packets and SSSAR frames. Each TX queue can contain different CIDs. Each TX queue is maintained by a Tx queue descriptor (TxQD) that holds the queue pointer and parameters to manage the queue.

When the transmitter fetches a packet out of an SSSAR TX Queue, it usually takes out of the SSSAR buffer a number of octets equal to TxQD[Seg_Len] (see Section 41.3.5.5, “SSSAR Tx Queue Descriptor). The channel CID is taken from the BD of the first buffer of the SSSAR frame (see Section 41.3.5.6, “SSSAR Transmit Buffer Descriptor”). A CPS UUI = 27 is used for all the in-frame packets until the last packet from the SSSAR frame is sent. The last packet can optionally contain a per frame, user-defined UUI. After an SSSAR buffer is completely sent, an optional interrupt event is issued to the host. Also, if an SSSAR TX queue is empty an optional interrupt event is issued to the host.

In case of CPS TX Queue, the transmitter fetches the packet header out of a Buffer Descriptor and the packet payload out of a CPS buffer (see Section 41.3.5.4, “CPS Buffer Structure”). The HEC in the Packet Header is calculated by the RISC. After a CPS packet is sent, an optional interrupt event is issued to the host. Also, if the CPS TX queue is empty an optional interrupt event is issued to the host.

The optional partial filled mode (see Section 41.3.3, “Partial Fill Mode (PFM)”) limits the number of data octets per cell. This can be used to ensure that a cell does not contain a split packet or to limit transmission to one packet per TX cell by setting a low partial fill threshold (PFT).

The no-STF (no start of frame) mode (see Section 41.3.4, “No STF Mode”) enables the transmission of cells that do not include the STF byte, thus allowing for 48-byte packets.

41.3.2 Transmit Priority Mechanism

The transmit priority mechanism operates in the following modes:

- Round robin (TCT[Fix]=0).
- Fixed priority (TCT[Fix]=1).
- Weighted Fair Queueing (WFQ) mode.

The following sections describe the priority options.

41.3.2.1 Round Robin Priority

In round robin priority mode, the Tx queues all have equal priority. The transmitter starts with the TxQD pointed to by TCT[FirstQueue], as shown in Figure 41-4. The number of packets that the transmitter services from each queue is determined by the one-packet bit (TCT[OneP]). If TCT[OneP]=0, the transmitter tries to process as many packets in the queue as needed to fill up the cell. Only when the queue is empty does the transmitter move on to the next queue (assuming the cell is not completed). If TCT[OneP]=1, the transmitter attempts to take only one packet out of each queue. (Set TCT[OneP] for implementations where each queue contains only one CID.)

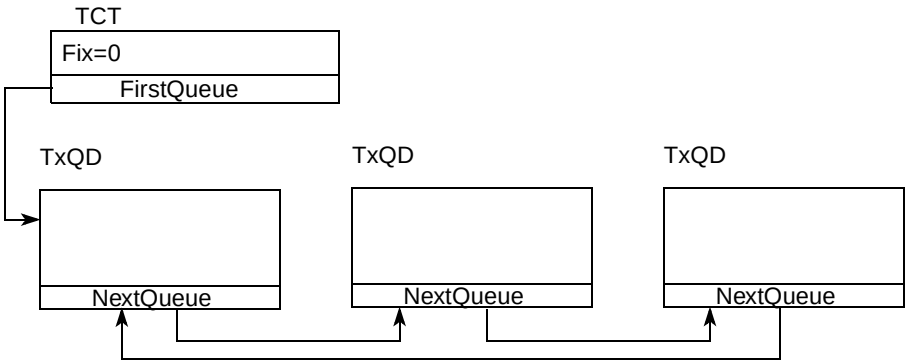

Figure 41-4. Round-Robin Priority

The transmitter steps from one TxQD to the next along the queue links. The TCT[MaxStep] parameter limits the number of TX Queues that the transmitter visits during a cell time. If MaxStep is reached before the cell has been completely filled, one of the following events takes place:

- TCT[ET]=0 (CNT CU disabled). The cell is padded with zeros and sent.
- TCT[ET]=1 (CNT CU enabled). If the Counter CU has not expired, the cell is not sent. (The transmitter attempts to fill the cell the next time this channel is scheduled.) If the Counter CU has expired, the cell is padded with zeros and sent.

After the transmitter sends a cell, it saves the queue link of the last TxQD serviced in TCT[FirstQueue].

41.3.2.2 Fixed Priority

In fixed priority mode (TCT[Fix]=1), the transmitter, with each new cell, starts with searching the highest priority queue and then moves on to the lower priority queues. The TCT[FirstQueue] points to the highest priority queue, as shown in Figure 41-5, and remains unchanged by the RISC.

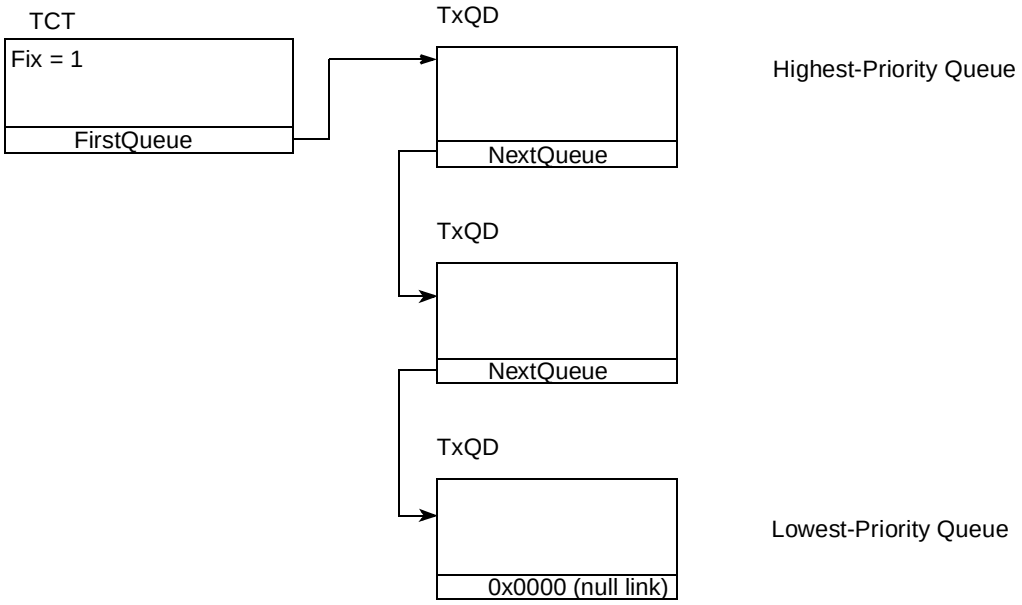

Figure 41-5. Fixed Priority Mode

The TCT[OneP] determines the number of packets that the transmitter attempts to take from each queue (see the explanation in round robin mode).

The NextQueue field of the lowest priority TxQD should be cleared (null link), and TCT[MaxStep] should be programmed to the total number of TX queues in the channel. When the transmitter reaches the null link and the cell is still not complete, the transmitter checks the TCT[ET] mode as described above for the round robin mode.

41.3.2.3 AAL2 Switch - Weighted Fair Queuing (WFQ) Prioritization

The Weighted Fair Queueing priority mode is enabled for an AAL2 channel by setting the TCT[WFQ_En] and RCT[WFQ_En] bits respectively. It is available for the AAL2 Switch mode only. This mode performs selection of up to four queues per channel, giving flexibility in scheduling and prioritization on a per queue basis.

The WFQ table contains a pointer to the TxQD base for this channel. An array of up to four TxQD is located in this memory location. These queues can be located in internal or external memory depending on the TCT[ExtTQD] bit. See Table 41-1.

This mode, when enabled, has enhanced queue management features which are important for switch mode. Another feature which could be invoked in this mode is scheduling which is based on the load of the system. The features are described in Section 41.4.3.1.1, “Queue Management” and in Section 41.4.3.1.2, “Automatic Bandwidth Allocation”.

Figure 41-6 describes the WFQ priority mode.

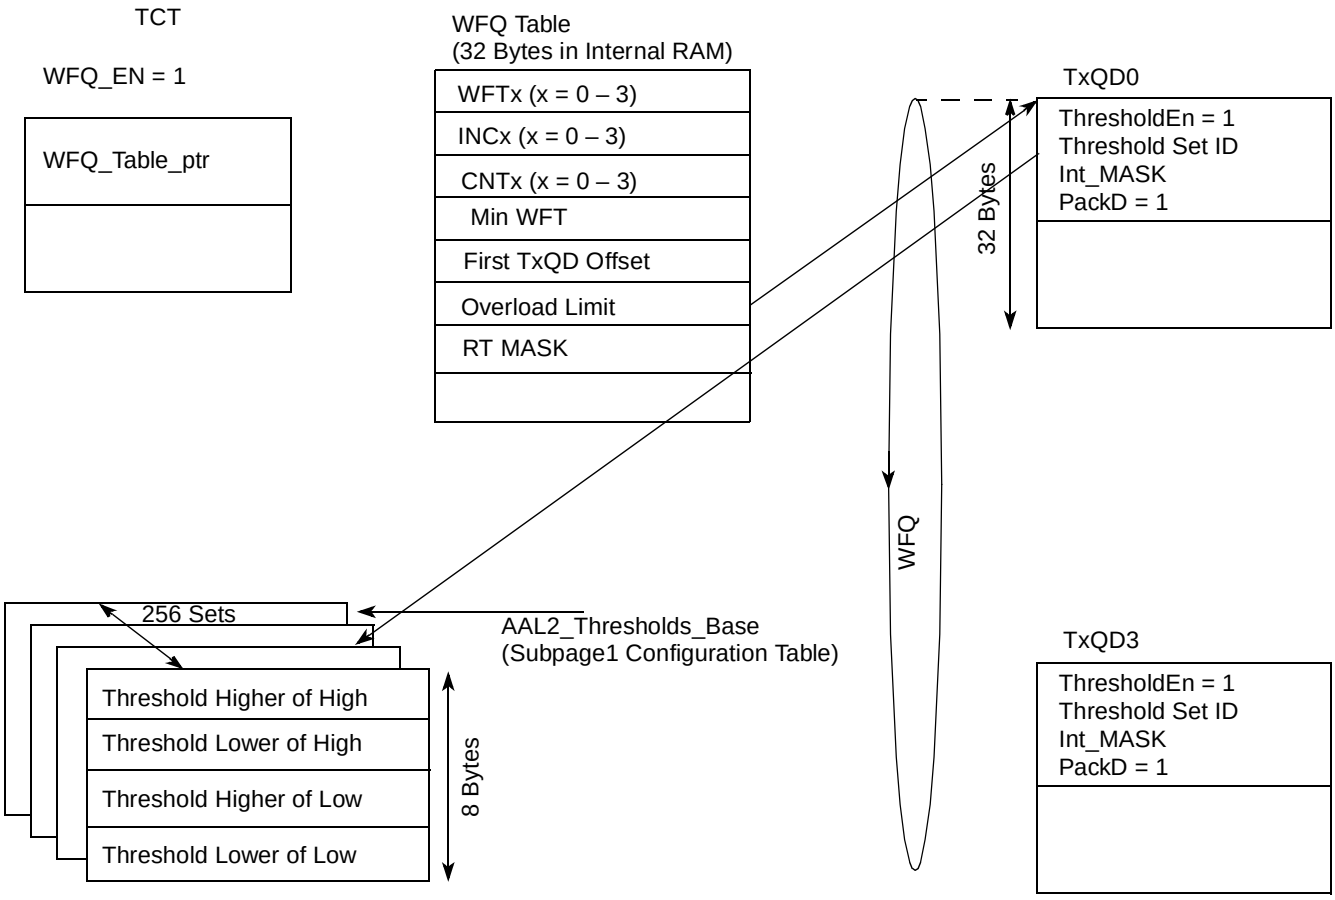

Figure 41-6. AAL2 WFQ Scheme

Each AAL2 channel supports up to four Tx queues (TxQDs) selected by the WFQ algorithm. These TxQDs are located consecutively in memory, each occupies 32 bytes. The first TxQD is pointed by the 'First_TxQD_offset' field in the WFQ Table. A queue is selected only if it has data ready for transmission. There is an automatic activation and deactivation of a queue by the receiver and transmitter respectively. This is done by setting and clearing the TxQD Queue Empty bit (QE) according to the number of packets in the queue which is maintained by the CNT entry of each queue.

When the transmitter has searched all the TxQDs and the cell is still not completed, the transmitter checks the TCT[ET] mode as described above for the round robin mode.

The WFQ table resides in the RAM and contains the management and parameters for the WFQ operation. (See Table 41-1) Each queue has a weight associated with it - WINC and scheduling is determined by this weight multiplied by each packet length.

NOTE

Since each weight is multiplied by the packet length factor, it is important that the weights would be as smaller as possible to improve performance (less WFT wrap scenario). Also the maximum value allowed for WINC is 511.

There are two modes of operation for queue selections. This is determined by the TCT[OneP] bit:

1. OneP mode is enabled - the WFQ selection is done for each packet in the cell.
2. OneP mode is disabled - the WFQ selection is done at the beginning of a cell (or after part condition), and the selected TxQD remains valid as long as there is data ready for transmission in this queue. Once there are no more packets to transmit, a new selection is done.

The formula for the setting the WINC value is:

i=0..3

TxQD#i packet rate = highest packet rate* (1/INCi)/[1/INC1+1/INC2+1/INC3+1/INC4]

41.3.2.3.1 WFQ Table

Under each TCT up to 4 TxQDs are available, therefore 4 weighted values are needed. The WFQ table occupies 32 bytes in RAM, and it is accessed by a pointer from the TCT[WFQ_Table_ptr].

Table 41-1. WFQ Table

Offset	Bits	Name	Width	Description
0x0-0x7	—	**WFTi (i=0..3)**	Hword *4	Weighted Finish Time. Eight 16 bit WFTs, one for each TxQD. The WFT is used to determine the finish time of the next packet being transmitted from the queue. WFT at offset zero corresponds to TxQD0, WFT at offset 0x06 corresponds to TxQD3. see Initialization instructions in Table 41-2
0x8-0xf	—	**WINC (i=0..3)**	Hword *4	Weighted Increment value. See Table 41-3.
0x10-0x17	—	CNTi (i=0..3)	Hword *4	TxQD Counter. Counts the number of packets in each TxQD. Should be initialized to 0.
0x18	—	**First TxQD Offset**	Hword	TxQD Base Address Offset. User initialized to the base address of the first TxQD entry. Could be internal or external memory address. Aligned to 32 bytes. In case TCT[ExtTQD]=1 this entry acts as an offset from TxQDExtBase address multiplied by 32. See Section 41.3.5.2, “External TxQD versus Internal TxQD”. **Note:** The user must allocate the TxQDs, if they resides in external memory, so that each TxQD occupies 32 bytes of memory, even that the actual TxQD size is 16 bytes.
0x1A	—	MinWFT	Hword	Initialized to 0. Used by the QUICC Engine block.

Table 41-1. WFQ Table (continued)

Offset	Bits	Name	Width	Description
0x1C	—	**Overload_Limit**	Hword	Overload Limit (in slot number units). When the number programmed in this field is zero this mode is **disabled**. APC scheduling: Overload Limit is given in slot number units. The maximum APC slot difference between [RPTR-SPTR] mod APC slot number, that behind it the APC would not send any best effort (BE) cell (assuming no RT cells are available). See Section 41.4.3.1.2, "Automatic Bandwidth Allocation". **Note:** If APC is working in scalable mode, and the Overload Limit mode is enabled, then the user must set the Ext_CS bit in the control slot, and allocate additional 4-6 bytes after the control slot, see Figure 32-53. GCRA scheduling: Overload Limit is given in time stamp units. The maximum time between the system time and the channel finish time in time stamp units, that behind it the APC would not send any best effort (BE) cell (assuming no RT cells are available), see Section 32.2.12, "GCRA Scheduler."
0x1E	0-3	**RT MASK**	—	Real-Time traffic Mask. Bits 0-3 identify which of the TxQDs are Real Time traffic (RT- masked by ones) and which of the queues are Best Effort traffic (BE masked by zeros). e.g. 0xc0- means that TxQD0 and TxQD1 are RT, and TxQD 3 and TxQD4 are BE. Valid only if Overload_limit is bigger than 0.
	4-7	RT MASK TMP	—	Should be cleared. Used by the QUICC Engine block.
	8-15	—	Byte	Reserved, should be cleared.

41.3.2.3.2 WFTi

Figure 41-7 shows the format of the Weighted Fair Queueing (WFQ) Finish Time entry. There are four such entries in the table, one for each queue. These entries are initialized by the CPU, and are not accessed by it when the switching function is enabled.

0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
QE	**FTM**													**QID**	

Figure 41-7. WFT Entry

Table 41-2 describes the WFT fields.

Table 41-2. WFT Field Descriptions

Bits	Name	Description
0	QE	TxQD Queue Empty. **Initialized to 1**. This will disable the transmission from this TxQD until the event of receiving a packet to this TxQD. **Note:** This bit is set automatically by the QUICC Engine block if the corresponding TxQD has no packets to transmit under its TxQD, and on the other hand this bit is cleared on the event of receiving a packet to this queue.
1-13	FTM	Finish time. This bit is automatically updated by the QUICC Engine block. **Initialize with zero**.
14-15	QID	TxQD ID. The CPU initializes the TxQD ID number in this field. This will be used as the index to the TxQD structure. Note that the QID is also part of the comparison algorithm, so if there is a case of 2 TxQDs with the same Finish Time values, the lowest TxQD will be selected.

41.3.2.3.3 INCi

Figure 41-8 shows the format of the Weighted Fair Queueing (WFQ) Increment entry. There are four such entries, one in each TxQD.

0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
—	INC													Reserved	

Figure 41-8. WINC Entry

Table 41-3 describes the WINC fields.

Table 41-3. WINC Field Descriptions

Bits	Name	Description
0		Reserved. Initialize to zero.
1–13	INC	Weighted Increment value. This value determines the relative bit rate for the TxQD. It is multiplied by each transmitted packet length in order to determine the next FTM value.
14–15		Reserved. Initialize to zero.

NOTE

The WFQ algorithm can implement Strict/Fixed Priority by setting INC=0 for all queues, or as round robin, by setting equal INC values for all queues.

41.3.3 Partial Fill Mode (PFM)

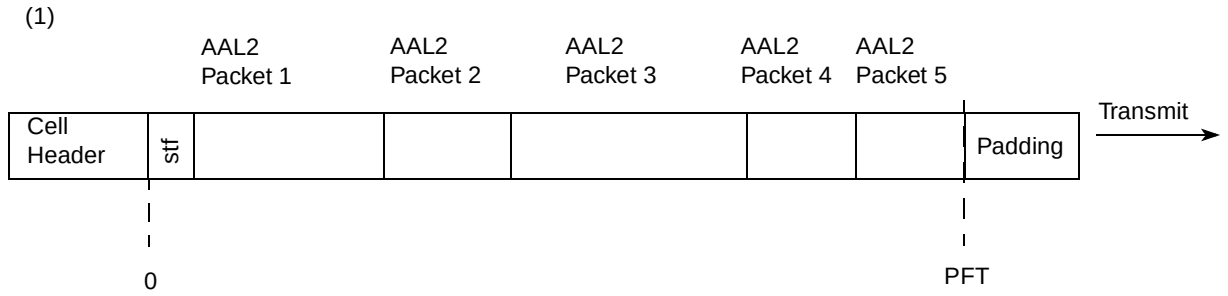
The partial fill mode (TCT[PFM]=1) allows the user to specify a partial fill threshold (TCT[PFT]), which limits the number of data octets sent with each ATM cell. Partial fill mode assures that packets are not split over two cells, unless the first packet of the cell is greater than 47 bytes.

In partial fill mode, the transmitter starts by filling the ATM cell with the first packet. After the first packet, the QUICC Engine block determines if including the next packet in the cell would exceed the PFT limit.

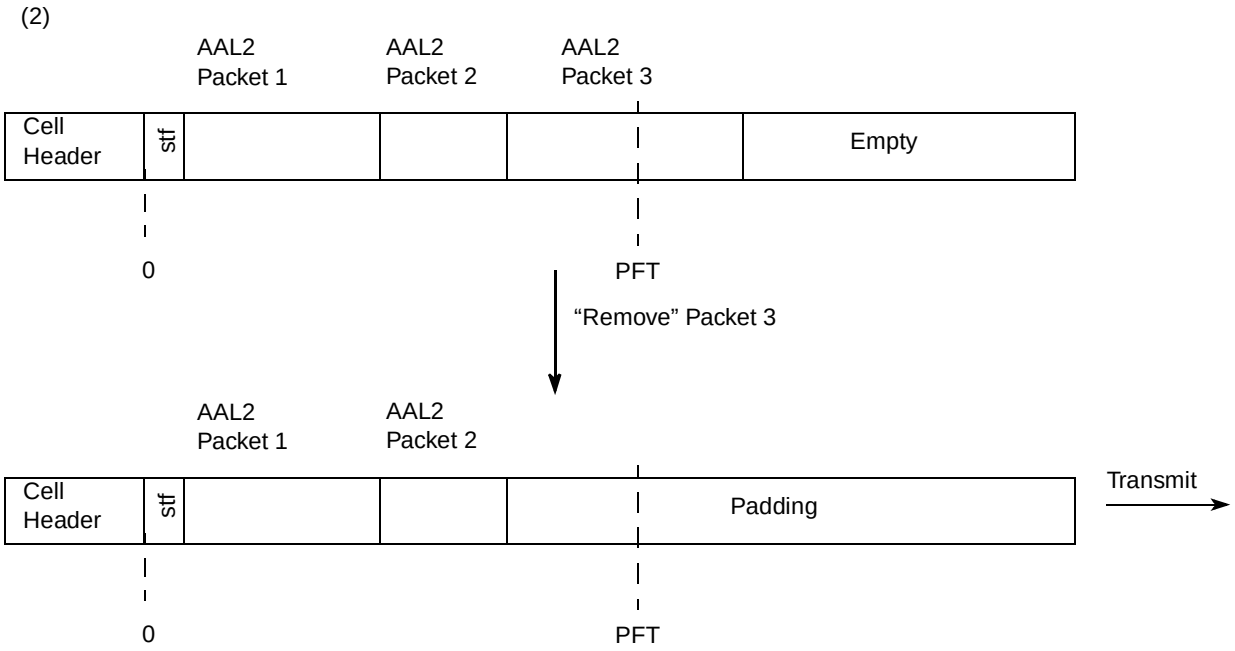
If so, the second packet is not inserted into the current cell, the unused payload is padded with zeros, and the cell is sent. If the second packet does not exceed PFT, the QUICC Engine block inserts it into the CPS_PDU and moves on to the third packet, and so on.

By programming PFT = 1, the partial fill mode can also serve to assure that only one packet is sent per cell.

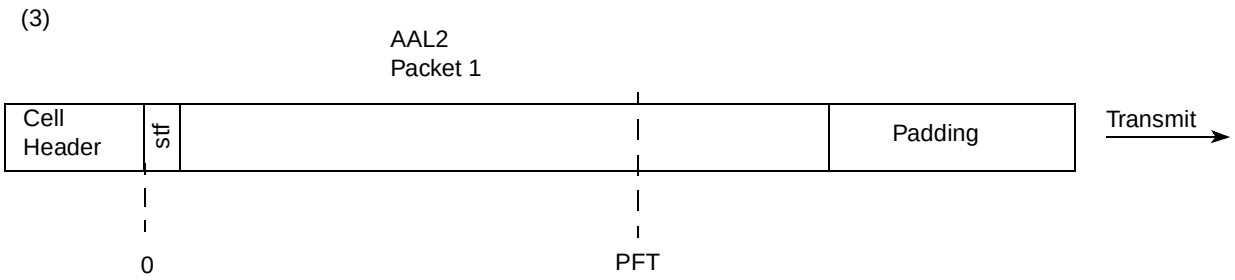
The following figures provide examples of partial fill mode operation:



In example (1), five packets fit exactly within the PFT limit.



In example (2), because PFT is less than the combined lengths of packet1, packet2 and packet3, the ATM cell is sent only with packets 1 and 2. (Packet3 will be sent with the next cell.)



In example (3), because the first packet exceeds the PFT value, the CPS-PDU consists only of this packet (and the unused octets are padded with zeros).

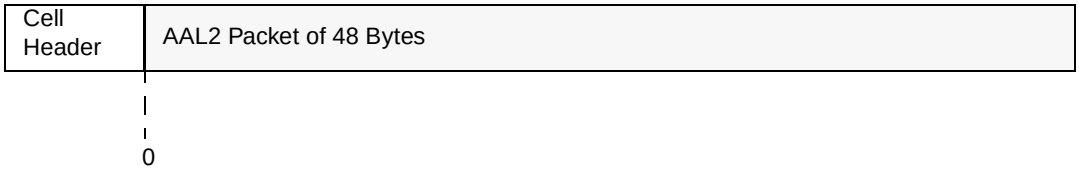
41.3.4 No STF Mode

The no-STF (no start of frame) mode enables the transmission of 48-byte packets by not including the STF byte in the CPS PDU. The no-STF mode should always be used with PFT programmed to 48 in order to prevent split and partial packets. For the AAL2 channels that use this mode, packets must not be larger than a maximum packet size of 48.

The user activates this mode per ATM channel by:

- setting the TCT[NoSTF] bit,
- and establishing a partial fill threshold by programming TCT[PFM]=1 and TCT[PFT]=48.

The following figure shows a cell using no-STF mode:



41.3.5 AAL2 Tx Data Structures

The following sections describe the TCT and the structures in which CPS packets and SSSAR SDUs are stored in memory.

41.3.5.1 AAL2 Transmit Connection Tables

The transmit connection table (TCT) is a VC-level table and is where the AAL type for the ATM channel number is selected. The parameters related to the ATM channel number or to all the TX Queues of the ATM channel are maintained here. Figure 41-9 shows the AAL2-specific TCT.

Figure 41-9. AAL2 TCT

NOTE

When the channel is active, the QUICC Engine block fetches the TCT (32 bytes) using burst cycle and writes back only the first (24 bytes).

Table 41-4 describes the AAL2 TCT fields.

Table 41-4. AAL2 TCT Field Descriptions

Offset	Bits	Name	Description
0x00	0–1	—	Reserved, should be cleared during initialization.
	2	**GBL**	Global. Setting GBL enables snooping of data buffers, BD, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	**BO**	Byte ordering. This field is used for data buffers. 00, 01, 11 Reserved. 10 Big endian.
	5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1 and Section 5.4.3.7, "Debug Configuration."
	6	**DTB**	Data buffer and UDC table bus selection. 0 Data buffers and UDC table reside on the coherent system bus. 1 Data buffers and UDC table reside on the secondary bus.
	7	**BDB**	Bus selection for the BDs, interrupt queues, the free buffer pool, etc. TxQD and the CID Statistics Tables (Only if they resides in external memory - TCT[ExtStatsAddr]=1). 0 Reside on the coherent system bus. 1 Reside on the secondary bus.
	8	**AVCF**	Auto VC off. Determines APC behavior when the last buffer associated with this VC has been sent and no more buffers are in the VC's TxBD table. 0 The APC does not remove this VC from the scheduling table and continues to schedule it to transmit. 1 The APC removes this VC from the scheduling table.Functionality of the APC varies depending on other setting in the system. If the TCT[VCON] bit is set, indicating that the automatic activation for switch mode is disabled, the QUICC Engine block removes the VC from the scheduling table. It clears the VCON bit indicating removal of the channel. In order to resume transmission the host has to initiate a new ATM TRANSMIT command is needed. If the TCT[VCON] bit is cleared, indicating that the automatic activation for switch mode is enabled, the QUICC Engine block removes the VC from the scheduling table. Transmission is resumed automatically by the receiver with no need for any host intervention. See Section 41.4.3, "AAL2 Switching" for more description.

Table 41-4. AAL2 TCT Field Descriptions (continued)

Offset	Bits	Name	Description
	9	**PFM**	Partial fill mode. See Section 41.3.3, "Partial Fill Mode (PFM)." 0 Partially filled cells are not supported. 1 Partially filled cells are supported.
	10–11	**ATT**	ATM traffic type 00 Peak cell-rate pacing (regular traffic). The host must initialize PCR and PCR fraction. Other traffic parameters are not used. 01 Peak and sustain cell rate pacing (VBR traffic). The APC performs a continuous-state leaky bucket algorithm (GCRA) to pace the channel-sustain cell rate. The host must initialize PCR, PCR fraction, SCR, SCR fraction, and BT (burst tolerance). 10 Peak and Minimum cell rate pacing. The host must initialize PCR, PCR fraction, MCR, MCR fraction, and MDA. 11 Guaranteed Bit rate mode (GBR traffic). The host must initialize PCR & PCR fraction fields in this TCT and in the corresponding TCTE. For detailed description see Section 32.3.4.3, "GBR Programming Model," on page 32-94.
	12	**ET**	Enable CNT_CU. 0 CNT_CU operation in this channel is disabled. 1 CNT_CU operation in this channel is enabled.
	13	**VCON (status)**	Virtual channel is on. Should be set by the host before it issues an ATM TRANSMIT command. When the host sets the STPT (stop transmit) bit, the QUICC Engine block deactivates this channel and clears VCON. The same applies When the TCT[AVCF] is set. The host activates this channel by an ATM TRANSMIT command only when the QUICC Engine block clears VCON.
		VCON (mode)	Cleared by the host to enable the automatic activation in switch mode - AVCON/AVCF mechanism. When this mode is enabled, the TCT[AVCF] bit should be set. See Section 41.4.3, "AAL2 Switching" for more description.
	14–15	**INTQ**	Points to one of the four interrupt queues available.
0x02	0–11	—	Reserved, should be cleared during initialization.
	12	**NoSTF**	No STF byte. See Section 41.3.4, "No STF Mode." 0 Normal AAL2 cell structure. 1 The cell does not include the STF byte. In this mode each cell starts with a new packet and contains only whole packets (no split or partial).
	13–15	**AAL**	AAL type 000 AAL0 —Segmentation with no adaptation layer 001 AAL1 —ATM adaptation layer 1 protocol. (Use this configuration for rev A parts only, unless needed for backwards compatibility to existing software development.) 010 AAL5 —ATM adaptation layer 5 protocol 011 AAL3/4 —ATM adaptation layer 3/4 protocol 100 AAL2 —ATM adaptation layer 2 protocol 101 AAL1 with CES —ATM adaptation layer 1 protocol with optional support for circuit emulation service. (For rev B and later parts, this configuration is strongly recommended for all AAL1 applications, with or without CES.) All others reserved.
0x04		—	Reserved, should be cleared during initialization.
0x06		—	Reserved, should be cleared during initialization.
0x08		—	Reserved, should be cleared during initialization.

Table 41-4. AAL2 TCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x0A		**FirstQueue / FirstQD_Offset /** **WFQ_Table_ptr**	If **WFQ_En** bit is cleared: Points to the first queue to be serviced in the transmitter cycle. In round-robin priority mode (TCT[Fix]=0), this pointer could point to any one of the TxQDs related to this channel. In fixed priority mode (TCT[Fix]=1), this pointer should point to the highest priority TxQD. In case TCT[ExtTQD]=1 this entry acts as an offset from TxQDExtBase address multiplied by 32. See Section 41.3.5.2, “External TxQD versus Internal TxQD”. If **WFQ_En** bit is set: WFQ Table pointer. Allocates 32 bytes for the WFQ management. Should be 8 bytes aligned. See Table 41-1.
0x0C	0–7	**Rate Remainder**	Rate remainder. Used by the APC to hold the rate remainder after adding the pace fraction to the additive channel rate. Should be cleared during initialization by the user.
	8–15	**PCR Fraction**	Peak cell rate fraction. Holds the peak cell rate fraction of this channel in units of 1/256 slot for APC Mode/ or in CETSCR 1/256 time units in case of GCRA schedule.
0x0E	—	**PCR**	Peak cell rate. Holds the peak cell rate (in units of APC slots for APC Mode/ or in CETSCR time unit in case of GCRA scheduler) permitted for this channel according to the traffic contract.
0x10	0–7	**CNT_CU**	Count CU. Valid only if TCT[ET] is set. If the channel was scheduled CNT_CU plus one iterations and still the cell is uncompleted, the uncompleted cell is padded with zeros and sent; otherwise it is temporary stored in external memory till the next scheduling. Assures that the CPS-packet already packed in a cell wait at most the average channel period multiplied by the ‘CNT_CU-1’.
	8–15	**CNT_CU_Shadow**	Count CU Shadow. Valid only if TCT[ET] is set. This field must be initialized to the CNT_CU value.
0x12	—	Res	Reserved, should be cleared during initialization.
0x14	—	Res	Reserved, should be cleared during initialization.
0x16	—	**APCLC/** **GCRA_BT**	**APC Mode:** APC linked channel. Used by the QUICC Engine block. Should be cleared during initialization. **GCRA Scheduler:** When working in GCRA scheduler mode, this field should be initialized to the Burst tolerance Limit of this channel in the TSR time unit, see Section 32.2.12.1, “GCRA Scheduler Rate Programming.”
0x18	—	**ATMCH**	ATM cell header. Holds the full (4-byte) ATM cell header of the current channel. The transmitter appends ATMCH to the cell payload during transmission.
0x1C	0–1	—	Reserved, should be cleared during initialization.
	2–7	**PMT**	Performance monitoring table. Points to one of the available 64 performance monitoring tables. The starting address of the table is PMT_BASE+PMT*32.
	8–15	**MaxStep**	Valid only if WFQ_En bit is cleared. Holds the number of TX Queues visited for each cell being prepared for transmission. In fixed priority mode (TCT[Fix]=1), MaxStep should be set to the total number of TX queues in the channel. See Section 41.3.2, “Transmit Priority Mechanism.”

Table 41-4. AAL2 TCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x1E	0	**WFQ_En**	Weighted Fair Queueing Enable. 0 - WFQ priority mode is disabled. 1 - WFQ priority mode is enabled. See Section 41.3.2.3, “AAL2 Switch - Weighted Fair Queuing (WFQ) Prioritization”. **Note:** All TxQDs under a TCT with WFQ_En bit set, must be AAL2 switch TxQDs.
	1	**StatsIE**	Statistics Interrupt Enable. 0 - Tx CID Statistics / ATM cell counters overflow interrupt is disabled. 1 - Tx CID Statistics / ATM cell counters overflow interrupt is enabled. SeeSection 41.3.5.7, “Transmitter Statistics Structure”.
	2–7	**PFT**	Partial fill threshold. Used for partially filled cells only; see Section 41.3.3, “Partial Fill Mode (PFM).” Specifies the maximum number of packet bytes allowed in a CPS PDU. The range 1–48 are valid values. If PFT=48 in partial fill mode, performance is adversely affected. When not in partial fill mode, PFT must be initialized to 47.
	8	**ExtTQD**	External TxQD. 0- TxQDs which belong to this TCT, are located in internal RAM. See Section 41.3.5.2, “External TxQD versus Internal TxQD”. 1- TxQDs which belong to this TCT, are located in external RAM. See Section 41.3.5.2, “External TxQD versus Internal TxQD”.
	9	**—**	Reserved, should be cleared.
	10	**ExtStats Addr**	Using External TxCIDStatsAddress Table or internal multi-user RAM TxCIDStatsOffset Table for getting the TxCID Statistics Table Entry location. See Section 41.3.5.7, “Transmitter Statistics Structure”. 0- TxCIDStatsOffset Table and the TxCID Statistics Table itself resides in internal multi-user RAM. The Offset in the TxCIDStatsOffset Table is the offset from internal RAM to the TxCID Statistics Table (which can consist up to 256 2 bytes CID counters) - which belongs to this Tx channel. 1- TxCIDStatsAddress Table and the TxCID Statistics Table itself resides in external memory. The Address in the TxCIDStatsAddress Table, which is of 4 bytes length, is the direct external address to the TxCID Statistics Table entry (which can consist up to 256 2 bytes CID counters) - which belongs to this Tx channel.
	11	**StatsEn**	Statistics mode Enable bit. 0- CID and Cell counters are disabled for this VC. 1- CID and Cell counters are enabled for this VC. See Section 41.3.5.7, “Transmitter Statistics Structure”.
0x1E	12	**OneP**	One packet per queue. Valid also when WFQ_En is set. See Section 41.3.2, “Transmit Priority Mechanism.” 0 The transmitter reads as many packets as possible from each TX queue before moving to the next queue. 1 The transmitter reads only one packet from each TX queue before advancing to the next queue.

Table 41-4. AAL2 TCT Field Descriptions (continued)

Offset	Bits	Name	Description
	13	**STPT**	Stop transmit. Should be cleared during initialization. This bit should not be used when AVCON/AVCF mode is enabled (other than debug purposes). When the host sets this bit, the QUICC Engine block removes this channel from the APC and clears TCT[VCON] flag. **Note:** When working in GBR mode, the sequence of stopping a channel is as follows: First the CBR priority takes the channel from the scheduling table and indicates to the UBR priority level to stop rescheduling the channel on the next appearance of it in the APC. At this point the TCT[VCON] bit is cleared
	14	**Fix**	Fixed priority. Valid only if WFQ_En bit is cleared. See Section 41.3.2, "Transmit Priority Mechanism." 0 Round robin priority. The TX Queues related to this channel all share the same priority. 1 Fixed priority. The TX Queues are ordered in a fixed priority ladder.
	15	**PM**	Performance monitoring 0 No performance monitoring for this VC. 1 Performance is monitored for this VC. When a cell is sent for this VC, the performance monitoring table indicated in PMT field is updated.
NOTE: Entries in boldface must be initialized by the user.			

41.3.5.2 External TxQD versus Internal TxQD

There is an option to use External TxQDs together with Internal TxQDs, in order to support up to 64K TxQDs. This mode is enabled, per channel (TCT), by setting TCT[ExtTQD]. The QUICC Engine block fetches the external TxQD by adding to the TxQDExtBase, see Table , the FirstQD_Offset/NextQD_Offset multiplied by 32. The TxQDExtBase and each TxQD located in external memory should be located in 32 bytes aligned address. Internal TxQDs should be located in address which is aligned to their size (CPS TxQD - 16 bytes, and Switch TxQD/ SSSAR TxQD 32 bytes). See Figure 41-10 for description of the External TxQDs Structure.

Selection of the Bus is according to TCT[BDB] bit.

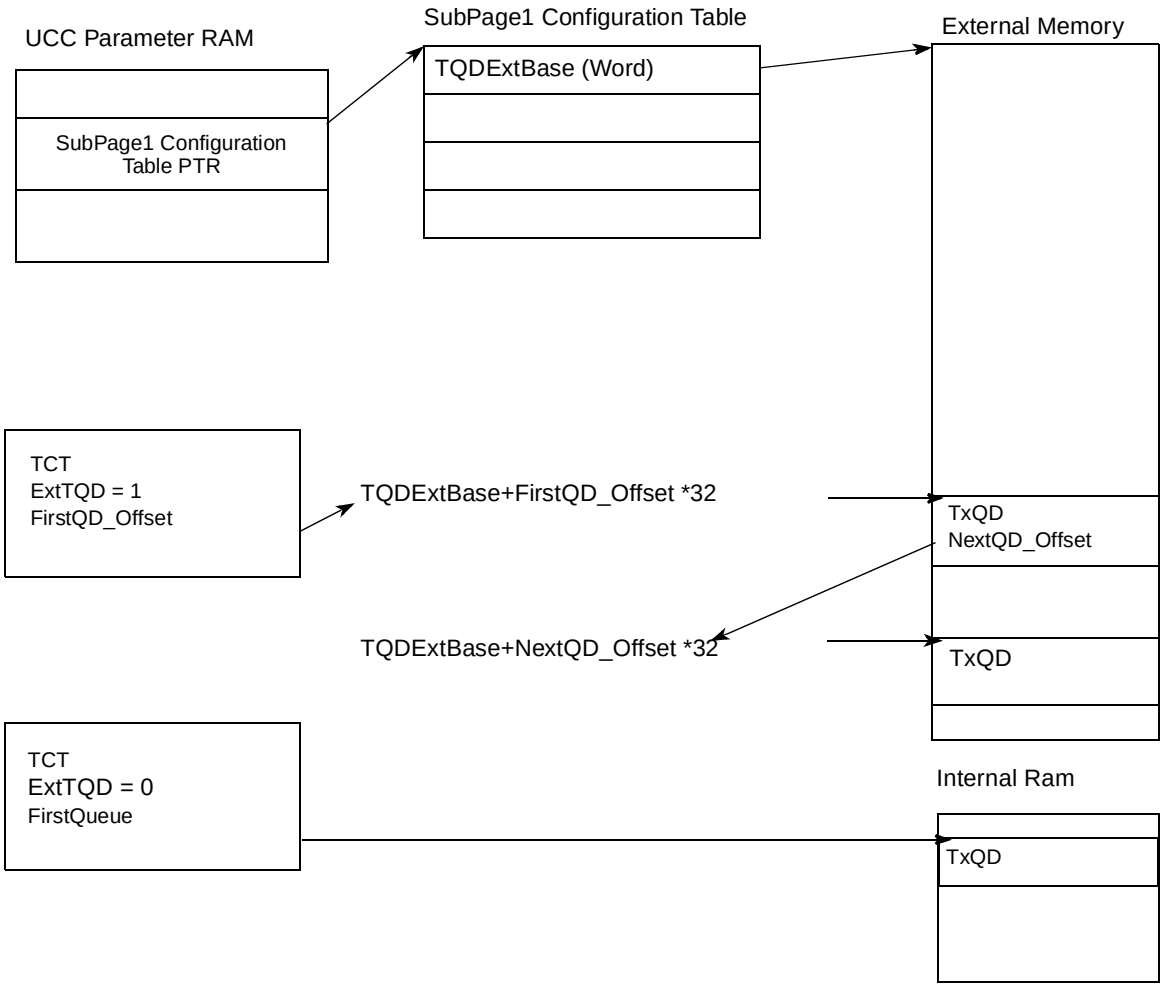

Figure 41-10. External TxQD Structure

41.3.5.3 CPS Tx Queue Descriptor

Each CPS TxBD table is managed by a CPS Tx queue descriptor (TxQD), as shown in Figure 41-11. The TxQD contains the address of the next BD to be serviced, and other queue-specific parameters. The NextQueue pointer is used to create a linked list of TxQDs, as described in Section 41.3.2, "Transmit Priority Mechanism." The CPS TxQD could be located in the multi-user RAM, or in external memory, and it consumes 16 bytes for non Switch CPS and 32 bytes for Switch CPS.

Figure 41-11. CPS Tx Queue Descriptor (TxQD)

Table 41-5 describes the CPS TxQD fields.

NOTE

When working in switch mode Type-1, and TxQD[PackD] bit is cleared - a number-of-packets-in-queue counter is available in the TxQD. The QUICC Engine block increments the counter for each packet received and decrements it for each packet sent. The host can poll the counter periodically to verify that the switching queues are not over-loaded.

With TxQD[PackD] bit is set, and working in switch mode (Type-1 or Type-2)- a number_of_discarded_packets counter is available in the TxQD. The QUICC Engine block increments this counter whenever a received packet is discarded due to unavailable buffers. When there is Overflow in number_of_discarded_packets counter, then a PackDOF event is issued in the interrupt queue. See Section 41.8.1, “Interrupt Entry for CID Statistics.”

When working in switch mode using Type-2 (see Figure 41-29), TxQD[PackD] bit must be set.

.

Table 41-5. CPS TxQD Field Descriptions

Offset	Bits	Name	Description
0x00	0–7	—	Reserved for internal use. (Used to save the BD status of the open BD.)
	8	**BNM**	Buffer not-ready interrupt mask of the TxBD table. 0 The transmit buffer-not-ready event for this queue is masked. (The event is not sent to the interrupt queue.) 1 The buffer-not-ready event for this queue is enabled.
	9	**SW**	Switching queue. 0 Normal TX Queue. 1 This TxQD handles a switching queue. The receiver and transmitter share this queue.
	10	**HEC**	HEC calculation. 0 Transmitter calculates the CPS header HEC. 1 The CPS header HEC is taken from the CPS buffer descriptor.
	11	**CPS**	Sublayer type. For a CPS TxQD, this field must be set. 0 SSSAR. 1 CPS packet.
	12	**TBM**	Transmit buffer interrupt mask. 0 The transmit buffer event of this queue is masked. (The event is not sent to the interrupt queue). 1 The transmit buffer event of this queue is enabled.
	13–14	—	Reserved, should be cleared during initialization.
	15	**PackD**	Packet Discard. This bit is relevant ONLY for Switch mode. For External TxQD this bit MUST be set to 1. 0 - Count number of packets in Queue (Only for Switch Type-1). 1 - Count number of discarded packets in Switched queue. When TCT[WFQ_En] is set then PackD should be set, since the number of packets in queue is available in the WFQ table (see Table 41-1).
0x02	—	**TxBD Table Offset In**	Used only when this queue is used for switching (SW=1). Should be cleared during initialization.
0x04	—	**TxBD Table Base**	This pointer points to the base address of the BD table. Should be 8 byte aligned.
0x08	—	**TxBD Table Offset Out**	Holds the offset from the TxBD table base to the next BD to be opened by the transmitter. Should be cleared during initialization.
0x0A	—	**Number of Packets In Queue/Discarded Packets**	It could have two different meanings: When TxQD[PackD]=0: ->Number of Packets in Queue This field is NOT valid when working with Switch Type-2. Counts the number of packets currently in the queue. If this queue is switch Type-1, then the receiver increments this counter with each new received packet and the transmitter decrements it with each packet sent. For switch Type-1, the user should initialize this counter to zero. When this queue is not switched, this counter counts down with every packet sent. (This can have various purposes such as evaluating the packet rate that is transmitted from this queue.). When TxQD[PackD]=1: -> Discarded packets. Relevant Only for Switched TxQD. Count the discarded packets for this Switched TxQD due to unavailable Buffer Descriptors (buffer BSY condition).

Table 41-5. CPS TxQD Field Descriptions (continued)

Offset	Bits	Name	Description
0x0C	—	**NextQueue/ NextQD_Offset**	**Valid only when TCT[WFQ_En] is cleared:** Points to the next TxQD to be serviced after this one. See Section 41.3.2, "Transmit Priority Mechanism." In case TCT[ExtTQD]=1 this entry acts as an offset from TxQDExtBase address multiplied by 32. See Section 41.3.5.2, "External TxQD versus Internal TxQD".
0x10	—	**SIZE**	**Valid For switch mode only.** Size of BD Ring, in byte units. e.g., if BD ring consists of n BDs then set this value to n*8.
0x12	—	**Queue Management**	**Valid only when TCT[WFQ_En] is set.** See details in Figure 41-12.
0x14–0x1F	—		Reserved. Should be cleared.

NOTE: Entries in boldface must be initialized by the user.

Figure 41-12 describes the Queue Management Field, which is valid for WFQ mode only.

Table 41-6. Queue Management Field description

Offset	Bits	Name	Description
0x12	0	**Thr_En**	**Valid only when TCT[WFQ_En] is set:** Threshold Enabled. Valid only when working in WFQ Mode (TCT[WFQ_En]=1). 0- Threshold mechanism is disabled. 1- Threshold mechanism is enabled. For more description see Section 41.4.3.1.1, “Queue Management”.
	1	**—**	reserved. Should be cleared.
	2	**Full Speed to Decelerate interrupt Mask**	**Valid only when TCT[WFQ_En] is set:** Full Speed to Decelerate interrupt Mask. 0 - this interrupt is disabled. 1 - this interrupt is enabled. For more description see Section 41.4.3.1.1, “Queue Management”.
	3	**Decelerate to Full Stop interrupt Mask**	**Valid only when TCT[WFQ_En] is set:** Decelerate to Full Stop interrupt Mask. 0 - this interrupt is disabled. 1 - this interrupt is enabled. For more description see Section 41.4.3.1.1, “Queue Management”.
	4	**Accelerate to Decelerate interrupt Mask**	**Valid only when TCT[WFQ_En] is set:** Accelerate to Decelerate interrupt Mask. 0 - this interrupt is disabled. 1 - this interrupt is enabled. For more description see Section 41.4.3.1.1, “Queue Management”.
	5	**Full stop to Accelerate interrupt**	**Valid only when TCT[WFQ_En] is set:** Full Stop to Accelerate interrupt Mask. 0 - this interrupt is disabled. 1 - this interrupt is enabled. For more description see Section 41.4.3.1.1, “Queue Management”.
	6	**Accelerate to Full Speed interrupt**	**Valid only when TCT[WFQ_En] is set:** Accelerate to Full Speed interrupt Mask. 0 - this interrupt is disabled. 1 - this interrupt is enabled. For more description see Section 41.4.3.1.1, “Queue Management”.
	7	**Decelerate to Accelerate interrupt**	**Valid only when TCT[WFQ_En] is set:** Decelerate to Accelerate interrupt Mask. 0 - this interrupt is disabled. 1 - this interrupt is enabled. For more description see Section 41.4.3.1.1, “Queue Management”.
	8–15	**Thr_Set_ID**	Threshold Set ID. Selects one of the available thresholds sets (0-255). This field can be changed dynamically by the user, by writing to directly to the **byte** containing these bits. For more description see Section 41.4.3.1.1, “Queue Management”.

NOTE: Entries in boldface must be initialized by the user.

41.3.5.4 CPS Buffer Structure

The CPS buffer structure consists of a BD table that points to data buffers. The BDs contain, apart from the buffer pointer, also the packet header. The buffers contain the packet payload. See Figure 41-13.

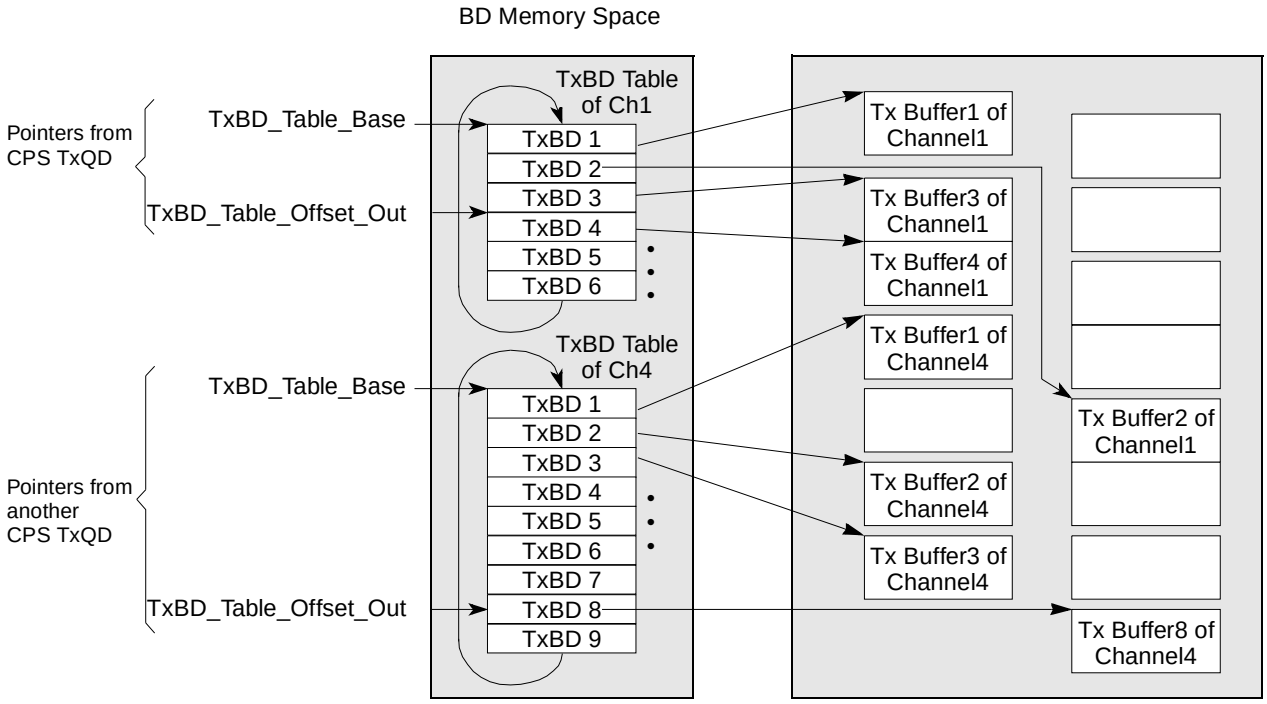

Figure 41-13. Buffer Structure Example for CPS Packets

Figure 41-14 shows a CPS TxBD.

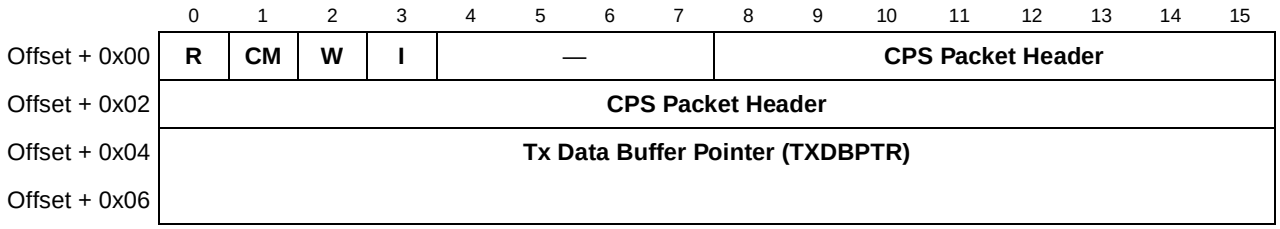

Figure 41-14. CPS TxBD

Table 41-7 describes the CPS TxBD fields.

Table 41-7. CPS TxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**R**[1]	Ready 0 The buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated buffer. The QUICC Engine block clears R after the buffer is sent or after an error condition is encountered. 1 The user-prepared buffer has not been sent or is currently being sent. No fields of this BD may be written by the user once R is set.
	1	**CM**[2]	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear R after this BD is closed, allowing the associated buffer to be retransmitted automatically when the QUICC Engine block next accesses this BD. However, the R bit is cleared if an error occurs during transmission, regardless of the CM bit setting.
	2	**W**	Wrap (final BD in table) 0 This is not the last BD in the TxBD table. 1 This is the last BD in the TxBD table. After this buffer is used, the QUICC Engine block transmits outgoing data for this channel from the first BD in the table (the BD pointed to by the channel's TxBD_table_Base in the TxQD). The number of TxBDs in this table is determined only by the W bit.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer has been serviced. 1 A Tx Buffer event is sent to the interrupt queue after this buffer is serviced. The GHIN/GLIN bit in the event register is set when the INT_CNT counter reaches terminal count.
	4–7	**—**	Reserved, should be cleared during initialization.
	8–15	**CPS Packet Header**	This field contains the beginning (MSB) of the 3-byte packet header. See Figure 41-15 for the CPS packet header format.
0x02		**CPS Packet Header**	This field contains the rest of the packet header. If TxQD[HEC] = 0, the HEC part of the packet header is calculated by the QUICC Engine block, and the user may disregard the five least-significant bits of this field. See Figure 41-15 for the CPS packet header format.
0x04	—	**TXDBPTR**	Tx data buffer pointer. Points to the address of the associated buffer. There are no byte-alignment requirements for the buffer, and it may reside in either internal or external memory. This pointer is not modified by the QUICC Engine block.

NOTE:

1 Entries in boldface must be initialized by the user.

2 Setting Continuous mode (TxBD[CM] = 1) is not allowed in CID switching mode.

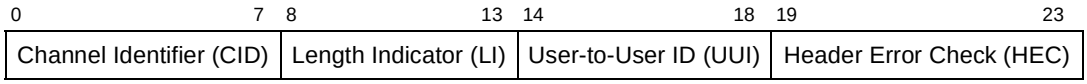

Figure 41-15. CPS Packet Header Format

41.3.5.5 SSSAR Tx Queue Descriptor

The SSSAR TX Queue Descriptor is described in Figure 41-16. The TxQD contains the base address of the BD table, the offset of the next BD to be serviced, the data buffer pointer, and other queue-specific

parameters. The NextQueue pointer is used to create a linked list of TxQDs, as described in Section 41.3.2, “Transmit Priority Mechanism.” The SSSAR TxQD is located in the multi-user RAM or in external memory in a 32-byte aligned address.

Figure 41-16. SSSAR Tx Queue Descriptor

Table 41-8 describes the SSSAR TxQD fields.

Table 41-8. SSSAR TxQD Field Descriptions

Offset	Bits	Name[1]	Description
0x00	0–7	—	Reserved, should be cleared during initialization.
	8	**BNM**	Buffer-not-ready interrupt mask of the TxBD table. 0 The transmit buffer-not-ready event for this queue is masked. (The event is not sent to the interrupt queue.) 1 The buffer-not-ready event for this queue is enabled.
	9	**UUI**	UUI insertion mode 0 UUI of last CPS packet is 26. 1 UUI of last CPS packet is taken from the next byte after the end of the buffer.[2]
	10	**INF**	Indicates the current state of the frame. 0 The next packet will be the first of a new frame. 1 Currently in the middle of the frame.
	11	**CPS**	Sublayer type. For an SSSAR TxQD, this field must be cleared. 0 SSSAR. 1 CPS packet.
	12	**TBM**	Transmit buffer interrupt mask for TxBD table. 0 The transmit buffer event of this queue is masked. (The event is not sent to the interrupt queue.) 1 The transmit buffer event of this queue is enabled.
	13	**SSSAR**	SSSAR bit. This bit must be set.
	14–15	—	Reserved, should be cleared during initialization.
0x02	0–7	**Seg_Len**	Specifies the maximum length in bytes of the SSSAR PDU (excluding the packet header). Seg_Len is limited to 45 in NoSTF=1 mode. The QUICC Engine block always attempts to segment the SSSAR SDU according to this length, but if the buffer is ended then the packet length can be less than this value.
	8–15	—	Reserved, should be cleared during initialization.
0x04	—	**TxBD Table Base**	Must be initialized to the first TxBD by the user. Should be 8 byte aligned.
0x08	—	**TxBD Table Offset Out**	Used to calculate the pointer to the next TxBD to be used for transmission. Should be cleared during initialization.
0x0A	—	—	Reserved, should be cleared during initialization.

Table 41-8. SSSAR TxQD Field Descriptions (continued)

Offset	Bits	Name[1]	Description
0x0C	—	**NextQueue/Next QD_Offset**	Points to the next TxQD to be serviced after this one. See Section 41.3.2, "Transmit Priority Mechanism". In case TCT[ExtTQD]=1 this entry acts as an offset from TxQDExtBase address multiplied by 32. See Section 41.3.5.2, "External TxQD versus Internal TxQD".
0x0E–0x1f	—	**—**	Reserved, should be cleared during initialization.

1 Entries in boldface must be initialized by the user.

2 The 5-bit UUI field is inserted into the header of the last packet of an SSSAR SDU. The user must append the UUI to the last buffer as an additional byte. This additional byte is then inserted into the UUI field of the last packet header (note that, it is important that this additional byte—the byte after the last byte in the last data buffer of the SSSAR frame—contains the 5 bits of the UUI). The 3 MSB bits of this extra byte should be cleared; refer to Figure 41-15.

41.3.5.6 SSSAR Transmit Buffer Descriptor

The SSSAR buffer structure consists of a BD table that points to data buffers. The buffers may contain SSSAR SDUs belonging to different CIDs. Each buffer may contain a whole SSSAR SDU or part of it. The CPS CID is located in the first BD of the SSSAR SDU. See Figure 41-17.

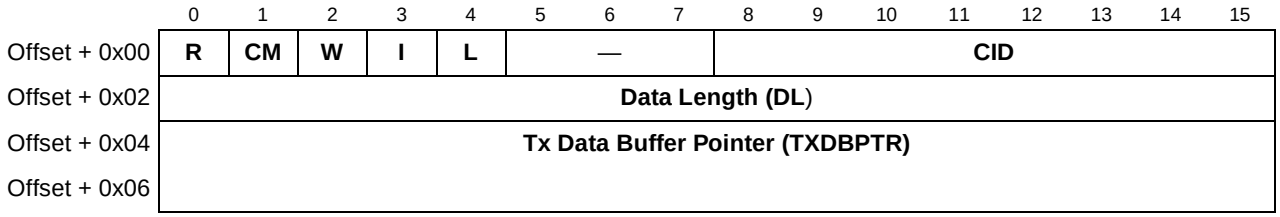

Figure 41-17. SSSAR TxBD

Table 41-9. SSSAR TxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**R**	Ready 0 The buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated buffer. The QUICC Engine block clears R after the buffer is sent or after an error condition is encountered. 1 The user-prepared buffer has not been sent or is currently being sent. No fields of this BD may be written by the user once R is set.
	1	**CM**	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear R after this BD is closed, allowing the associated buffer to be retransmitted automatically when the QUICC Engine block next accesses this BD. However, the R bit is cleared if an error occurs during transmission, regardless of the CM bit setting.
	2	**W**	Wrap (final BD in table) 0 This is not the last BD in the TxBD table. 1 This is the last BD in the TxBD table. After this buffer is used, the QUICC Engine block transmits outgoing data for this channel from the first BD in the table (the BD pointed to by the channel's TxBD_table_Base in the TxQD). The number of TxBDs in this table is determined only by the W bit.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer has been serviced. 1 A Tx Buffer event is sent to the interrupt queue after this buffer is serviced. The UCC[GINTx] bit in the event register is set when the INT_CNT counter reaches terminal count.
	4	**L**	Last. 0 This is not the last buffer of the SSSAR SDU. 1 This is the last buffer of the SSSAR SDU.
	5–7	—	Reserved, should be cleared during initialization.
	8–15	**CID**	Contains the CID number of the SSSAR SDU pointed by this BD. This field is only valid if this is the first BD of a SSSAR SDU.
0x02		**Data Length**	Contains the length of the buffer associated with this BD. If this is the last buffer (L=1) and the UUI bit in the SSSAR TxQD is set, the 5-bit UUI field is located at (TXDBPTR+Data Length)[3:7] with bit [3] being the msb, that is, in the byte (right justified) immediately following the last byte of the buffer. For best bandwidth utilization and optimized partioning of the SDU to packets of exactly SegLen size when SDU is spread over multiple BD's, the application should set Data Length to be an integer multiply of SegLen. (Data Length == n* SegLen). For an SDU on a single BD this recommendation does NOT apply.
0x04	—	**TXDBPTR**	Tx data buffer pointer. Points to the address of the associated buffer. There are no byte-alignment requirements for the buffer, and it may reside in either internal or external memory. This value is not modified by the QUICC Engine block.

NOTE: Entries in boldface must be initialized by the user.

41.3.5.7 Transmitter Statistics Structure

The structure of transmitted CPS packet / SSSAR frame counters per CID in each Transmit VC is illustrated in Figure 41-18. This mode is enabled ONLY if TCT[StatsEn] is set. Each Entry in the TxCIDstatsOffset / TxCIDstatsAddr Table gives the location of a set of up to 256 - 16 bits counters

representing a per CID transmitted statistics for CPS packets / SSSAR frames. The first Entry in each Statistic Table (“CID0” Entry) is designated for ATM Cell Counter for this AAL2 VC.

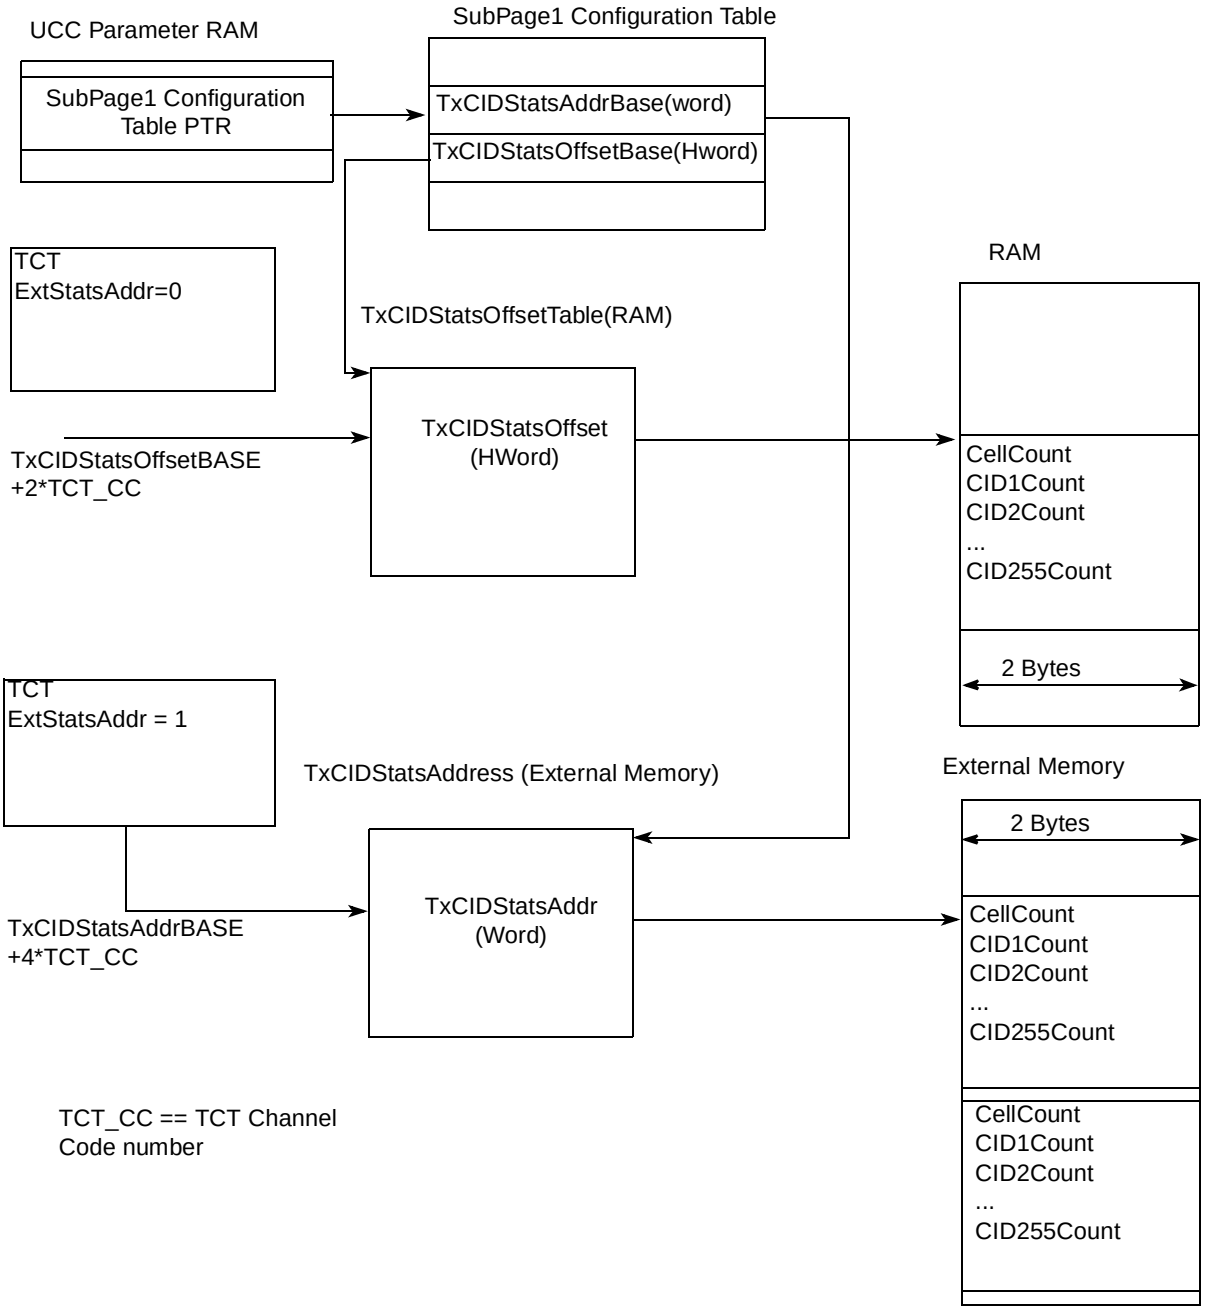

Figure 41-18. TxCIDStats and CellStats structure

As described in Figure 41-18, there are two possible ways to access the TxCID Statistics counters:

1. TCT[ExtStatsAddr] =0 - Using TxCIDStatsOffset, see Table , and TxCID Statistics Tables, which resides in internal multi-user RAM. In this case the access to the TxCIDstatsOffset Entry is by adding TxCIDStatsOffsetBase + 2*TX_CH. The TxCIDStatsOffset Entry is of 2 bytes length, and is used as the direct RAM address of the TxCIDStatistics Table’s entry related to the specific TX

channel (which consist up to 256 CID counters). In order to reach the specific CID counter, use TxCIDStatsOffset + 2*CID. The user could use this method, for a limited number of Tx channels and CID's statistics counters, since this method has better performance than the second one, but consumes a lot of RAM resources.

2. TCT[ExtStatsAddr] =1 - Using TxCIDstatsAddr, see Table , and TxCID Statistics Tables, which resides in external memory. In this case the access to the TxCIDstatsOffset Entry is by adding TxCIDStatsAddressBase + 4*TX_CH. The TxCIDstatsAddr Entry is of 4 bytes length, and is used as the direct External address of the TxCIDStatistics Table's entry related to the specific TX channel (which consist up to 256 CID counters). In order to reach the specific CID counter, use TxCIDStatsAddr + 2*CID. This method can support all 64K Channels in the systems, and doesn't consumes any of the internal multi-user RAM resources, since all the relevant tables resides in external memory. Bus is selected by TCT[BDB].

A Transmitter interrupt is generated when there is an overflow of any of the TxCID Statistics counter or of the Tx ATM cell counter. In this case the TxOF bit is set in the interrupt Entry, and the relevant CID is indicated - for Tx ATM cell overflow the CID field is equal to 0. See Table 41-21 for further information.

NOTE

User can use less than 255 CIDs per TCT channel, since the 2 different mechanisms described above uses a direct memory pointer, to internal or external memory. In this way there should be No 'holes' in memory which are dedicated for unused CIDs.

41.4 AAL2 Receiver

The following sections describe the AAL2 receiver.

41.4.1 Receiver Overview

The receiver cycle starts after the UCC receives a cell. If the cell header is successfully mapped to an ATM channel number, the corresponding RCT is fetched and the AAL type is read. For AAL2 cells, the receiver begins by checking if the last cell received in this channel has an uncompleted (split) CPS packet. If so, the receiver first finishes handling this packet.

The receiver then goes through a validation process. The receiver matches the OSF field in the STF with the expected OSF based on the actual split packet (if the first packet is not split, the OSF should be zero). If the two values do not match, an OSF error interrupt is issued and the receiver drops the last packet. Also, if the STF parity check, or the OSF>47 check results in an error, the receiver issues an interrupt and discards the whole cell. For an SN error the split, or part, of the cell is discarded, an interrupt is issued, and the rest of the cell is being processed as usual.

If any of the above errors has occurred and the cell has started with the remainder of an uncompleted packet, the receiver does the following:

- For a CPS sublayer CID, the packet's RxBD[UP] (uncompleted packet) bit is set.
- For an SSSAR sublayer CID, the buffer is closed with RxBD[RxError = US = 10] (uncompleted SDU), and the rest of the frame is dropped.

The receiver now begins the process of extracting new CPS packets out of the cell with another round of error checking. The receiver examines each CPS packet header for the following errors:

- Incorrect packet HEC. The packet and rest of the cell are discarded.
- Packet length (LI+1) is larger than CPS_Max_SDU_Length. The receiver discards the packet and then continues to extract the next packet in the cell. However, if the packet belongs to an SSSAR CID, the receiver closes the SSSAR buffer with RxBD[RxError = OS = 11] (oversized) and discards the rest of the frame.

The receiver issues an interrupt for each of the above errors.When a SSSAR buffer is closed with RxBD[RxError = US or OS], indicating Uncompleted SDU or Oversized, then RxBD[L] is set, and if RxQD[RFM]=1 then the receiver also issues an RXF interrupt.

Then, if no errors have occurred in the packet header, the packet CID is used to match the PHY | VP | VC | CID with an RxQD; see Section 41.4.2, “Mapping of PHY | VP | VC | CID.” The match process yields an RxQD pointer. The RxQD indicates the type of SAR operation to be performed on the PHY | VP | VC | CID. Three SAR operation modes are supported:

- For the CPS sublayer, each packet from the CID is stored, as is, in a one packet buffer.
- For switching, the packet is stored directly into the transmit buffer, and the CID is translated.
- For the SSSAR sublayer, all packets received from the CID are reassembled into an SSSAR SDU similar to the BD and buffer structures used for AAL5 frames.
- For the SSSAR sublayer, last packet UUI indication is stored in last RxBD of the SDU.

For the SSSAR sublayer, two additional parameters are verified for each new packet received:

- RAS_Timer expiration. The RAS_Timer_Duration defined in the AAL2 parameter RAM limits the time (starting when the first packet is received) allowed to receive a complete SSSAR SDU. If this time limit is exceeded, the receiver closes the current buffer with RxBD[RxError = TE = 01] (Ras_Timer expired) and starts a new SSSAR frame with the next packet. When a buffer is closed with RxBD[RxError = TE = 01], RxBD[L] is not set and the receiver does not issue an RXF interrupt.
- SSSAR_Max_SDU_Length. With each new packet the receiver checks whether the current accumulated length of the SSSAR SDU exceeds the SSSAR_Max_SDU_Length. If so, the receiver closes the current buffer with RxBD[RxError = OS = 11] (oversized), discards the rest of the SSSAR SDU, RxBD[L] is set, and if RxQD[RFM]=1 issues an RXF interrupt.

NOTE

The user must not share the same RxQD table for multiple CIDs from different Rx ATM Channel or for multiple CIDs of the same Rx ATM Channel.

41.4.2 Mapping of PHY | VP | VC | CID

The AAL2 mapping mechanism translates a PHY | VP | VC | CID combination into a unique RxQD. There is no support for mapping different combinations of PHY | VP | VC | CID into a single RxQD.

The mapping mechanism, shown in Figure 41-19, can be broken down as follows:

- Each ATM channel number (RCT) has its own CID mapping table. The mapping table can be placed in internal or external memory (according to RCT[MAP]) and is pointed to by RCT[CID Mapping Table Base]. The CID of the received packet is used as an index into the mapping table.
- Each entry in the mapping table contains a 2-byte RxQD offset. This offset, multiplied by 4, is the offset to an RxQD in either the internal or external RxQD table.
- The two RxQD tables serve all the ATM channel numbers of an UCC. (RxQD_Base_Int and RxQD_Base_Ext are defined in the UCC SubPage0 Configuration Table.)
- RxQD offsets from 1 through 511 point into the internal RxQD table located in multi-user RAM at RxQD_Base_Int. Note that the user should not allocate RxQD_Base_Int memory, in case that there are only external RxQDs in use under this UCC. In this case, the external RxQDs are DMA'd into the memory allocated by the RxQD_tmp parameter in UCC/Distributor/Thread Local Parameter Table.
- RxQD offsets greater than 511 point into the external RxQD table located at RxQD_Base_Ext + (512*4).
- Because the three types of RxQDs are different sizes, some offset numbers may not be used.
- RxQD offsets for unused CIDs would be cleared. This way they will be ignored.
- CID MASK mechanism. See Section 41.4.4.4, "CID MASK".

NOTE

RxQDs should be located in 4 byte aligned addresses. But it is recommended that external RxQDs will be located in addresses that are aligned to their size, inorder to optimize the bus latency,

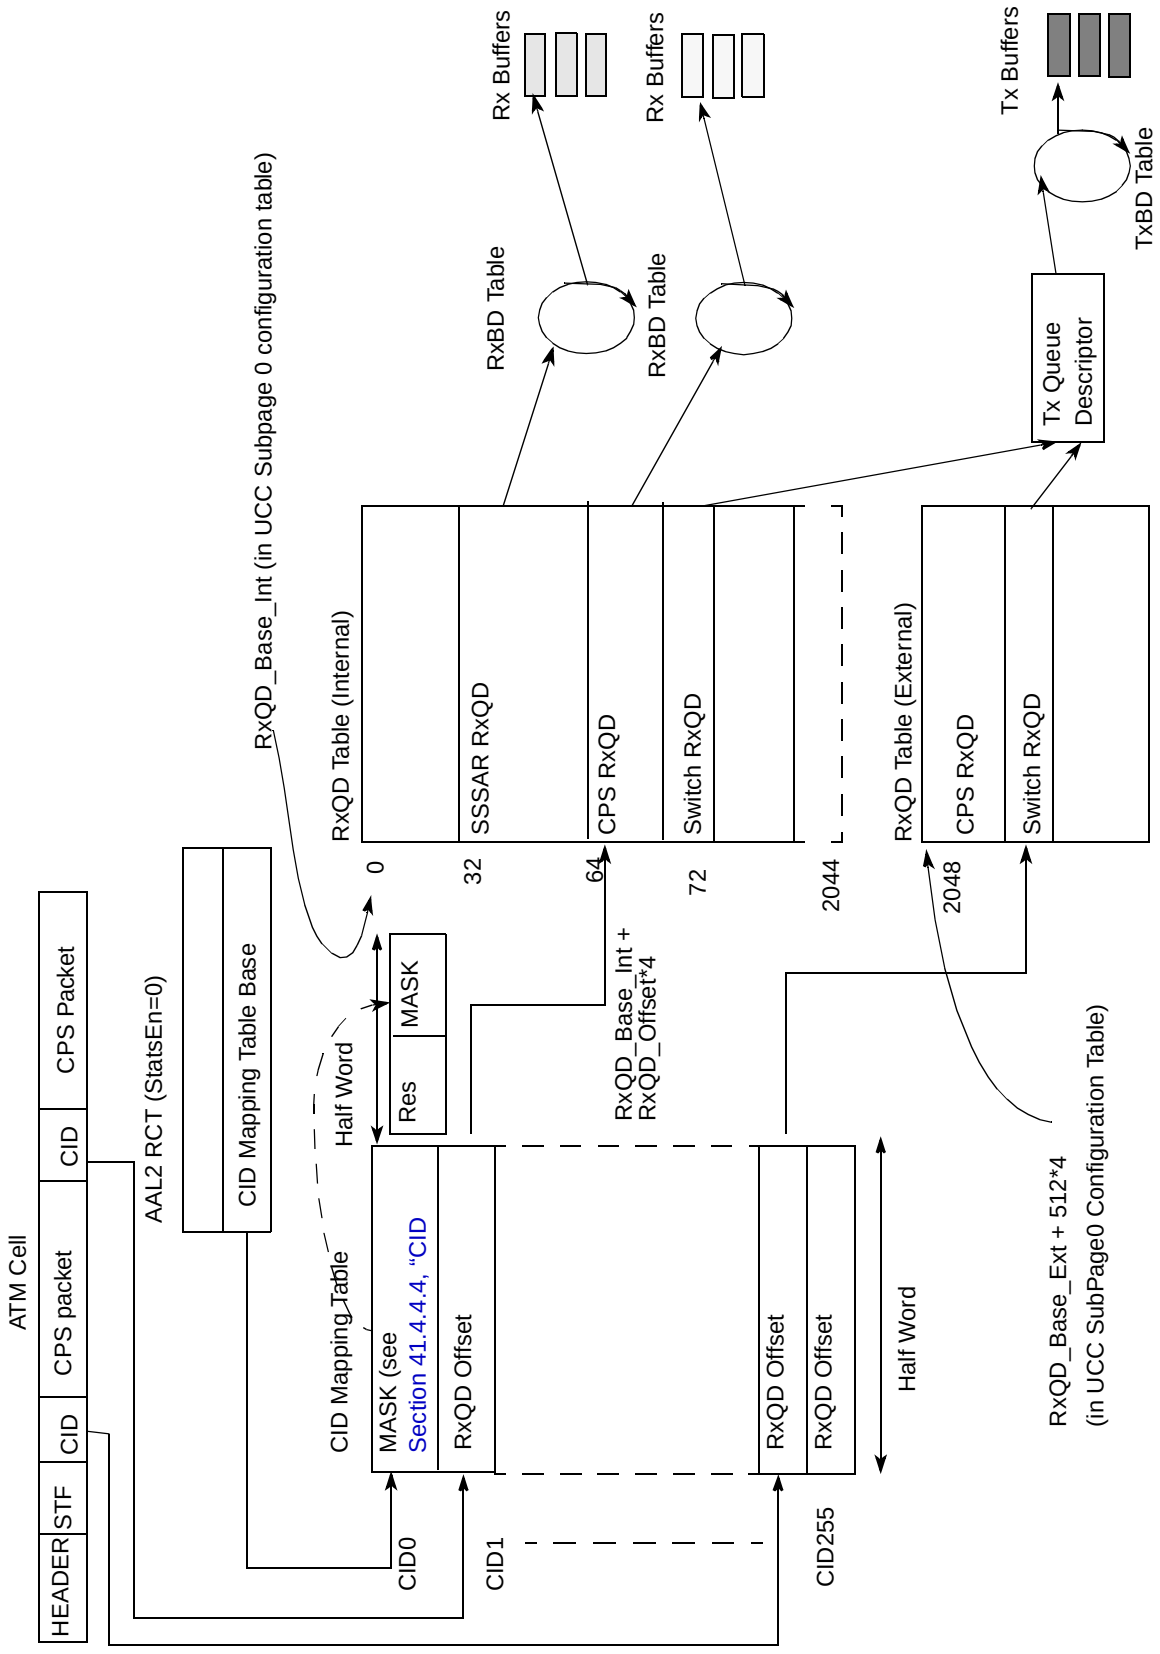

Figure 41-19. CID Mapping Process

41.4.3 AAL2 Switching

Two types of descriptors are available. Both descriptors hold a translation CID number. Type-1 descriptor has a pointer to a CPS TxQD which resides in multi-user RAM. Type-2 descriptor holds a pointer to a CPS TxQD which resides in external memory.

The TxQD structure for both types holds the BD ring management which is common both to the receiver and transmitter. Offset_in is handled by the receiver and offset_out by the transmitter. The transmit scheduling of the packet is done by the APC according to the programmed bit rate of the ATM channel that holds the switched queue.

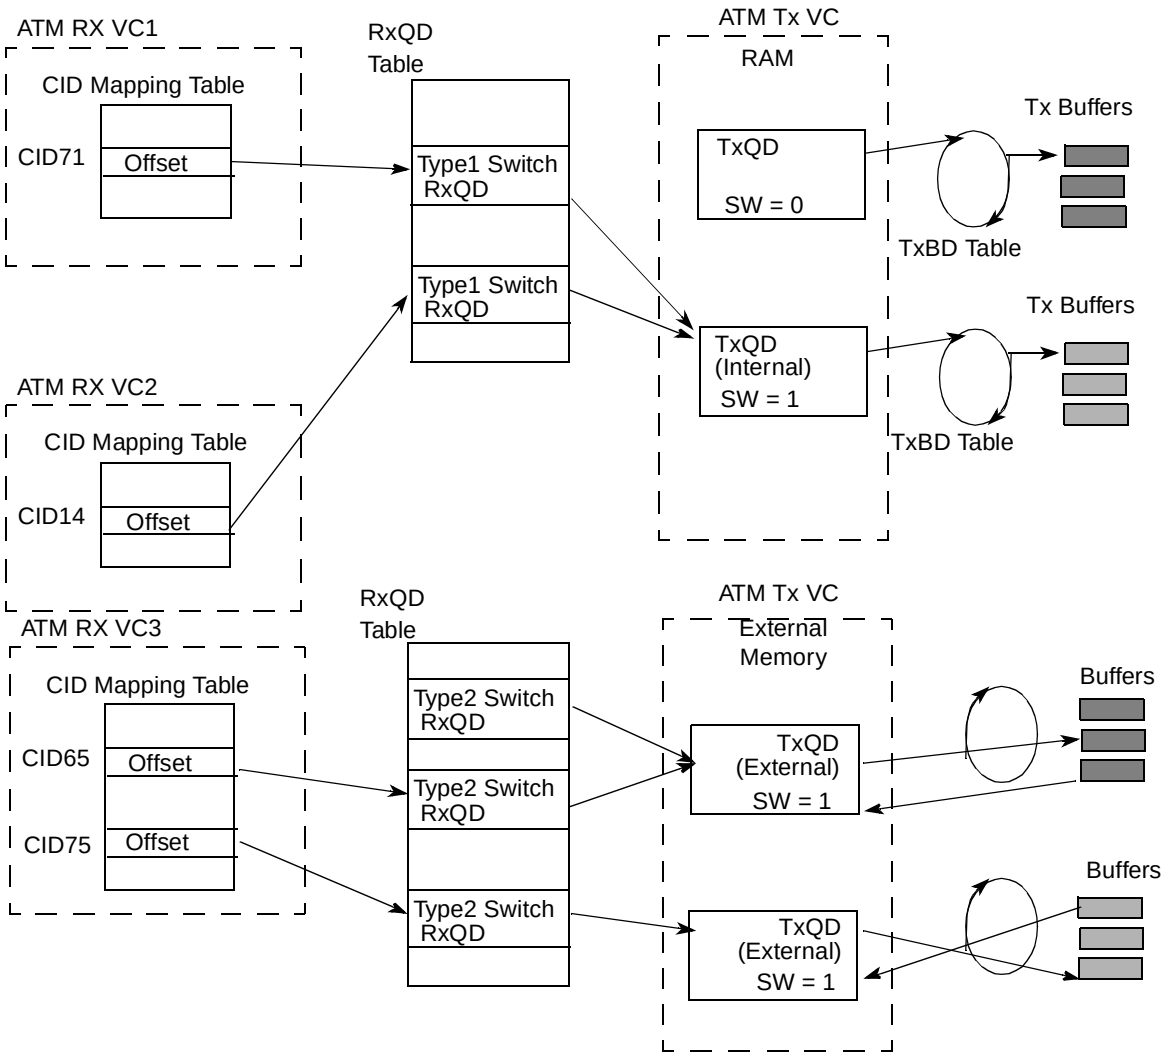

Figure 41-20. AAL2 Switching

A mechanism of Automatic activation and deactivation of ATM channels (Auto VC ON and Auto VC OFF) is defined for the AAL2 switching. In this mode when the receiver receives a packet, the corresponding TCT channel, which is the channel that is pointed by the RxQD[TCC] field, is activated (assuming that this channel was not already in the APC scheduling table) by inserting the TCT channel

code into the APC scheduling table. When the ATM transmitter has a situation where there is no packets ready for transmission in the queue (TxQD) the channel is automatically removed from scheduling table. The RQD data structure for this mode is different then the standard switched RQD. This mechanism is enabled, by setting RxQD[AVCON] bit and configuring the TAPTR and TCC parameters in the RxQD on the receiver's side, and setting TCT[AVCF] bit and clearing TCT[VCON] bit on the transmitter side.

NOTE

AVCON/AVCF mechanism does not supported for GBR mode.

When working in traditional APC AVCON/AVCF mode, an internal data structure- AVCON table should be allocated and cleared, see Table , for the ATM_AVCON_BASE description. The AVCON table contains one bit per TCT channel. For better memory utilization it is recommended that these TCTs are consecutive, to avoid gaps in the AVCON table. The area dedicated for this table is equal to the integer "round up" number of switched TCTs (which participate in the AVCON/AVCF mechanism) divided by 8. The transmitter clears the corresponding TCT bit on event of deactivating a channel, and the receiver, upon detecting that this bit is cleared, will activate the channel and set this bit.

IMPORTANT - When working in GCRA scheduler AVCON/AVCF mode, the ATM_AVCON_BASE parameter and table allocation is **not** necessary, since we already have the priority MASK bits, which have the same meaning as the ATM_AVCON_BASE parameter.

NOTE

When working in switch AVCON/AVCF mechanism:

1. Under the TCT there should be only TxQDs of switch mode.

2. It is possible in some scenarios that a packet would be stuck in the BD ring till the next packet would be received to the same queue - this can introduce a transmission packet delay.

A partial packet discard mode is provided for the AAL2 switched channels that perform end-to-end SSSAR. When this mode is enabled (switch RxQD[PPD]=1), if no buffer is available to receive a packet in the middle of a frame, the subsequent middle packets of the SSSAR SDU are discarded. When the last packet of the SSSAR SDU arrives, the receiver attempts to re-open a buffer.

The receiver will mark an open BD which is partially filled as UP (Un-completed packet). In normal operation when the packet is fully received, the UP mark is removed, the Empty bit is set and switching operation continues. In case of an error which is detected by the receiver the BD is marked as Empty (set to 1) and the UP indication is still on. In this case the transmitter will skip this BD and proceed to the next one.

If the transmitter is currently pointing to a BD that is marked as UP (part of the packet is received and reception of the rest of the packet has not yet occurred), the transmitter cannot advance past this point until the remaining data of the packet has arrived or there is an error detected in the receiver. See Figure 41-30.

In cases where there is aggregation of several receiver channels into a single transmitter TxQD, a common BD ring is shared. A slow receiver may create stall conditions on the switched transmitter due to partial packet conditions. That is, a slow channel receives a partial packet and will mark the BD as UP. Faster channels may fill the BD ring before the remainder of the partial packet from the slow channel is

completed thus data will be dropped from the faster channels, creating RxBSY conditions. One way to compensate for the stalled conditions would be to increase the BD ring size.

If a channel stops receiving data in the middle of a packet, the transmitter will be in a stuck state as it cannot advance past the BD with UP set until the rest of the packet has been completed or a receiver error is detected. This would require host intervention to unstick the stuck BD ring.

In order to avoid the transmitter from getting stuck state and to minimize stalling, one can make use of the TBNR Time-out mechanism, which is enabled in the RCT[TBNR Time-Out CNT] field. The receiver marks the BD with the Time-Out value upon entering a partial packet state on a BD. The transmitter monitors this counter and decrements it on each try. When the counter expires the transmitter will skip this "stuck" BD, so the BD ring is available again for the other receivers. See Table 41-11 for more information. The transmitter will also reset the proper receiver from it's "stuck" state so in case this receiver starts operation it will use a new BD from the BD ring.

Another option is to use is Partial Packet Receive Storage mode (PPRS). When this mode is enabled, when a partial packet is received it is written to external memory to offset 'PPRS_EXT_BASE + 64*RCT Channel Code,' see Table . Only when the packet is completely received does the packet get written into the BD ring. This eliminates the UP condition in the BD ring, thus removing the stalled/stuck condition. Using this mode may also minimize the BD ring size as now a slow receiver will not influence the switched transmitter.

41.4.3.1 AAL2 Switch - WFQ PRIORITY Mode

When working in AAL2 Switch mode and WFQ mode is enabled, there are two additional features which are supported:

1. Queue Management.
2. Automatic bandwidth allocation between High and Low priority traffic types. (Real-Time Vs. Best Effort traffic).

NOTE

In systems where multiple CID's are received on different ATM channels are routed to a common TxQD for transmission, and WFQ mode is enabled, the user must enable the PPRS mode.

41.4.3.1.1 Queue Management

There are up to 256 available thresholds sets in the system, each one consists of 8 bytes, that are available for each TxQD. These thresholds sets are placed from 'Thresholds_Base' parameter in Subpage1

Configuration Table, see Table . Each threshold set contains 4 levels (see Figure 41-6). The structure of each threshold set table is described in Figure 41-21 and Table 41-10.

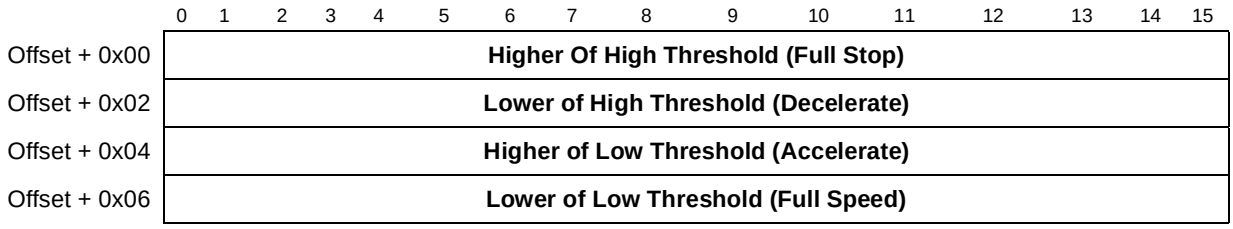

Figure 41-21. Threshold Set Table

Table 41-10. Threshold Set Table

Offset	Name	Description
0x00	**Higher Of High Threshold (Full Stop)**	Higher of High Threshold. The user set the number of packets in queue that corresponds to the Full Stop scenario (queue is too full).
0x02	**Lower of High Threshold (Decelerate)**	Lower of High Threshold. The user set the number of packets in queue that corresponds to the Decelerate scenario (queue is about to be too full).
0x04	**Higher of Low Threshold (Accelerate)**	Higher of Low Threshold. The user set the number of packets in queue that corresponds to the accelerate scenario (queue is about to be too empty).
0x06	**Lower of Low Threshold (Full Speed)**	Lower of Low Threshold. The user set the number of packets in queue that corresponds to the Full Speed scenario (queue is too empty).

There are six types of events each corresponds to a different scenario of threshold crossing, see Figure 41-22. In the following list when one of the thresholds is hit, only the next active threshold that corresponds to it is active, and all the other thresholds are inactive.

1. Full Speed was hit previously, and currently the Decelerate threshold is crossed (crossed means equal or bigger than Decelerate threshold) - Full Speed to Decelerate interrupt is driven.
2. Decelerate was hit previously, and currently the Full Stop threshold is crossed (crossed means equal or bigger than Full Stop threshold) - Decelerate to Full Stop interrupt is driven.
3. Accelerate was hit previously, and currently the Decelerate threshold is crossed (crossed means equal or bigger than Decelerate threshold) - Accelerate to Decelerate interrupt is driven.
4. Full stop was hit previously, and currently the Accelerate threshold is crossed (crossed means equal or less than Accelerate threshold) - Full stop to Accelerate interrupt is driven.
5. Accelerate was hit previously, and currently the Full Speed threshold is crossed (crossed means equal or less than Full Speed threshold) - Accelerate to Full Speed interrupt is driven.
6. Decelerate was hit previously, and currently the Accelerate threshold is crossed (crossed means equal or less than Accelerate threshold) - Decelerate to Accelerate interrupt is driven.

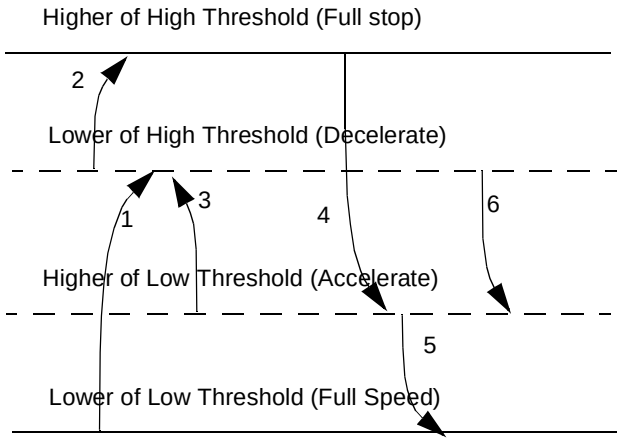

Figure 41-22. Thresholds Events diagram

Each of these events can trigger a maskable interrupt, according to the TxQD[Queue_management] field. See more description of the queue management events in Table 41-22.

The QUICC Engine block implements a hysteresis mechanism, which assures that multiple events are avoided.

NOTE

The threshold set used by each TxQD can be changed dynamically, by writing to the byte which contains the TxQD[Thr_Set_ID] bits.

If the user would like to know which is the specific CID that over-loaded the TxQD, check the Rx CID statistics in the RCT Mapping table of this channel. The user even may have an additional copy of the RCT mapping table, with all the statistics entries cleared, and on event of high threshold interrupt it is possible to switch between these two RCT mapping table bases, by writing to the RCT[CID Mapping Table Base /CIDstatsAddress].

41.4.3.1.2 Automatic Bandwidth Allocation

Up to 4 TxQDs under each TCT can support various types of traffics, as Real-Time (RT) or Best-Effort (BE) traffic. Each queue has a corresponding bit in the ‘RT_MASK’ parameter (Table 41-1), that identifies it as RT (bit set to 1) queue or BE queue. Assuming all of the AAL2 switched channels that use the WFQ mode, have certain guaranteed transmission rate that should not be exceeded by the RT traffic:

The application may require that BE cells not interfere with the RT traffic of other channels in cases of overload. This is achieved by not transmitting the BE channel if the following conditions applies for the channel:

1. RT queues are empty and BE queue non-empty,
2. [Rptr-Sptr]mod slot number > predefined overload limit, and
3. The overload limit parameter in the WFQ Table (see Table 41-1) is not zero

These conditions implies that the system is overloaded, and the objective is to decrease the BE traffic rate by not transmitting the BE cells. The channel is rescheduled for transmission based on PCR without transmitting any data at the current time.

Figure 41-23 depicted the operation of the APC.

NOTE

The same mechanism applies for GCRA scheduler mode, but instead of checking RPTR-SPTR in time slots, the TSR-[Channel FT] is checked in TSR units.

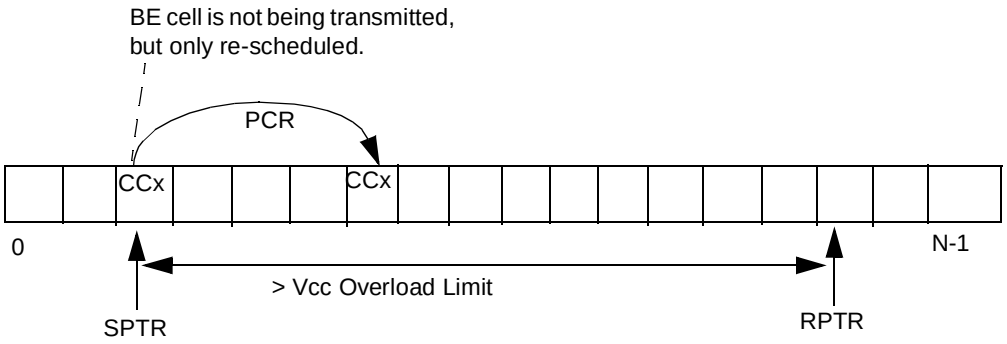

Figure 41-23. Automatic Stop of BE Transmission.

41.4.4 AAL2 RX Data Structures

The following sections describe the RCT and the structures in which CPS packets and SSSAR SDUs are stored in memory.

41.4.4.1 AAL2 Receive Connection Tables

The receive connection table (RCT) is a VC-level table and is where the AAL type for the ATM channel number is selected. The parameters related to the ATM channel number or to all the RX Queues of the ATM channel are maintained here. The RCT also contains the pointer to the CID mapping table for the ATM VC. Figure 41-24 shows the AAL2-specific RCT.

Figure 41-24. AAL2 Receive Connection Table (RCT)

NOTE

For an active channel, the QUICC Engine block uses a burst cycle to fetch the 32-byte RCT and writes back only the first 24 bytes. Therefore the user can change dynamically the last 8 bytes of the RCT.

Table 41-24 describes the AAL2 RCT fields.

Table 41-11. AAL2 RCT Field Descriptions

Offset	Bits	Name	Description
0x00	0–1	—	Reserved, should be cleared during initialization.
	2	**GBL**	Global. Setting GBL enables snooping of data buffers, BDs, interrupt queues and free buffer pool. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
	3–4	**BO**	Byte ordering—used for data buffers. 00, 01, 11 Reserved 10 Big endian
	5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1 and Section 5.4.3.7, "Debug Configuration."
	6	**DTB**	Data buffer and UDC table bus selection. 0 Reside on the coherent system bus. 1 Reside on the secondary bus.
	7	BDB	Bus selection for the BDs, interrupt queues, CID mapping and Statistics table, RxQDs, and the free buffer pool. 0 Reside on the coherent system bus. 1 Reside on the secondary bus. If Type-2 switch mode is being used under this RCT, it implies that this bit value should match the value of the corresponding TCT.
	8–9	—	Reserved, should be cleared during initialization.
	10	**SEGF**	OAM F5 segment filtering 0 Do not send cells with PTI=100 to the raw cell queue. 1 Send cells with PTI=100 to the raw cell queue.
	11	**ENDF**	OAM F5 end-to-end filtering 0 Do not send cells with PTI=101 to the raw cell queue. 1 Send cells with PTI=101 to the raw cell queue.
	12	—	Reserved should be cleared
	13	**MAP**	CID mapping table memory location select 0 Resides in the multi-user RAM. 1 Resides in external memory.
	14–15	**INTQ**	Assigns one of the four available interrupt queues to this ATM channel number.

Table 41-11. AAL2 RCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x02	0–11	—	Reserved, should be cleared during initialization.
	12	**NoSTF**	No STF byte. 0 Normal AAL2 cell structure. 1 The cell does not include the STF byte. In this mode each cell starts with a packet and contains only whole packets (no split or part).
	13–15	**AAL**	AAL type 000 AAL0 —Reassembly with no adaptation layer 001 AAL1 —ATM adaptation layer 1 protocol. (Use this configuration for rev A parts only, unless needed for backwards compatibility to existing software development.) 010 AAL5 —ATM adaptation layer 5 protocol 011 AAL3/4 —ATM adaptation layer 3/4 protocol 100 AAL2 —ATM adaptation layer 2 protocol 101 AAL1 with CES —ATM adaptation layer 1 protocol with optional support for circuit emulation service. (For rev B and later parts, this configuration is strongly recommended for all AAL1 applications, with or without CES.) All others reserved.
0x04 - 0x17	—	—	Reserved, should be cleared during initialization.
0x18	—	**CID Mapping Table Base /CIDstatsAddress**	For StatEn=0: Points to the base address of the CID mapping table (see Figure 41-19). If RCT[MAP] = 0, the pointer contains a multi-user RAM address and the MSB Hword (bytes in addresses 0x18 and 0x19) **must** be cleared. If MAP = 1, the pointer is a full 32-bit address in the memory space. For StatEn=1: Points to the location of the CID mapping and statistics table, which contains 256 (or less) received CID statistics counters and CID RxQD Offsets, per VC. See Figure 41-25. RCT[MAP] bit still has the same functionality as described above.
0x1C	0–1	—	Reserved, should be cleared during initialization.
	2–7	**PMT**	Performance monitoring table. Assigns one of the available 64 performance monitoring tables to this VC. The table's starting address is PMT_BASE+PMT*32.
	8–15	**TBNR Time-Out CNT**	The **TBNR Time-Out CNT** is a parameter that describes the amount of attempts the transmitter tries to transmit a packet on a Switch BD ring which is currently marked as partially filled i.e. waiting for a receiver to finish reception of a packet. This value will be used internally by the transmitter which is the destination for this packet and decremented by the QUICC Engine block on each attempt. Upon reaching the value 1the transmitter will act as if the receiver is stuck in error condition and proceed to the next BD in the BD ring. This parameter is valid in switch mode ONLY and should be programmed to a higher value than the ratio between the transmitter rate and the lowest receiver rate in the BD ring. The 8 bit value is scaled by 4 (setting **TBNR Time-Out CNT=1** yields a value of 4) so that the max number is 1K. Clearing this field will disable this feature completely. **Note:** This parameter should be cleared if **PPRS** mode is enabled.

Table 41-11. AAL2 RCT Field Descriptions (continued)

Offset	Bits	Name	Description
0x1E	0–7	**Max_CPS_SDU_Deliver_Length**	Indicates the maximum size CPS_SDU in bytes that is allowed to be transported on this channel. This value is compared to the length of each CPS_SDU before it is received, as specified in the ITU-T recommendation I.363.2. If the packet length exceeds this value it is discarded, and an interrupt with error_code=5 is asserted.
	8	**PPRS**	Partial Packet Receive Storage. Valid only for switch mode. In this mode when a partially packet is received to a switched RxQD, then instead of writing the packet into the TxQD BD ring immediately, it will be temporarily stored in external memory. Only after the complete packet is received, then it will be stored in the TxQD BD ring. 0 - Partial Packet Receive Storage mode is disabled. 1 - Partial Packet Receive Storage mode is enabled. See more description in Section 41.4.3, “AAL2 Switching”. **Note:** If **PPRS** mode is enabled then the user should clear the **TBNR Time-Out CNT** field.
	9	**WFQ_En**	Weighted Fair Queueing mode Enabled. 0- The Switched RQD doesn’t point to a TxQD which operate in WFQ mode. 1- Switched RxQDs under this RCT **must** point to TxQDs which works in WFQ mode. **Note:** In systems where multiple CID’s are received on different ATM channels are routed to a common TxQD for transmission, and WFQ mode is enabled, the user **must** enable the PPRS mode.
	10	—	Reserved, should be cleared during initialization.
	11	**StatsEn**	Statistics mode Enable bit. 0- CID and Cell counters are disabled for this VC. 1- CID and Cell counters are enabled for this VC.
	12	**CIDMASK**	0 - CID MASK mode is disabled 1 - CID MASK Mode is enabled. See Section 41.4.4.4, “CID MASK”.
	13	**StatsIE**	Statistics Interrupt Enable. 0 - Rx CID Statistics / ATM cell / Switch Packet Discard counters overflow interrupt is disabled. 1 - Rx CID Statistics / ATM cell / Switch Packet Discard counters overflow interrupt is enabled. See Section 41.4.4.3, “Receiver Statistic Structure—Expanded CID Table”.
	14	**EM**	Receive error mask for AAL2 protocol-specific events. Note that buffer-not-ready, Rx buffer, Rx frame and Rx Statistics events are not affected by this mask. 0 Disable AAL2 receive error events. 1 Enable AAL2 error events.
	15	**PM**	Enable performance monitoring 0 No performance monitoring for this VC. 1 Perform performance monitoring for this VC. Whenever a cell is received by this VC, the associated performance monitoring table is updated.

NOTE: Entries in boldface must be initialized by the user.

41.4.4.2 CID Mapping Tables and their RxQDs

Each PHY | VP | VC | CID combination is assigned an RxQD using a CID mapping table. To multiplex several receive CIDs into a single common queue, map each multiplexed PHY | VP | VC | CID combination to one RxQD.

The ATM channel's RCT contains the base address of the associated CID mapping table. This base address is external (32 bits) when RCT[MAP]=1; otherwise, when RCT[MAP]=0 the table resides in the multi-user RAM and the base address is two bytes. The CID of the received packet is used as an index into the mapping table. The mapping table entries are 2-byte RxQD offsets. If the CID mapping table is external, it must be on the same bus as the BDs and interrupt queues as specified by RCT[BDB].

RxQD offsets between 1–511 point into the internal RxQD table located in multi-user RAM at RxQD_Base_Int. The address of an internal RxQD is RxQD_Base_Int (see Table 41-17) + 4*RxQD_Offset. Note that the user should not allocate RxQD_Base_Int memory, in case that there are only external RxQDs in use under this UCC. In this case, the external RxQDs are dma'd into the memory allocated by the RxQD_tmp parameter in UCC/Distributor/Thread Local Parameter Table.

Offsets between 512–65535 belong to the external RxQD table. The address of an external RxQD is RxQD_Base_Ext, see Table 32-18, + 4*RxQD_Offset. The external RxQD table must be on the same bus as the BDs and interrupt queues as specified by RCT[BDB].

RxQD offsets for unused/unwanted CIDs should be cleared. This will ensure that data is not received on these CIDs.

Because the three kinds of RxQDs are each a different size (for example, an SSSAR RxQD is 32 bytes and a CPS switch RxQD could be only 4 bytes), some of the offset numbers are left unused.

NOTE

RxQDs should be located in 4 byte aligned addresses. But it is recommended that external RxQDs will be located in addresses that are aligned to their size, in order to optimize the bus latency,

41.4.4.3 Receiver Statistic Structure—Expanded CID Table

When RCT[StatsEn]=1 the CID mapping table changes it's format and it contains statistical data gathering in addition to the regular CID mapping information, for each CID under this VC. The structure contains counters of received CPS packets / SSSAR frames per CID in each Receive VC. In this case the entry RCT [CID Mapping Table Base] in the RCT acts as a pointer to this data structure. It is described in Figure 41-25. The first Entry in the Statistic Table ("CID0" Entry) is designated for ATM Cell Counter per AAL2 receive VC. Accessing to this table is by using the RCT[CIDstatsAddress] pointer - if RCT[MAP] equals 0 then use only 2 least significant bytes of this address, that points to internal map offset, else if RCT[MAP] equals 1 then use the all 4 bytes entry as an external memory pointer. The process of fetching the RxQD after locating the RxQDOffset remains exactly the same as was defined in Section 41.4.4.2, "CID Mapping Tables and their RxQDs".

The Structure is defined as a max of 256 entries each entry has two fields, a 16 bit CID counter and the RxQD offset which is similar to the CID mapping table.

A Receiver interrupt is generated when there is an overflow in any of the RxCID Statistics counters or the Rx ATM cell counter. In this case the RxOF bit is set in the interrupt Entry, and the relevant CID is indicated - for Rx ATM cell overflow the CID field is equal to 0. See Table 41-21 for further information.

Note - The structure of the Expanded CID mapping table could contain less than 256 entries, since the mechanism of CID MASK, See Section 41.4.4.4, "CID MASK". RxQD offsets for unused CIDs would be

cleared. This way they will be ignored, and their Statistic counters wouldn't be updated.

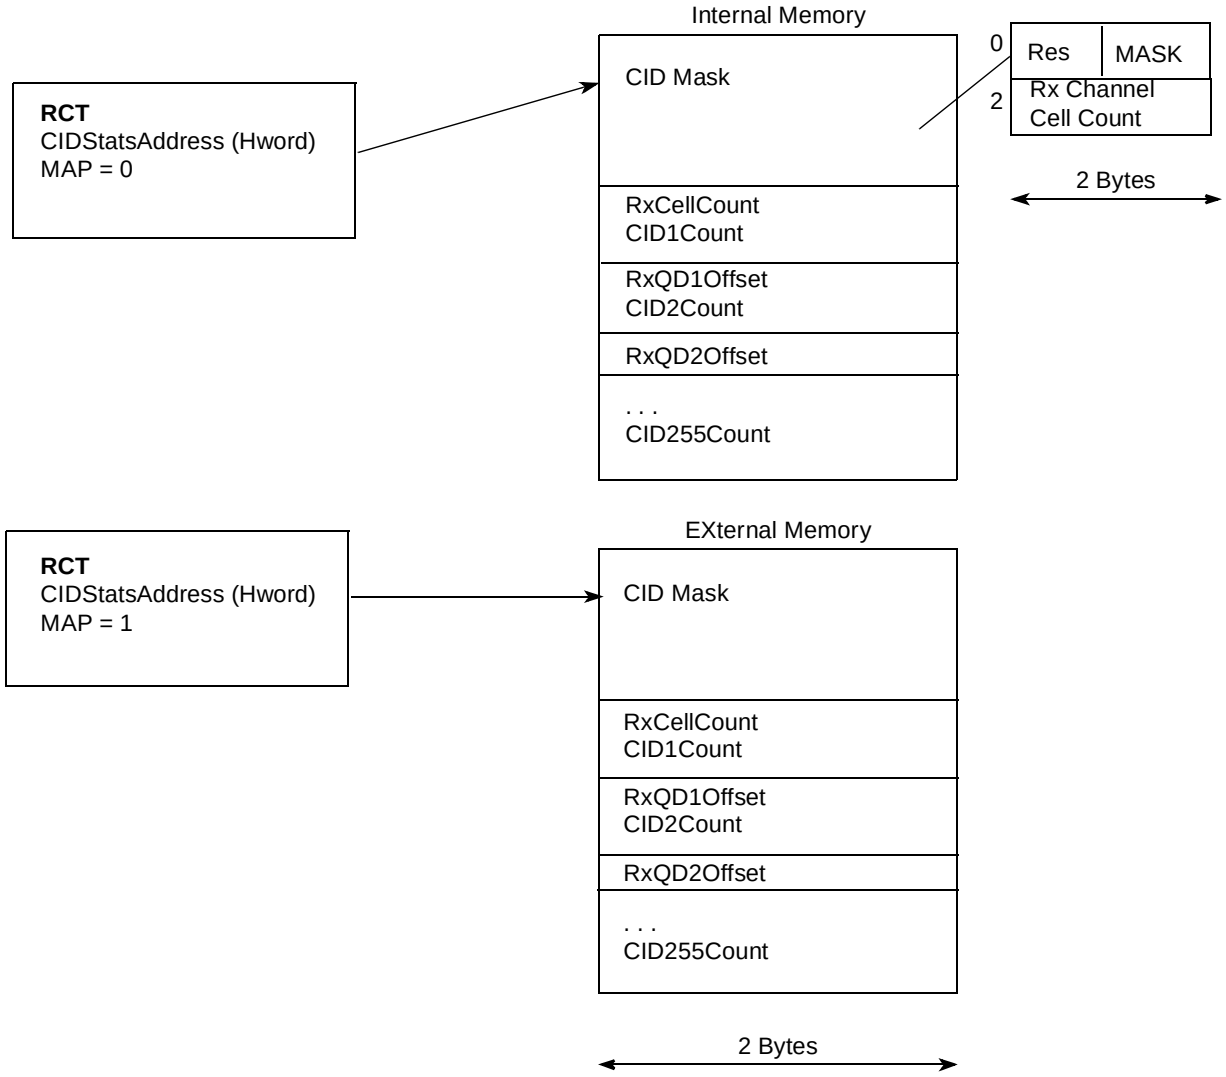

Figure 41-25. RCT Statistics Structure (Valid Only for RCT[StatsEn] = 1)

41.4.4.4 CID MASK

In order to support fast and efficient discard for invalid CIDs, there is a 8 bit CID mask value per receiver channel. Any packet with a CID value outside the mask value is discarded. i.e. writing 0 to a bit in the mask implies that any incoming packet with CID that has this bit value equal to 1 will be discarded. This could decrease the size of the CID Mapping/Statistic Table as there is no need to program all entries in the table. This mode is enabled by setting RCT[CIDMASK].

The MASK is located at the second byte of the first 16 bits entry ("CID0" location) of the CID Mapping table (See Figure 41-19) if RCT[StatsEn]=0, or of the Expanded CID mapping table (See Figure 41-25) if RCT[StatsEn]=1.

Notice - As described in Section 41.4.2, "Mapping of PHY | VP | VC | CID", RxQD offsets for unused CIDs would be cleared. Therefore also the Receiver CID Statistics counters wouldn't be incremented.

41.4.4.5 CPS Rx Queue Descriptors

The CPS RxQDs are grouped into RxQDs Tables (one for internal queues and one for external). Each CPS RxQD, as shown in Figure 41-26, points to an CPS RxBD table.

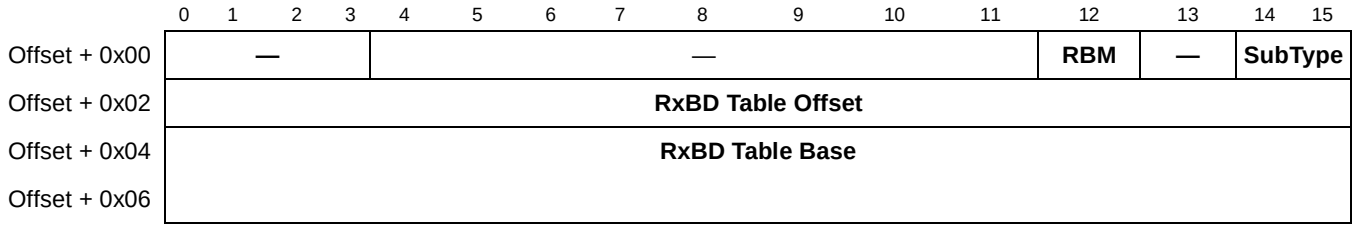

Figure 41-26. CPS Rx Queue Descriptor

Table 41-12 describes the CPS RxQD fields.

Table 41-12. CPS RxQD Field Descriptions

Offset	Bits	Name	Description
0x00	0–11	—	Reserved
	12	**RBM**	Receive buffer mask. 0 Disable receive buffer interrupt. 1 Enable receive buffer interrupt.
	13	—	Reserved, should be cleared during initialization
	14–15	**SubType**	SubType. Sublayer type, should be 00 (CPS) for this descriptor. 00 CPS sublayer. 01 CPS switched. 10 SSSAR. 11 Reserved.
0x02	—	**RxBD Table Offset**	Holds the offset to the next BD to be opened by the receiver. Should be cleared during initialization.
0x04	—	**RxBD Table Base**	Holds the pointer to the first BD in the BD table. Should be 8 byte aligned.
NOTE: Entries in boldface must be initialized by the user.			

41.4.4.6 CPS Receive Buffer Descriptor (RxBD)

The CPS buffer structure consists of a BD table that points to data buffers. The RxBDs contain, apart from the buffer pointer, the packet header, as shown in Figure 41-27. The buffers contain the packet payload.

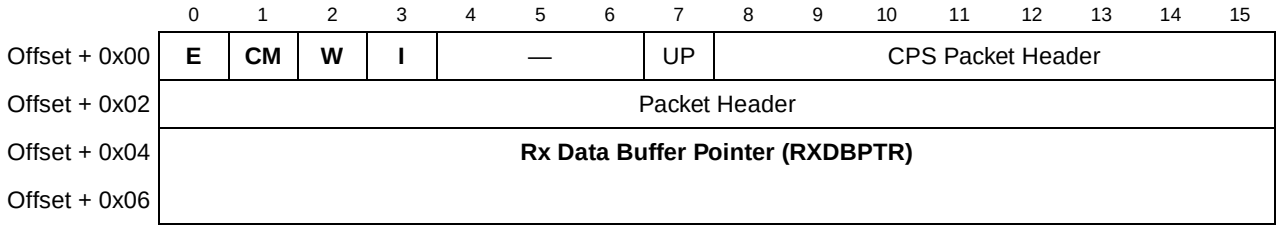

Figure 41-27. CPS Receive Buffer Descriptor

Table 41-13 describes the CPS RxBD fields.

Table 41-13. CPS RxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**E**	Buffer empty bit. 0 The CPS RX buffer is full or data reception was aborted due to an error. The core can read or write any fields of this RxBD. The QUICC Engine block does not use this BD while E remains zero. 1 The CPS RX buffer is empty or reception is in progress. This is controlled by the QUICC Engine block. Once E is set, the core should not access any fields of this buffer.
	1	**CM**	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear E after this BD is closed, allowing the associated buffer to be reused automatically when the QUICC Engine block next accesses this BD. However, the E bit is cleared if an error occurs while receiving, regardless of the CM bit setting.
	2	**W**	Wrap (final BD in table) 0 This is not the last BD in the RxBD table. 1 This is the last BD in the RxBD table of this current channel. After this buffer has been used, the QUICC Engine block receives incoming data for this channel into the first BD in the table. The number of RxBDs in this table is programmable and is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	**I**	Interrupt. 0 The QUICC Engine block will not issue an interrupt after this buffer is serviced. 1 The QUICC Engine block will issue an interrupt after this buffer is serviced if the RBM bit in the RxQD is set.
	4-6	—	Reserved, should be cleared during initialization
	7	UP	Uncompleted packet. 0 No error occurred in this packet. 1 A receive error occurred that caused this packet to be uncompleted. The receive error type is reported to the interrupt queue.
	8-15	CPS Packet Header	Contains the beginning of the packet header. See Figure 41-15 for the CPS packet header format.
0x02		CPS Packet Header	Contains the rest of the packet header. The QUICC Engine block checks the packet HEC and if appropriate, indicates a packet HEC error in an interrupt queue entry with CID = 0. See Figure 41-15 for the CPS packet header format.
0x04	—	**RXDBPTR**	Rx data buffer pointer. Points to the address of the associated buffer. There are no byte-alignment requirements for the buffer, and it may reside in either internal or external memory. This value is not modified by the QUICC Engine block.

NOTE: Entries in boldface must be initialized by the user.

41.4.4.7 CPS Switch Rx Queue Descriptors

Switch RxQD, shown in Figure 41-28 and Figure 41-29, are used for CIDs that are being switched from one $PHY_1 \mid VP_1 \mid VC_1 \mid CID_1$ to another $PHY_2 \mid VP_2 \mid VC_2 \mid CID_2$. The switch RxQD contains the translation CID that is sent with the packet in the transmit buffer. A PPD mode enables the discarding of the rest of an SSSAR frame when a buffer is not available. It is possible to aggregate multiple RQD's

(CID’s residing under the same ATM Rx channel) into a single TxQD. i.e. aggregate multiple CID’s into a single ATM channel.

The switch RxQD contains the translation CID that is saved with the packet in the transmit buffer. A PPD mode enables the discarding of the rest of a SSSAR frame when a buffer is Note that the CPS switch RxQD must be unique for every Rx switched CID.

Two types of RQD’ are available:

Type-1: This RxQD contains a pointer to a TxQD which resides in the RAM. (Internal TxQD’s).

Type-2: This RQD points to an external TxQD. The size of this data structure is expanded now as it points to an address in external memory.

The switch RxQD size could be 4 bytes (Type-1) or 8 bytes (Type-2), in case that the AVCON/AVCF mechanism is disabled, or it could be 8 bytes (Type-1) or 12 bytes (Type-2), in case that the AVCON/AVCF mechanism is enabled (see Section 41.4.3, “AAL2 Switching”).

Figure 41-28. Type-1 CPS Switch Rx Queue Descriptor

Table 41-14 describes the CPS switch RxQD fields.

Table 41-14. Type-1 CPS Switch RxQD Field Descriptions

Offset	Bits	Name	Description
0x00	0-7	**TX CID**	Translation CID. The received CID is saved in a TX Queue with this new CID number.
	8	**AVCON**	Auto VC On. Automatic Scheduling of a channel into the APC. If set, the receiver automatically schedules, if needed, the TCC into the APC scheduling table. Valid also for GCRA scheduler mode. 0 Automatic scheduling is disabled. 1 Automatic scheduling is enabled. See Section 41.4.3, “AAL2 Switching”.
	9	**GCRA_AVCON**	GCRA Scheduler AVCON. Valid only if AVCON bit is set. Indicates which type of APC is used to activate the channel. 0 - Traditional APC. 1 - GCRA Scheduler.
	10	**SWTYPE**	Switch Type- For this RQD’s this bit should be cleared. 0 Type 1. 1 Type-2
	11		Reserved, should be cleared during initialization.
	12	**RBM**	Receive buffer mask. 0 Disable receive buffer interrupt. 1 Enable receive buffer interrupt.
	13	**PPD**	Partial packet discard. 0 Normal mode. 1 When a buffer-not-ready event causes a packet to be discarded, the remainder of the SSSAR SDU is also discarded. This allows for better performance for switched channels that implement SSSAR.
	14-15	**SubType**	Sublayer type. Should be 01 (CPS switched) for this descriptor. 00 CPS sublayer. 01 CPS switched. 10 SSSAR. 11 Reserved.
0x02	—	**TxQD Pointer /** **WFT#i_ptr**	**If TCT[WFQ_En] is cleared:** Points to the TxQD which resides in RAM into which the packets of this CID are stored and later sent. **If TCT[WFQ_En] is set:** Weighted Finish Time #i Pointer. Pointer to the corresponding TxQD WFT entry. i.e., if TxQD is #i= 2 (#i=0..3), then **WFT#i_ptr = TCT[WFQ_Table_ptr]+4**.
0x04	—	**TCC**	Transmit channel code. Valid only when the switch AVCON/AVCF mechanism is enabled (see Section 41.4.3, “AAL2 Switching”). Used by the QUICC Engine block to automatically insert a connection into the APC scheduling table.

Table 41-14. Type-1 CPS Switch RxQD Field Descriptions (continued)

Offset	Bits	Name	Description
0x06	—		Valid only when the switch AVCON/AVCF mechanism is enabled (see Section 41.4.3, "AAL2 Switching"). This is used by the QUICC Engine block to automatically insert a connection into the APC scheduling table**.**
	0-15	**TAPTR**	**Traditional APC mode:** Transmit APC pointer. Pointer to the APC priority Table entry in multi-user RAM.
	0-13	**GCRA Scheduler PHY Parameter Table ptr**	**GCRA Scheduler mode:** 14 most significant bits of the pointer to the GCRA Scheduler PHY Parameter Table, see Section 32.3.7.1, "GCRA Scheduler PHY Parameter Table."
	14-15	**PRI**	**GCRA Scheduler mode:** Indicates the priority number of the inserted channel.
NOTE: Entries in boldface must be initialized by the user.			

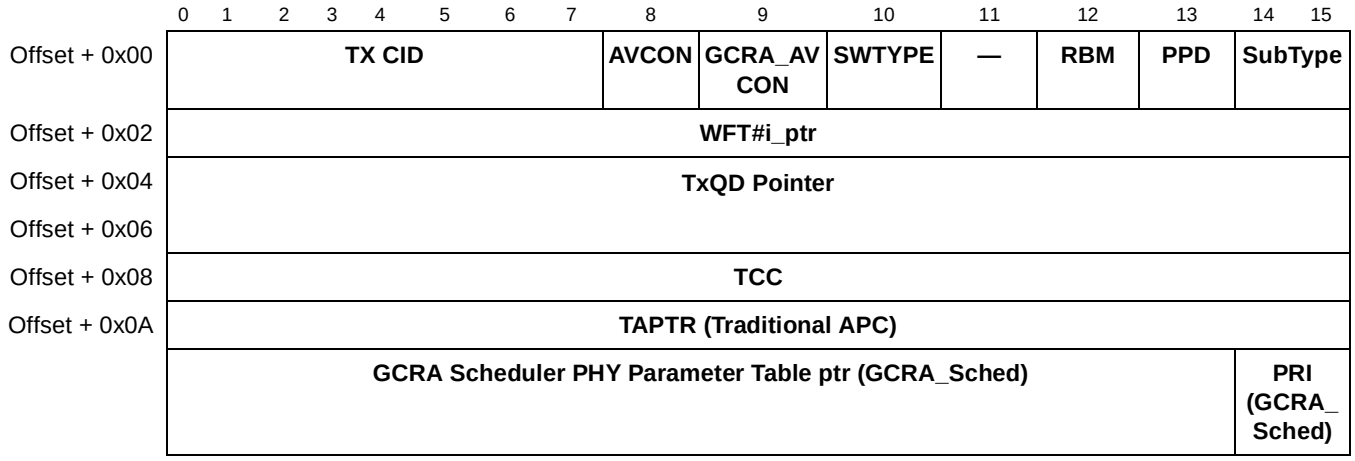

Figure 41-29. Type-2 CPS Switch Rx Queue Descriptor

Table 41-15. Type-2 CPS RxQD Field Descriptions

Offset	Bits	Name	Description
0x00	0-7	**TX CID**	Translation CID. The received CID is saved in a TX Queue with this new CID number.
	8	**AVCON**	Auto VC On. Automatic Scheduling of a channel into the APC. If set, the receiver automatically schedules, if needed, the TCC into the APC scheduling table. Valid also for GCRA Scheduler mode. 0 Automatic scheduling is disabled. 1 Automatic scheduling is enabled. See Section 41.4.3, “AAL2 Switching”.
	9	**GCRASched_AVCON**	GCRA Scheduler AVCON. Valid only if AVCON bit is set. Indicates which type of APC is used to activate the channel. 0 - Traditional APC. 1 - GCRA Scheduler.
	10	**SWTYPE**	Switch Type- For this RQD’s this bit should be set 0 Type 1. 1 Type-2.
	11	**-**	Reserved, should be cleared during initialization.
	12	**RBM**	Receive buffer mask. 0 Disable receive buffer interrupt. 1 Enable receive buffer interrupt.
	14-15	**SubType**	SubType. Sublayer type, should be 01 (CPS switched) for this descriptor. 00 CPS sublayer. 01 CPS switched. 10 SSSAR. 11 Reserved.
0x02	0-15	**WFT#i_ptr**	**Valid only if TCT[WFQ_En] is set:** Weighted Finish Time #i Pointer. Pointer to the corresponding TxQD WFT entry. i.e., if TxQD is #i= 2 (#i=0..3), then **WFT#i_ptr = TCT[WFQ_Table_ptr]+4**.
0x04	—	**TxQD Pointer**	Points to the TxQD which resides in external memory into which the packets of this CID are stored and later sent.
0x08	—	**TCC**	Transmit channel code. Valid only when the switch AVCON/AVCF mechanism is enabled (see Section 41.4.3, “AAL2 Switching”). Used by the QUICC Engine block to automatically insert a connection into the APC scheduling table.

Table 41-15. Type-2 CPS RxQD Field Descriptions (continued)

Offset	Bits	Name	Description
0x0A	—		Valid only when the switch AVCON/AVCF mechanism is enabled (see Section 41.4.3, "AAL2 Switching"). This is used by the QUICC Engine block to automatically insert a connection into the APC scheduling table.
	0-15	**TAPTR**	**Traditional APC mode:** Transmit APC pointer. Pointer to the APC priority Table entry in multi-user RAM.
		GCRA Scheduler PHY Parameter Table ptr	**GCRA Scheduler mode:** 14 most significant bits of the pointer to the GCRA Scheduler PHY Parameter Table, see Section 32.3.7.1, "GCRA Scheduler PHY Parameter Table."
	14-15	**PRI**	**GCRA Scheduler mode:** Indicates the priority number of the inserted channel.
NOTE: Entries in boldface must be initialized by the user.			

41.4.4.8 SWITCH Receive/Transmit Buffer Descriptor (RxBD)

The Switch buffer structure consists of a BD table that points to data buffers. The RxBDs contain, apart from the buffer pointer, the packet header, as shown in Figure 41-30. The buffers contain the packet payload. This BD is common to the receiver and the transmitter.

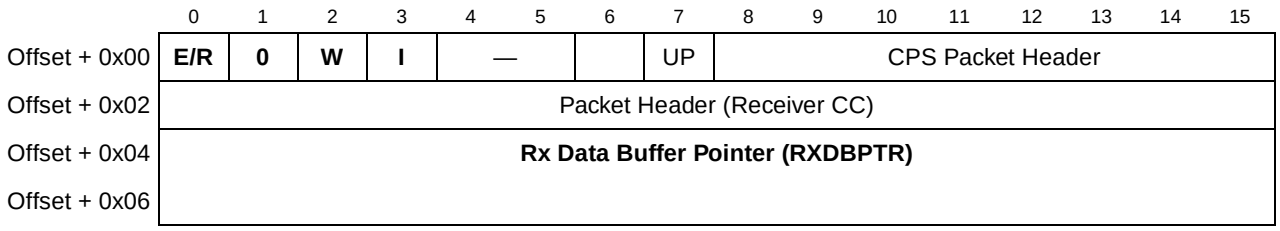

Figure 41-30. Switch Receive/Transmit Buffer Descriptor

Table 41-16 describes the Switch RxBD fields.

Table 41-16. SWITCH RxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**E/R**	Buffer Ready bit. 1The RX buffer is full, or data reception was aborted due to an error. The transmitter will transmit the data if the UP bit is cleared i.e. no errors detected. 0 The RX buffer has been transmitted and ready for receiver reception. If the UP bit is set the receiver started reception of part of a packet.
	1	**0**	Should be cleared
	2	**W**	Wrap (final BD in table) 0 This is not the last BD in the RxBD table. 1 This is the last BD in the RxBD table of this current channel. After this buffer has been used, the QUICC Engine block receives incoming data for this channel into the first BD in the table. The number of RxBDs in this table is programmable and is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	**I**	Interrupt. 0 The QUICC Engine block will not issue an interrupt after this buffer is serviced. 1 The QUICC Engine block will issue an interrupt after this buffer is serviced if the RBM bit in the RxQD is set.
	4-6	—	Reserved. Should be cleared during initialization
	7	UP	Uncompleted packet. 0 No error occurred in this packet and the complete packet has been received. 1 if R/E=1 a receive error occurred that caused this packet to be uncompleted. The receive error type is reported to the interrupt queue. The transmitter will skip this BD when in this state and continue to the next BD in the ring. if R/E=0 a receiver has received the first part of a packet and is waiting for the rest of it to be received on the next ATM cell.
	8-15	CPS Packet Header	Contains the beginning of the packet header. See Figure 41-15 for the CPS packet header format.
0x02		CPS Packet Header (Receiver CC)	Contains the rest of the packet header. The QUICC Engine block checks the packet HEC and if appropriate, indicates a packet HEC error in an interrupt queue entry with CID = 0. See Figure 41-15 for the CPS packet header format. In case of a “stuck” receiver in **switch** mode, where the BD ring in common to Tx and Rx, this field indicates the last Receiver Channel Code number which has been received. The terminology for “stuck” implies a receiver which started receiving a packet and the rest of the packet hasn’t been received. If the Time-out mechanism is being used this field is being used internally by the QUICC Engine block.
0x04	—	**RXDBPTR**	Rx data buffer pointer. Points to the address of the associated buffer. There are no byte-alignment requirements for the buffer, and it may reside in either internal or external memory. This value is not modified by the QUICC Engine block.

NOTE: Entries in boldface must be initialized by the user.

41.4.4.9 SSSAR Rx Queue Descriptor

The SSSAR RxQD, as shown in Figure 41-31, points to the RxBD table and contains other parameters specific to the SSSAR sublayer. This descriptor can belong to only one PHY | VP | VC | CID.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Figure 41-31. SSSAR Rx Queue Descriptor

Table 41-17 describes the SSSAR RxQD fields.

Table 41-17. SSSAR RxQD Field Descriptions

Offset	Bits	Name	Description
0x00	0–10	—	Reserved, should be cleared during initialization
	11	**RasT**	Ras Timer enable. 0 Ras Timer disabled (Time Stamp field is still valid). 1 Ras Timer enabled. The Ras Timer duration is set by the Ras Timer Duration parameter in the parameter RAM. If the current SSSAR SDU is not completed before the RasTimer expires, the BD is closed showing the Ras_Timer expired (TE) (SSSAR RxBD[RxError] = 01) and the next packet starts a new SDU.
	12	**RBM**	Receive buffer mask. 0 Disable receive buffer interrupt. 1 Enable receive buffer interrupt.
	13	**RFM**	Receive frame mask. 0 Disable receive frame interrupt. 1 Enable receive frame interrupt.
	14-15	**SubType**	Sublayer type. Should be 10 (SSSAR) for this descriptor. 00 CPS sublayer. 01 CPS switched. 10 SSSAR. 11 Reserved.

Table 41-17. SSSAR RxQD Field Descriptions

Offset	Bits	Name	Description
0x02	—	**RxBD Table Offset**	Points to the next BD to be handled by the QUICC Engine block. The user should initialize this pointer to zero.
0x04	—	**RxBD Table Base**	Points to the beginning of the BD table. Should be 8 byte aligned.
0x08	—	—	Reserved, should be cleared during initialization.
0x0c		Time Stamp	Used for reassembly time-out of the SSSAR SDU. Whenever the first packet of an SSSAR SDU arrives the timestamp timer is sampled and stored here (regardless of the RasT bit).
0x14	—	**MRBLR**	Maximum receive buffer length. Holds the maximum receive buffer length. The actual buffer size can be less.
0x16	—	**Max_SSSAR_SDU_ Length**	Holds the maximum SSSAR SDU length. Upon each new packet the accumulated frame size is compared with this value. If the limit is exceeded, the QUICC Engine block discards the rest of the packets of the current frame.
0x18-0x1f	—	**—**	Reserved, should be cleared during initialization.

NOTE: Entries in boldface must be initialized by the user.

41.4.4.10 SSSAR Receive Buffer Descriptor

The SSSAR SDU is stored in a BD-buffer structure similar to the structures used for AAL5 frames. The buffer size is determined by SSSAR RxQD[MRBLR]; the actual buffer space used may be smaller. If the received SSSAR SDU is greater than MRBLR, the SDU spans over multiple buffers. UUI of Last packet of the SDU is stored in the RxBD where the L bit set.

The SSSAR RxBD is shown in Figure 41-32.

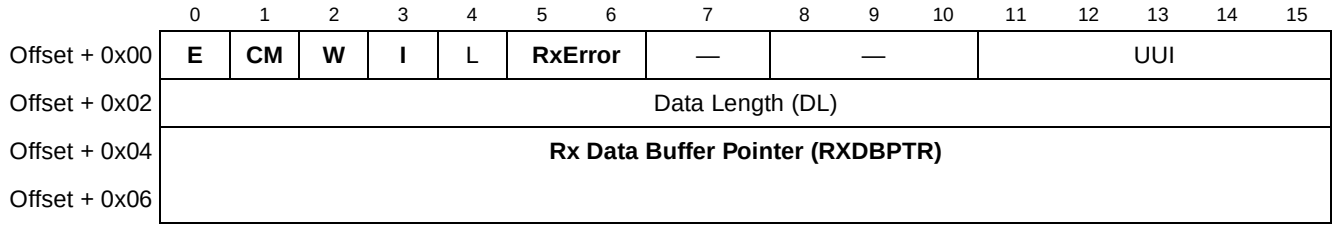

Figure 41-32. SSSAR Receive Buffer Descriptor

Table 41-18 describes the SSSAR RxBD fields.

Table 41-18. SSSAR RxBD Field Descriptions

Offset	Bits	Name	Description
0x00	0	**E**	Empty. 0 The buffer associated with this RxBD is full or data reception was aborted due to an error. The core can read or write any fields of this RxBD. The QUICC Engine block does not use this BD again while E remains zero. 1 The buffer associated with this RxBD is empty or reception is in progress. This RxBD and its receive buffer are controlled by the QUICC Engine block. Once E is set, the core should not write any fields of this RxBD.
	1	**CM**	Continuous mode 0 Normal operation. 1 The QUICC Engine block does not clear E after this BD is closed, allowing the associated buffer to be reused automatically when the QUICC Engine block next accesses this BD. However, the E bit is cleared if an error occurs while receiving, regardless of the CM bit setting.
	2	**W**	Wrap (final BD in the table) 0 This is not the last BD in the RxBD table of the current channel. 1 This is the last BD in the RxBD table of this current channel. After this buffer has been used, the QUICC Engine block receives incoming data for this channel into the first BD in the table. The number of RxBDs in this table is programmable and is determined only by the W bit. The current table cannot exceed 64 Kbytes.
	3	**I**	Interrupt. 0 No interrupt is generated after this buffer has been serviced. 1 An Rx buffer event is sent (provided that RxQD[RBM] is set) to the interrupt queue after this buffer is serviced. The GHIN/GLIN bit in the event register is set when the INT_CNT counter reaches terminal count.
	4	L	Last. Set by the QUICC Engine block. 0 This is not the last buffer of the SSSAR SDU. 1 This is the last buffer of the SSSAR SDU.
	5-6	RxError	Rx error occurred 00 No Rx error occurred 01 TE—Ras_Timer expired. The Ras Timer expired before this buffer could be completed. The SSSAR SDU stored in this buffer is not completed.[1] 10 US—Uncompleted SDU. A receive error caused a packet belonging to this SSSAR SDU to be lost. The receiver discarded the rest of this SSSAR SDU. 11 OS—Oversized. The size of the SSSAR SDU has exceeded the Max_SSSAR_SDU_Size parameter. The rest of the SDU was discarded.
	7-10	—	Reserved, should be cleared during initialization.
	11-15	UUI	Contains the UUI of the last packet in received SDU. Valid only where the L bit is set.

Table 41-18. SSSAR RxBD Field Descriptions (continued)

Offset	Bits	Name	Description
0x02		Data Length	Contains the length of the buffer associated with this BD. If this is the last buffer (L=1) of the SSSAR SDU, this field contains the total frame length.
0x04	—	**RXDBPTR**	Rx data buffer pointer. Points to the address of the associated buffer. There are no byte-alignment requirements for the buffer, and it may reside in either internal or external memory. This value is not modified by the QUICC Engine block.

[1] When RAS timer expires the RxBD is closed with RAS timer expired indication, the Last (L) bit is not set, and RXF interrupt is not issued. A new RxBD is opened for the next incoming AAL2 packet and the frame is processed as normal and is treated as a new frame. When the next SSSAR end-of-frame indication is received, the RxBD at that time is closed with an L indication, and if RxQD[RFM] = 1, the receiver issues an RXF interrupt.

41.5 AAL2 Parameter RAM

See more description in Table 32-18..

41.6 Enhanced AAL2 Extended Parameter RAM

See description in Table .

41.7 User Defined Cells in AAL2

The user defined cell (UDC) mode for ATM, see Section 32.2.16, “User-Defined Cells (UDC),” applies generally to AAL2 operation as well. However, for AAL2 operation only, the UDC headers reside in a table in external memory, not in the BDs. This table resides in the same bus as the data buffers, as indicated in the RCT/TCT DTB bit.

For transmit channels in AAL2 UDC mode, initialize its UDC header entry in the TX UDC header table before activating the channel. The header can be up to 12 bytes. The TX_UDC_Base parameter in the parameter RAM, see Table 32-18, points to the beginning of the TX UDC header table.

The UDC header of a specific AAL2 transmit VC is located at the following address:

TX_UDC_Base + CH# *16 (where CH# is the ATM channel number)

For receive channels in AAL2 UDC mode, the receiver copies the UDC header from the first cell received by the VC to the RX_UDC header table. The UDC headers of subsequent cells of that VC are discarded; UDC extended address mode (UEAD) is not affected.

The UDC header of a specific AAL2 receive VC is located at the following address:

RX_UDC_Base + CH#*16 (where CH# is the ATM channel number)

The structure of a UDC header table (receive or transmit) is shown in Figure 41-33.

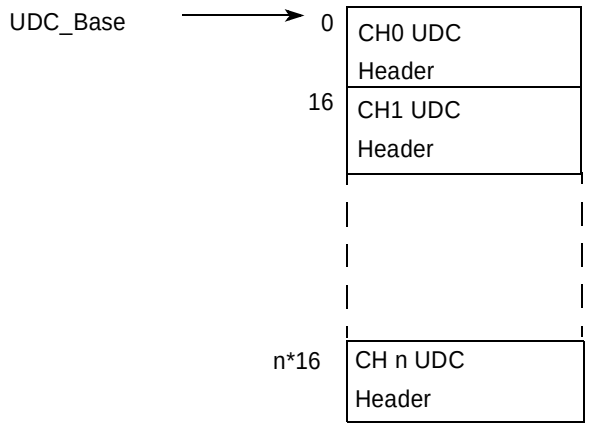

Figure 41-33. UDC Header Table

41.8 AAL2 Exceptions

For each VC, four circular interrupt queues are available. By programming RCT[INTQ] and TCT[INTQ] for each VC, the user assigns an interrupt queue number.

When one of the CIDs generates an interrupt request, the QUICC Engine block writes a new entry to the interrupt queue containing the ATM channel number, the CID, and a description of the exception. Because CID = 0 is a unique CID number, it is used to specify that the event is related to the VC rather than the CID. As with all ATM exceptions, the valid (V) bit is then set and INTQ_PTR is incremented. When INTQ_PTR reaches a location with the W bit set, it wraps to the first entry in the queue. More details can be found in Section 32.3.13.2, “Interrupt Queues.”

An interrupt entry for a CID is shown in Figure 41-34.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Offset + 0x00	**V**	—	**W**	CID								TBNR	RXB	BSY	TXB	RXF
Offset + 0x02	Channel Code (CC)															

Figure 41-34. AAL2 Interrupt Queue Entry CID ≠ 0

Table 41-19 describes the interrupt queue entry fields for a CID.

Table 41-19. AAL2 Interrupt Queue Entry CID ≠ 0 Field Descriptions

Offset	Bits	Name	Description
0x00	0	**V**	Valid interrupt entry 0 This interrupt queue entry is free and can be used by the QUICC Engine block. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	—	—
	2	**W**	Wrap bit. When set, this is the last interrupt entry in the circular table. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	3–10	CID	CID number. The exception occurred for this CID.
	11	TBNR	Tx buffer not ready interrupt. This interrupt is issued when the QUICC Engine block tries to open a TxBD, which is not ready (R = 0). This interrupt is sent only if TxQD[BNM] = 1. The interrupt has an associated channel code. **Note:** The CID number which is placed in the interrupt queue in case of TBNR is always set to 0, since the CID is not updated as the BD is not ready.
	12	RXB[1]	Rx buffer interrupt. This interrupt is issued when the I bit is set for an RxBD and the RxQD[RBM] bit is set. This interrupt has an associated channel code and CID.
	13	BSY	Busy condition. The RxBD table associated with this channel's CID is busy. Packets were discarded due to this condition.
	14	TXB	Transmit buffer interrupt. This interrupt is issued when the TxBD[I] bit is set. This interrupt is sent only if TxQD[TBM] is set. This interrupt has an associated channel code and CID.
	15	RXF[1]	Receive SSSAR SDU (frame). An SSSAR frame belonging to this channel's CID has been received. This interrupt is sent only if RxQD[RFM]=1.
0x02	—	CC	Channel code specifies the ATM channel number associated with this interrupt.

[1] These interrupt queue fields are defined differently for other AAL types, see Table 32-67.

An interrupt entry for the VC is shown in Figure 41-35.

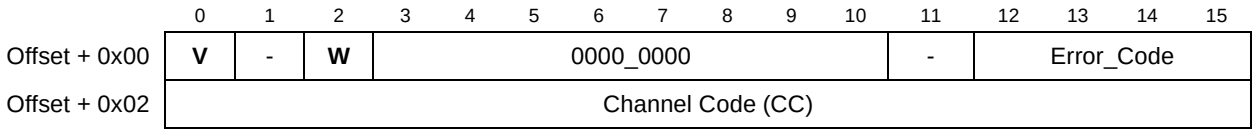

Figure 41-35. AAL2 Interrupt Queue Entry CID = 0

Table 41-20 describes the interrupt queue entry fields for the VC. All the receive error events are enabled by setting RCT[EM].

Table 41-20. AAL2 Interrupt Queue Entry CID = 0 Field Descriptions

Offset	Bits	Name	Description
0x00	0	**V**	Valid interrupt entry 0 This interrupt queue entry is free and can be used by the QUICC Engine block. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	-	Reserved. Should be cleared.
	2	**W**	Wrap bit. When set, this is the last interrupt circular table entry. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	3–10	CID	CID number. Equals zero. This exception applies to the whole cell.
	11	-	Reserved. Should be cleared.
	12-15	Error_Code	If QM1 and QM2 are cleared: A receive error was detected. 0000 Parity error of the OSF. 0001 The STF sequence number is incorrect. 0010 The number of octets expected to overlap into this cell does not match the OSF. 0011 OSF is greater than 47. 0100 A packet HEC error was detected. 0101 The length of the CPS packet exceeds the Max_SDU_Length. 0111 A packet HEC error was detected in a split header packet.
0x02	—	CC	Channel code specifies the ATM channel number associated with this interrupt.

41.8.1 Interrupt Entry for CID Statistics

For CID Statistics Mode there is an additional interrupt entry format, that contains also a CID field. Figure 41-36 describes this Entry.

Upon getting an overflow in any of the statistics table and the Mask bit in the RCT/TCT is set an interrupt is generated.

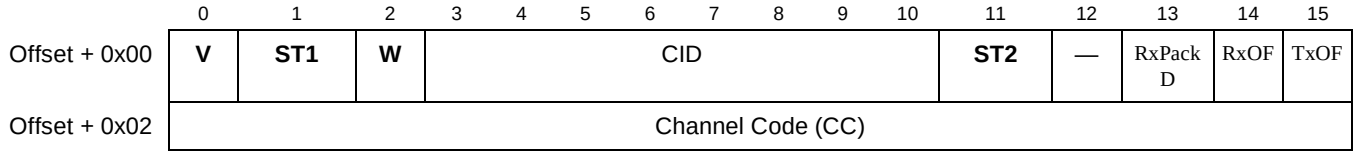

Figure 41-36. AAL2 Interrupt Entry for CID Statistics

Table 41-21 describes the interrupt queue entry fields.

Table 41-21. AAL2 Interrupt Queue for CID Statistics Field Descriptions

Offset	Bits	Name	Description
0x00	0	**V**	Valid interrupt entry 0 This interrupt queue entry is free and can be used by the QUICC Engine block. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	ST1	Set to 1 by the QUICC Engine block when this is a Statistics type interrupt. This gives the host a mean to distinguish this type of interrupt from other AAL2 interrupts.
	2	**W**	Wrap bit. When set, this is the last interrupt circular table entry. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	3–10	CID	CID number on which the counter has overflown. This field could be a used as an index to the counters table with the exception of CID=0 on the receiver side. In this case the counter is not aligned as all the other counters in the CID mapping
	11	ST2	Set to 1 by the QUICC Engine block when this is a Statistics type interrupt. This gives the host a mean to distinguish this type of interrupt from other AAL2 interrupts.
	12	—	Reserved. Should be initialized to 0.
	13	RxPackD	Rx Packet Discard counter overflow. Valid Only for Switch mode with TxQD[PackD] bit set. This interrupt is sent only if RCT[StatsIE] is set.
	14	RxOF	Rx CID / ATM Cell counter overflow interrupt. If the CID field equals to 0, then it indicates that it is a Rx ATM Cell counter overflow, else it indicates the CID value in which the Rx CID counter overflow appears.This interrupt is sent only if RCT[StatsIE] is set.
	15	TxOF	Tx CID / ATM Cell counter overflow interrupt. If the CID field equals to 0, then it indicates that it is a Tx ATM Cell counter overflow, else it indicates the CID value in which the Tx CID counter overflow appears. This interrupt is sent only if TCT[StatsIE] is set.
0x02	—	CC	Channel code specifies the ATM channel number associated with this interrupt.

41.8.2 Interrupt Entry for WFQ Queue Management

For WFQ Queue Management mode there is an additional interrupt entry format, that it's CID field is cleared. Figure 41-37 describes this Entry.

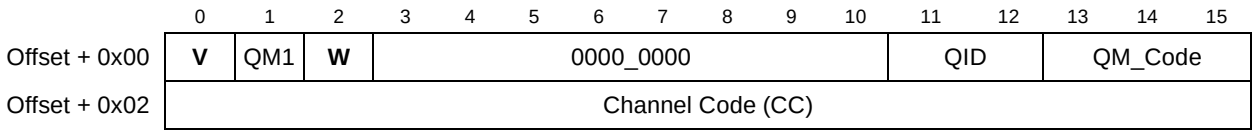

Figure 41-37. AAL2 Interrupt Queue Entry CID = 0 for WFQ Queue Management

Table 41-22 describes the interrupt queue entry fields for the VC. All the error events are enabled by the corresponding CPS_TxQD[Queue_Management] interrupt mask bits. See Table 41-6.

Table 41-22. AAL2 Interrupt Queue Entry CID = 0 Field Descriptions

Offset	Bits	Name	Description
0x00	0	**V**	Valid interrupt entry 0 This interrupt queue entry is free and can be used by the RISC. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	QM1	When set identifies that it is a Switch queue management threshold event.
	2	**W**	Wrap bit. When set, this is the last interrupt circular table entry. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	3–10	CID	CID number. Equals zero.
	11-12	QID	Queue ID. Indicates under which queue ID the queue management interrupt occurred.
	13-15	QM_Code	Queue Management Code. 000- Full Speed to Decelerate interrupt. 001- Res. (Not used so we can identify between statistic cell counter interrupt TxOF) 010- Res. (Not used so we can identify between statistic cell counter interrupt RxOF) 011- Decelerate to Full Stop interrupt. 100- Accelerate to Decelerate interrupt. 101- Full Stop to Accelerate interrupt. 110- Accelerate to Full Speed interrupt. 111- Decelerate to Accelerate interrupt. For more description see Section 41.4.3.1.1, “Queue Management”.
0x02	—	CC	Channel code specifies the ATM channel number associated with this interrupt.

41.9 AAL2 RAM Usage

Table 41-23 summarize the AAL2 RAM usage in multithread (mth) or non-multithread (non-mth) systems.

Table 41-23. AAL2 RAM Usage

Parameter	UCCs (If MTH disabled)	Threads (If MTH Enabled)	VCCs	AVCON	WFQ	CPS	SW/SW Type1	SSSAR	Threshold no.	Bytes
Parameter RAM	1-8	1-32	—	—	—	—	—	—	—	UCCs*512 (non-mth) or UCCs*352+Threads*224 (mth)
RxQD Tmp	1-8	1-32	—	—	—	—	—	—	—	UCCs*32 (non-mth) or Threads*32 (mth)

* these parameters are unlikely to reside in RAM in overloaded system

** no. of TxQDs is actually unlimited, but 9 seems to be a good upper limit.

*** The total no. of RQDs under a VCC is not bigger than 256.

Chapter 42
QMC (QUICC Multi-Channel Controller)

The QUICC multi-channel controller (QMC) functionality can emulate up to 64 time-division serial channels using a single unified communication controller (UCC) and a time-division multiplexed (TDM) physical interface. Each UCC has its own parameter table and the channel's specific parameters. Each UCC also has its own event register, so the functionality of each UCC is orthogonal to that of adjacent UCCs. Therefore, theoretically it enables support of up to 512 serial channels. The application must manage channel numbering since the numbering (0–63) is performed per UCC.

Each channel can be independently programmed to operate in either HDLC or transparent mode. Any available TDM in the serial interface (SI) can be used for the QMC protocol. The SI transfers data between the TDM interface and the UCC, which performs multiplexing/demultiplexing on the QMC channels. Figure 42-1 provides an overview of the QMC functionality.

Each UCC can work in QMC mode, either alone or together in any combination, spreading any of the 64 available QMC channels across the multiple UCCs. One TDM connection can be routed to one or more UCCs operating in QMC mode, with each UCC operating on different time slots.

Multiple TDMs can be used for QMC with combined routing to one UCC or separate UCCs. When multiple TDMs are connected to the same UCC, restrictions such as using common clocks and sync inputs apply; to avoid collisions, the serial interface (SI) routing is separated to ensure that only one TDM accesses the UCC at any given time.

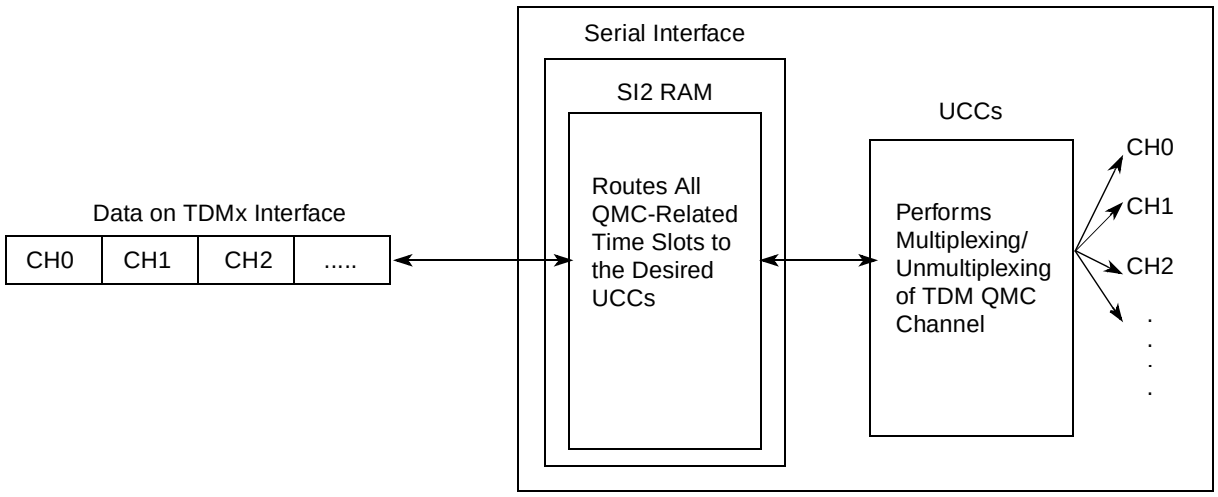

Figure 42-1. QMC Channel Addressing Capability

42.1 Features

QMC-specific features include the following:

- Up to 64 independent communication channels per UCC or split across multiple UCCs
- Arbitrary mapping of any of 0–63 channels to any TDM time slot
- Independent mapping possible for receive/transmit
- Supports either transparent or HDLC protocols for each channel
- Interrupt circular buffer with programmable size and overflow identification
- Global loop mode
- Individual channel loop mode through the SI
- Programmable frame length through the SI

QMC features related to the serial interface include the following:

- Serial-multiplexed (full duplex) input/output 2048-, 1544-, or 1536-Kbps PCM highways
- Compatible with T1/DS1 24-channel and CEPT E1 32-channel PCM highway, ISDN basic rate, ISDN primary rate and user-defined
- Subchanneling on each time slot
- Allows independent transmit and receive routing, frame syncs, and clocking
- Concatenation of any, not necessarily consecutive, time slots to channels independently for receive/transmit
- H0, H11, and H12 ISDN channels
- Dynamic allocation of channels

QMC features related to the system interface include the following:

- On-chip bus arbitration for serial DMAs with no performance penalty
- Efficient bus usage (no bus usage for nonactive channels and active channels that have nothing to transmit)
- Efficient control of the interrupts to the CPU
- Supports external buffer descriptors table
- Uses on-chip enlarged multi-user RAM for parameter storage

42.2 QMC and the Serial Interface

This section describes additional functionality that the SI provides to QMC operation. The QMC works in conjunction with the serial interface, taking advantage of its programmable SIRAM and additional functionality. See Chapter 36, “Serial Interface with Time-Slot Assigner,” for details on proper programming of the SI registers and SIRAM. However, the QMC can operate in non-multiplexed serial interface (NMSI) mode, directly using the UCC pins instead of the TDM interface pins. Functions such as frame synchronization, loopback, echo, and inverted signals are performed in the serial interface and cannot be achieved in NMSI mode. Use of the serial interface is recommended even if only one UCC is used for the TDM bus.

To connect a UCC to the SI or to its own pins in NMSI mode, program the appropriate CMX UCC clock route register (CMXUCRx). See Section 21.5.5, “CMX UCC Clock Route Register (CMXUCR1).”

42.2.1 Synchronization

Independent receive and transmit clocks and frame synchronization signals control the data transfer. In NMSI operation, synchronization occurs only once after activating QMC, to initiate transfer using the CD (receive) and CTS (transmit) signals in pulse mode. If any noise corrupts either signal or the clock, the QMC is out of synchronization until the whole protocol is restarted. In contrast, the more robust SI performs a synchronization on each frame, limiting the damage from noise error on the clock or synchronization lines. Noisy channels can be restarted individually without interrupting other channels.

42.2.2 Loopback Mode

The loopback from a transmitter to a receiver can be implemented on a per QMC channel basis. If channel-specific loopback is desired, it is important to have each individual QMC time slot represented as an entry in the SIRAM in order to achieve proper operation. A common transmit and receive clock as well as a common frame synchronization pulse must be provided for loopback mode to work. The loopback is done on a fixed time slot of the actual TDM.

42.2.3 Echo Mode

The SI can be programmed to echo incoming data. The complete TDM link is retransmitted from the incoming L1RXDx to the L1TXDx pin on a bit-by-bit basis. The receiver section of the selected UCC can operate normally and also receive the incoming bit stream. This is also known as global echo mode on the whole link. Individual time-slot echo is not possible with QMC without software intervention.

42.2.4 Inverted Signals

All QMC-related receive and transmit data can be logically inverted by setting the RINV and TINV bits of the GUMR_L register. A logical inversion on a per channel basis is not possible in the QMC without external hardware. To invert a specific channel, the SI can be programmed to send a strobe signal at the QMC channel’s corresponding time slot on the TDM interface. This strobe can then be connected to an external XOR gate to perform the inversion.

42.2.5 QMC Routing Changes On-The-Fly

Changes can be made on-the-fly in the QMC routing tables, but changes made to SI RAM require the QMC link to be disabled or require usage of a shadow RAM routing table. The shadow table can hold alternative routing information to be switched in at the appropriate time-slot boundary.

42.3 QMC Memory Organization

42.3.1 QMC Memory Structure

Figure 42-2 shows how data is addressed by the QMC protocol. It discusses addressing the multi-user RAM to access data within the buffers.

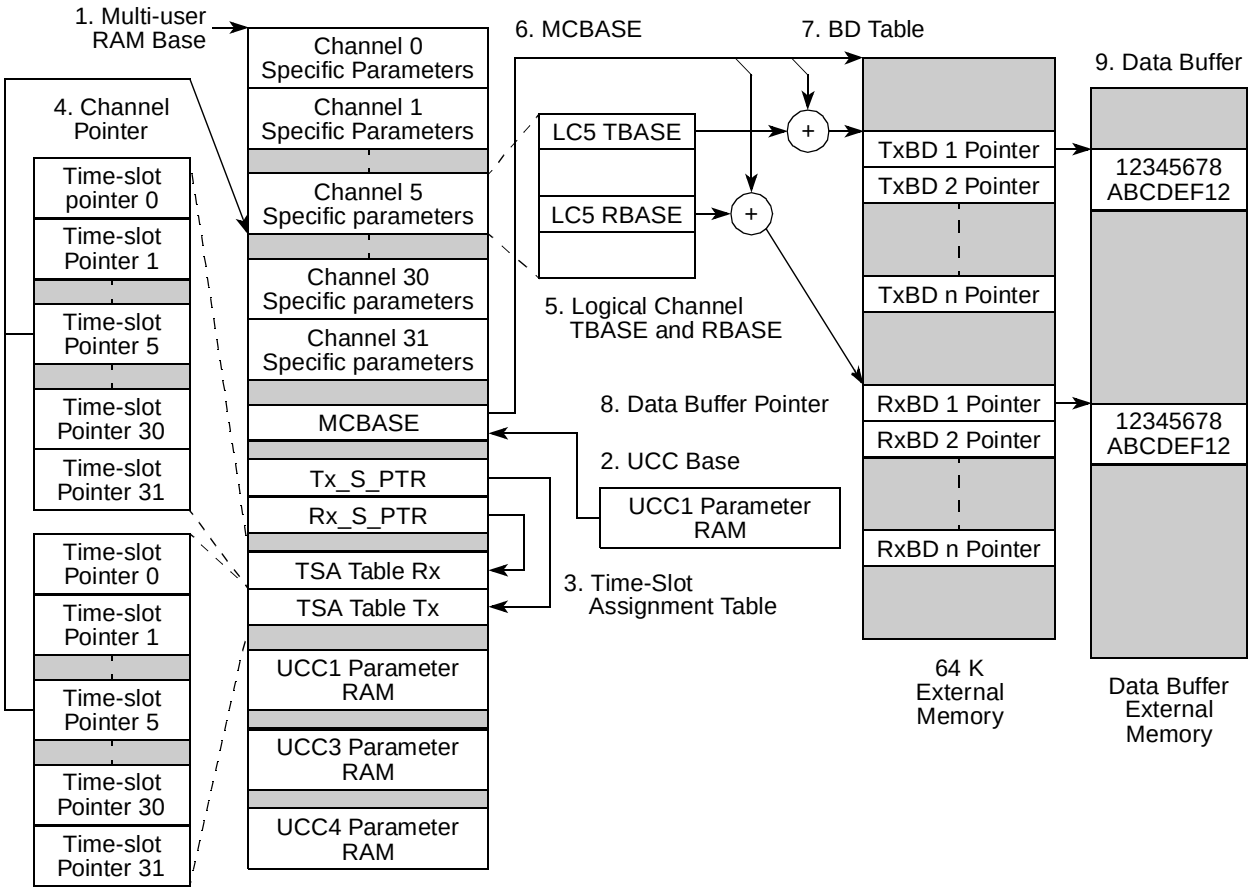

Figure 42-2. QMC Memory Structure

42.3.2 UCC Base and Global Multichannel Parameters

The UCC base points to the start of the parameter RAM for each UCC at 256-byte intervals. When the QMC protocol is enabled on a UCC, its parameter RAM is used to store the global multichannel parameters for all the logical channels. This area contains parameters and pointers that are common to all channels.

42.3.2.1 TSATRx/TSATTx Pointers and Time-Slot Assignment Table

The time-slot assignment table pointers are within the global multichannel parameters. There are two pointers—Tx_S_PTR for transmit and Rx_S_PTR for receive. The Rx_S_PTR is normally set to UCC Base + 20; this is the normal location of the receive time slot assignment table. The Tx_S_PTR is normally

set to UCC Base + 60; this is the normal location of the transmit time-slot assignment table. However, if the receiver and the transmitter have the same mapping for the logical channels, Tx_S_PTR can point to UCC base + 20 so that Rx and Tx have a common time-slot assignment table. Note that if a single TDM channel is routed to more than one UCC, they may also use just one time-slot assignment table for all UCCs. See Section 42.3.3, "Multiple UCC Assignment Tables," for more information. The time-slot assignment table holds one 16-bit entry for each time slot. It has options for subchanneling, a valid bit, and a logical channel pointer. For 64-channel support there is only space for one table; therefore, common Rx and Tx parameters must be used unless one of the TSA tables can be accommodated elsewhere in memory, such as in the parameter RAM area of another UCC. Associated with the Rx/Tx_S_PTR are the Rx/TxPTR pointers that are maintained by the QUICC Engine block and point to the current time slot.

42.3.2.2 TSATRx/TSATTx Channel Pointers

The channel pointers are 12-bit pointers to the channel-specific parameters in the internal multi-user RAM. These should not be confused with TSATRx/TSATTx pointers as described in Section 42.3.2.1, "TSATRx/TSATTx Pointers and Time-Slot Assignment Table." The 6 most-significant bits of the address are taken from the time slot assignment table. The 6 least-significant bits are zero, mapping out a 64-byte area for each of the channel-specific parameters. The channel-specific parameters are common for Rx and Tx. For 32-channel support, 2 Kbytes of multi-user RAM is required (32×64), and for 64-channel support, 4 Kbytes of multi-user RAM is required (64×64). In most cases, time slot 0 channel pointer addresses the base of multi-user RAM for logical channel 0, and time slot 1 channel pointer would address the base of multi-user RAM + 4 for logical channel 1. In Figure 42-2, time slot 5 channel pointer addresses logical channel 5, requiring the channel pointer being set to 0b000101.

NOTE

Multiple time slots can be concatenated to one logical channel by setting the channel pointers of the grouped time slots to the same logical channel.

42.3.2.3 Logical Channel TBASE and RBASE

TBASE and RBASE are within the channel-specific parameters. TBASE is the Tx buffer descriptor base address, and RBASE is the Rx buffer descriptor base address. These 16-bit offsets from MCBASE point to individual logical channel's buffer descriptors located within the buffer descriptor table. Note that there are individual TBASE and RBASE values for each logical channel.

42.3.2.4 MCBASE

MCBASE is located in the global multichannel parameters. Each UCC has a unique MCBASE value pointing to the base of the UCC's buffer descriptor table in external memory. For example, the address of logical channel five's Tx buffer descriptor table is MCBASE + logical channel five TBASE. MCBASE normally points to external RAM, but it is permissible to set it up so that some or all BDs are placed within free areas of the MURAM. This may save valuable access time if external memory is slow.

42.3.2.5 Buffer Descriptor Table

A buffer descriptor table for each UCC is located in a 64-Kbyte area of external memory. This block size is determined by the TBASE and RBASE addressing range. The memory segment must be long-word-aligned but can start anywhere in memory. Each UCC has a maximum of 8,192 (64 Kbytes memory ÷ 8-byte pointers) buffers. For a 32-channel implementation, each logical channel has a maximum of 128(8,192 / (32 × 2)) buffers for receive and 128 buffers for transmit. If any BDs are placed in internal memory, the GBL bit of RSTATE and TSTATE may not be set. For each logical channel, a circular queue exists with programmable start address and length.

42.3.2.6 Data Buffer Pointer

As with the standard QUICC Engine protocols, the data buffer is addressed by a 32-bit pointer within the buffer descriptor. This addresses the data received or transmitted from external memory.

42.3.2.7 Data Buffer

The data buffers in external memory can hold up to 64 Kbytes of data as determined by the data length in the buffer descriptor.

42.3.2.8 Global Multichannel Parameters

The global multichannel parameters reside in the UCC's parameter RAM page and are common to all logical channels.

The largest portion of the global area is the time-slot assigner tables for the receiver and transmitter section of the UCC. For 32-channel support, there is one table for Tx and one for Rx within the parameter RAM. If the connection is split over multiple UCCs, this table only needs to be present once for multiple UCCs operating in QMC mode. See Section 42.3.3, "Multiple UCC Assignment Tables," for more information. For 64-channel support there is only space for one table; therefore common Rx and Tx parameters must be used unless one of the TSA tables can be accommodated elsewhere in memory, such as in the parameter RAM area of another UCC.

The multi-user RAM is used for the channel-specific area for all UCCs. It is important that individual time slots are mapped to only one UCC, and that individual logical channels are separated to avoid contention.

Table 42-1 lists the global parameters. Note that the boldfaced parameters must be initialized by the user. See Section 42.7, "QMC Initialization," for more information.

Table 42-1. Global Multichannel Parameters

Offset to UCC Base	Name	Width (Bits)	Description
00	**MCBASE**	32	Multichannel base pointer—This host-initialized parameter points to the starting address of the 64-Kbyte buffer descriptor table in external memory. The MCBASE is used with the TBASE and RBASE registers in the channel-specific parameters.
04	**QMCSTATE**	16	Multichannel controller state (initialize to 0x8000)—Internal QMC state machine value used by RISC processor for global state definition.

Table 42-1. Global Multichannel Parameters (continued)

Offset to UCC Base	Name	Width (Bits)	Description
06	**MRBLR**	16	Maximum receive buffer length—This host-initialized entry defines the maximum number of bytes written to a receive buffer before moving to the next buffer for this channel. This value must be a multiple of 4 bytes.
08	**Tx_S_PTR**	16	Tx time-slot assignment table pointer (UCC base + 60 in normal mode; UCC base + 20 for common Rx & Tx time slot assignment tables)—This global QMC parameter defines the start value of the TSATTx table. The TSATTx table in the global multichannel parameter listing starts by default at UCC base + 60. Tx_S_PTR lets the user move the starting address of this table. If the same routing and masking are used for the transmitter and receiver, the tables can be overlaid, so Tx_S_PTR can point to UCC base + 20. This parameter is an offset from multi-user RAM BASE. This table must be present only once per UCC global area. Other UCCs can access this location.
0A	**RxPTR**	16	Rx pointer (initialize to UCC base + 20)—This global QMC parameter is a RISC variable that points to the current receiver time slot. The host must initialize this pointer to the starting location of TSATRx. The RISC processor increments this pointer whenever it completes the processing of a received time slot.
0C	**GRFTHR**	16	Global receive frame threshold—Used to reduce interrupt overhead when many short HDLC frames arrive, each causing an RXF interrupt. GRFTHR can be set to limit the frequency of interrupts. Set to 1 to get an interrupt per frame received. Note that the RXF event is written to the interrupt table on each received frame, but GINT is set only when the number of RXF events (by all channels) reaches the GRFTHR value. GRFTHR can be changed on-the-fly. For information about exception handling, see Section 42.5, “QMC Exceptions.”
0E	**GRFCNT**	16	Global receive frame count (initialized GRFCNT = GRFTHR)—A down-counter used to implement the GRFTHR feature. GRFCNT decrements for each frame received. No other receiver interrupts affect this counter. The counter value is set to the threshold during initialization. GRFCNT is automatically reset to the GRFTHR value by the QUICC Engine block after a global interrupt.
10	**INTBASE**	32	Multichannel interrupt base address (host-initialized)—This pointer contains the starting address of the interrupt circular queue in external memory. Each entry contains information about an interrupt request that has been generated by the QMC to the host. Each UCC operating in QMC mode has its own interrupt table in external memory. See Section 42.5, “QMC Exceptions.”
14	**INTPTR**	32	Multichannel interrupt pointer (host-initialized)—This global parameter holds the address of the next QMC interrupt entry in the circular interrupt table. The RISC processor writes the next interrupt information to this entry when an exception occurs. The host must copy the value of INTBASE to INTPTR before enabling interrupts.
18	**Rx_S_PTR**	16	Rx time-slot assignment table pointer (default = UCC base + 20 in normal mode)—This global QMC parameter defines the start value of the TSATRx table, which must be present only once per UCC global area. Other UCCs may access this location.
1A	**TxPTR**	16	TxPTR (initialize to UCC Base + 60)—This global parameter is a RISC variable that points to the current transmitter time slot. The host must initialize it to the starting location of TSATTx. The RISC processor increments this pointer whenever it completes the processing of a transmitter time slot.

Table 42-1. Global Multichannel Parameters (continued)

Offset to UCC Base	Name	Width (Bits)	Description
1C	**C_MASK32**	32	CRC constant (0xDEBB20E3)—Required to calculate 32-bit CRC-CCITT. C_MASK32 is written by the host during QMC initialization. It is used for 32-bit CRC-CCITT calculation if HDLC mode of operation is chosen for a selected channel. (This is a programmable option. For each HDLC channel, one of two CRCs can be chosen, as programmed in CHAMR.) For more information, see Section 42.3.4.1, "Channel-Specific HDLC Parameters." This entry must have a correct value if at least one HDLC channel is used; otherwise, it can be cleared (0).
20	**TSATRx**	32 Entries x 16	Time slot assignment table Rx—Host-initialized, 16-bit-wide table with 32 entries that define mapping of logical channels to time slots for the QMC receiver. The QMC protocol looks at chunks of 8 bits regardless of whether they come from one physical time slot of the TDM or whatever other combination of bits the TSA transfers to the UCC. These 8 bits are referred to as a time slot in the assignment table. It is recommended but not required to route all bits from the TDM to the UCC and to do all enabling and masking in the time-slot assignment table. See Figure 42-4.
60	**TSATTx**	32 Entries x 16	Time slot assignment table Tx—Maps a specific logical channel to each physical time slot. Time slot assignment table Tx is a host-initialized, 16-bit table with 32 entries that define the mapping of channels to time slots for the QMC transmitter. The QMC protocol looks at chunks of 8 bits regardless if they go to one physical time slot of the TDM or whatever other combination of bits are transferred from the UCC to the TDM through the TSA. These 8 bits are referred to as a time slot in the assignment table. It is recommended but not required to route all bits from the TDM to the UCC and to do all enabling and masking in the time slot assignment table. See Figure 42-4.
A0	**C_MASK16**	16	CRC constant (0xF0B8)—Required to calculate 16-bit CRC-CCITT. This constant is written by the host during QMC initialization. It is used for 16-bit CRC-CCITT calculation if HDLC mode of operation is chosen for a selected channel. (This is a programmable option. For each HDLC channel, one of two CRCs can be chosen, as programmed in CHAMR.) For more information, see Section 42.3.4.1, "Channel-Specific HDLC Parameters." This entry must have a correct value if at least one HDLC channel is used; otherwise, it can be cleared (0).
A4	TEMP_RBA	32	Temporary receive buffer address
A8	TEMP_CRC	32	Temporary cyclic redundancy check
AC	RX_FRM_Base	16	This entry contains a pointer to an area in the multi-user RAM where the receiver framer temporary parameters reside. The area designated for these parameters is a single byte per TDM channel.
AE	TX_FRM_Base	16	This entry contains a pointer to an area in the multi-user RAM where the receiver framer temporary parameters reside. The area designated for these parameters is a single byte per TDM channel.
B0–C3	Reserved		Should be initialized to zero
C4	**QMC_Global_Channel_specific_base**	32	QMC Global Channel Specific Parameters' Base. Internal pointer for the new channel base address. Must be cleared (Set to 0) if Channel Specific Parameters reside at the beginning of the MURAM.

NOTE

The receiver and transmitter cannot share the same structure of RX_FRM_Base as done on the TSA table when the TDM functionality of the receiver is identical to that of the transmitter.

The user must program the area pointed by RX_FRM_Base/TX_FRM_Base so that each 1-byte entry corresponds to a TDM channel numbered per the QMC time-slot assignment table. The number of entries is determined by the number of active channels in the system. Each time a channel is initialized, the corresponding entry should be programmed to this value.

0	1	2	3	4	5	6	7
0	0	0	0	0	0	0	1

Figure 42-3. RX Framer Entry

NOTE

The area between UCC base + 20 and UCC base + 9F is normally used for TSA tables. The preceding mapping is ideal for 32-channel support. The exact mapping of the TSA tables is determined by the configuration of Rx_S_PTR and Tx_S_PTR and is not fixed. For 64-channel support, common Rx and Tx parameters are recommended. The TSA table is common and has 64 entries starting at UCC base + 20; see Figure 42-5. Alternatively, another UCC parameter RAM can be used, as determined by Rx_S_PTR and Tx_S_PTR; see Figure 42-7. However implemented, the TSA tables can reside anywhere in internal memory.

Figure 42-4 shows a general time-slot assignment table for 32 16-bit time slots. The fields are used either to transmit or receive channels.

Time Slot 0	V	W	Mask(0:1)	Channel Pointer	Mask(2:7)	
Time Slot 1	V	W	Mask(0:1)	Channel Pointer	Mask(2:7)	
	V	W	Mask(0:1)	Channel Pointer	Mask(2:7)	
						32×16
	V	W	Mask(0:1)	Channel Pointer	Mask(2:7)	
	V	W	Mask(0:1)	Channel Pointer	Mask(2:7)	
Time Slot 30	V	W	Mask(0:1)	Channel Pointer	Mask(2:7)	
Time Slot 31	V	W	Mask(0:1)	Channel Pointer	Mask(2:7)	

Figure 42-4. Time-Slot Assignment Table

Table 42-2 describes the fields in the time-slot assignment table for receive.

Table 42-2. Time-Slot Assignment Table Entry Fields for Receive Section

Field	Description
V	Valid bit—Indicates whether this time slot is valid. • 0The data in this 8-bit time slot is totally ignored and not written to any buffer. • 1The data in this 8-bit time slot is valid and written to the current buffer, pointed to by the channel pointer entry, after protocol processing (e.g. zero deletion in HDLC). Individual bits can be masked out as described later.
W	Wrap bit—Identifies the last entry in TSATRx. • 0This is not the last time slot in the frame. • 1The RISC processor wraps around and handles time slot 0 or the first 8 bits transferred from the TSA in the next request. The next request is identified by a frame synchronization pulse.
Rx channel pointer	This 6-bit field of the TSATRx entry identifies the data channel routed to this time slot. The actual channel pointer is 12 bits long, and contains the starting address of the channel-specific parameter area (address of RBASE). The 6 most-significant bits are taken from the TSATRx channel pointer field, and the 6 least-significant bits are always internally set to zero.
Mask(0–7)	Mask bits—These 8 bits identify the valid bits in this time slot for subchanneling support. For 8-bit resolution, all mask bits should be set to 1. Any unmasked bit (1) is processed in the receiver for a valid time slot. Any masked bit (0) is ignored by the receiver for a valid channel and no bit counter is affected.

Table 42-3 describes the fields in the time-slot assignment table for transmit.

Table 42-3. Time-Slot Assignment Table Entry Fields for Transmit Section

Name	Description
V	• Valid bit—Indicates whether this time slot is valid. • 0Logic 1 is transmitted. If the Tx signal of the TDM interface is programmed to be an open drain output (port B programming), other devices can transmit on nonvalid time slots. • 1Data is transmitted from its associated buffer in combination with the mask bit settings.
W	• Wrap bit—Identifies the last entry in TSATTx. • 0This is not the last time slot in the frame. • 1The RISC processor wraps around and handles time slot 0 or the first 8 bits of data in the UCC in the next request. The next request is identified by a frame synchronization pulse.
Tx channel pointer	This 6-bit field of the TSATTx entry identifies the data channel routed to this time slot. The actual channel pointer is 12 bits long, and contains the starting address of the channel-specific parameter area (address of TBASE). The 6 most-significant bits are taken from the TSATTx channel pointer field, and the 6 least-significant bits are always internally set to zero.
Mask(0–7)	Mask bits—Identifies the valid bits in this time slot for subchanneling support. For 8-bit resolution, all mask bits should be set to 1. For a valid channel with an unmasked bit (1), the bit position is filled according to the protocol. A valid channel with a masked bit (0) transmits a logic high (1).

If the transmitter and receiver have the same mapping, a common time-slot assignment table can be used. It is initialized by setting both Tx_S_PTR and Rx_S_PTR to UCC Base + 20. For 64-channel support, common Rx and Tx parameters are recommended. The time-slot assignment table is then also common and has 64 entries starting at UCC Base + 20; see Figure 42-5.

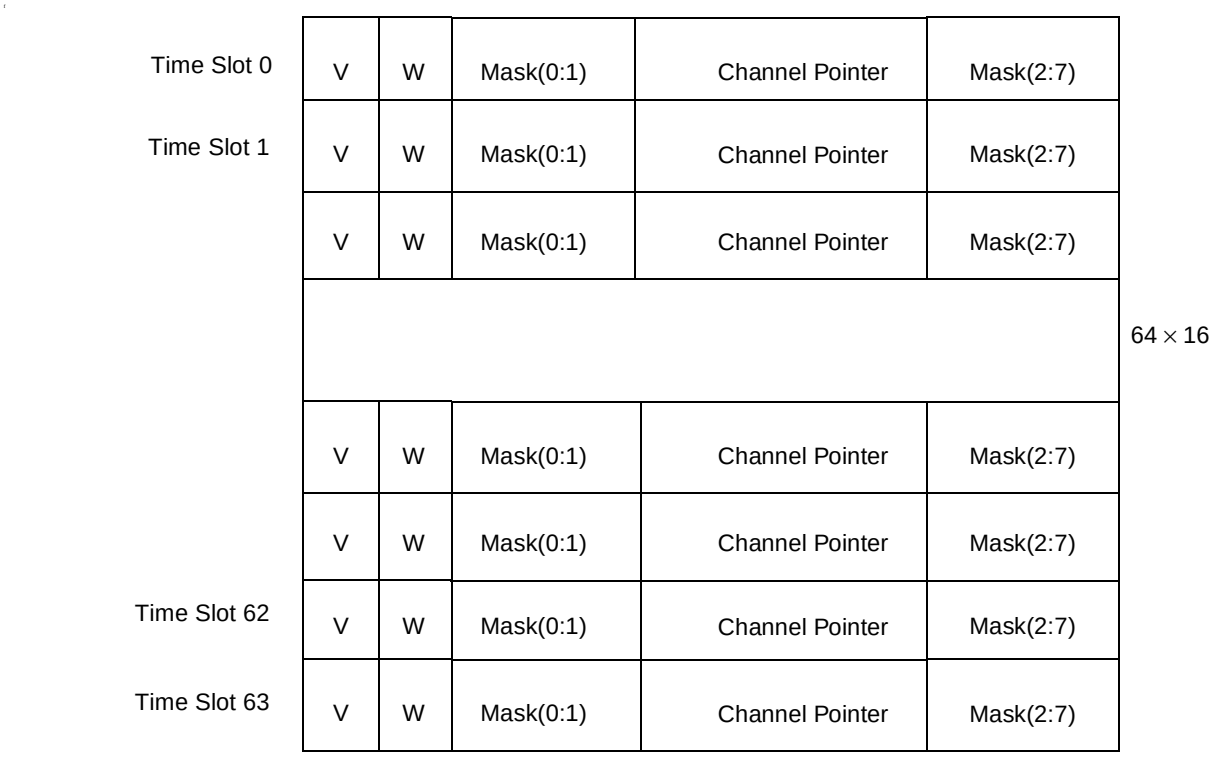

Figure 42-5. Time Slot Assignment Table for 64-Channel Common Rx and Tx Mapping

42.3.3 Multiple UCC Assignment Tables

Assume a scenario as depicted in Figure 42-6. A 2.048-Mbps TDM link is fed directly into the TSA. Within the SI RAM, the even channels (byte-wide) are multiplexed to UCC3 and the odd channels are multiplexed to UCC1. This arrangement spreads the load over two UCCs, effectively doubling the FIFO depth on the QMC protocol. Time slots are switched to alternate UCCs to avoid data bursts that may stress the FIFOs. Each UCC sees a continuous bit stream without any gaps as described earlier.

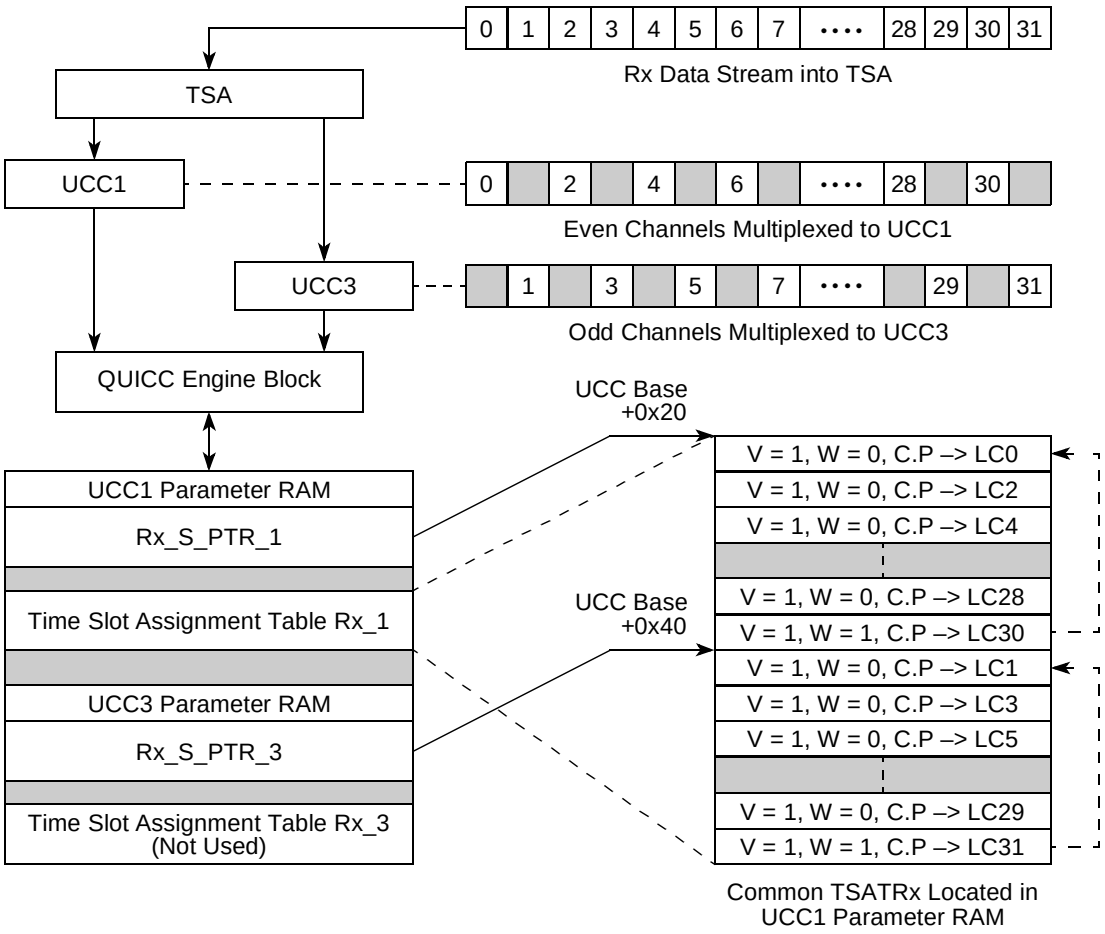

Figure 42-6. Rx Time Slot Assignment Table for 32 Channels over Two UCCs

NOTE

Route multiples of bytes to each UCC to delineate between time slots. Unused bits are routed to the UCC and masked in the time-slot assignment table.

In Figure 42-6, each UCC has its own pointer, Rx_S_PTR_1 and Rx_S_PTR_3, addressing the UCC1 time-slot assignment table. This table must be present only once in one of the UCC1 global parameter areas. Rx_S_PTR_1 points to the start of the table, address UCC base + 20. The 16 logical channels from UCC1 are located in the first 16 entries of the table. The entry for logical channel 30 has the wrap bit (W) set, causing the QUICC Engine block to wrap back to logical channel 0 on reception of the next byte routed to UCC1. Rx_S_PTR_3 addresses UCC base + 40, the start of the 16 entries for UCC3. The entry for

logical channel 31 has the wrap bit (W) set, causing the QUICC Engine block to wrap back to logical channel 1 on reception of the next byte routed to UCC3. Each entry within the table has a channel pointer to a logical channel. It is important that different UCCs do not point to the same logical channel. The TSATTx is also located in UCC1 parameter RAM, so the area reserved for the TSA tables in UCC3 parameter RAM is free for alternative use.

A second scenario is depicted in Figure 42-7. A 4.096-Mbps TDM link is fed directly into the TSA. Again, within the SI RAM, the even channels (byte-wide) are multiplexed to UCC3 and the odd channels are multiplexed to UCC1 to spread the load over two UCCs and facilitate separate routing for the Rx and Tx logical channels. This requires two 64-entry tables with 256 bytes, but only 128 bytes are allocated in the parameter RAM of an UCC for time-slot assignment tables. In this case, the Rx table is located in UCC1 parameter RAM, and the TX table is located in UCC3 parameter RAM, making most efficient use of memory.

Changes on-the-fly are easily accomplished by setting or clearing the valid bit for each time slot. Changes to the mask bits can also be made on-the-fly. This does not cause any problems to the QMC microcode itself, but may cause protocol errors on the channel in question depending on when this change is done.

There can be a time-slot assignment table for every UCC in its corresponding RAM page and with all the TDM routed to the different UCCs. The result is a very flexible system that can be changed on-the-fly without disconnecting the TDM interface. The user must ensure that no collisions occur on the transmit lines from several UCCs.

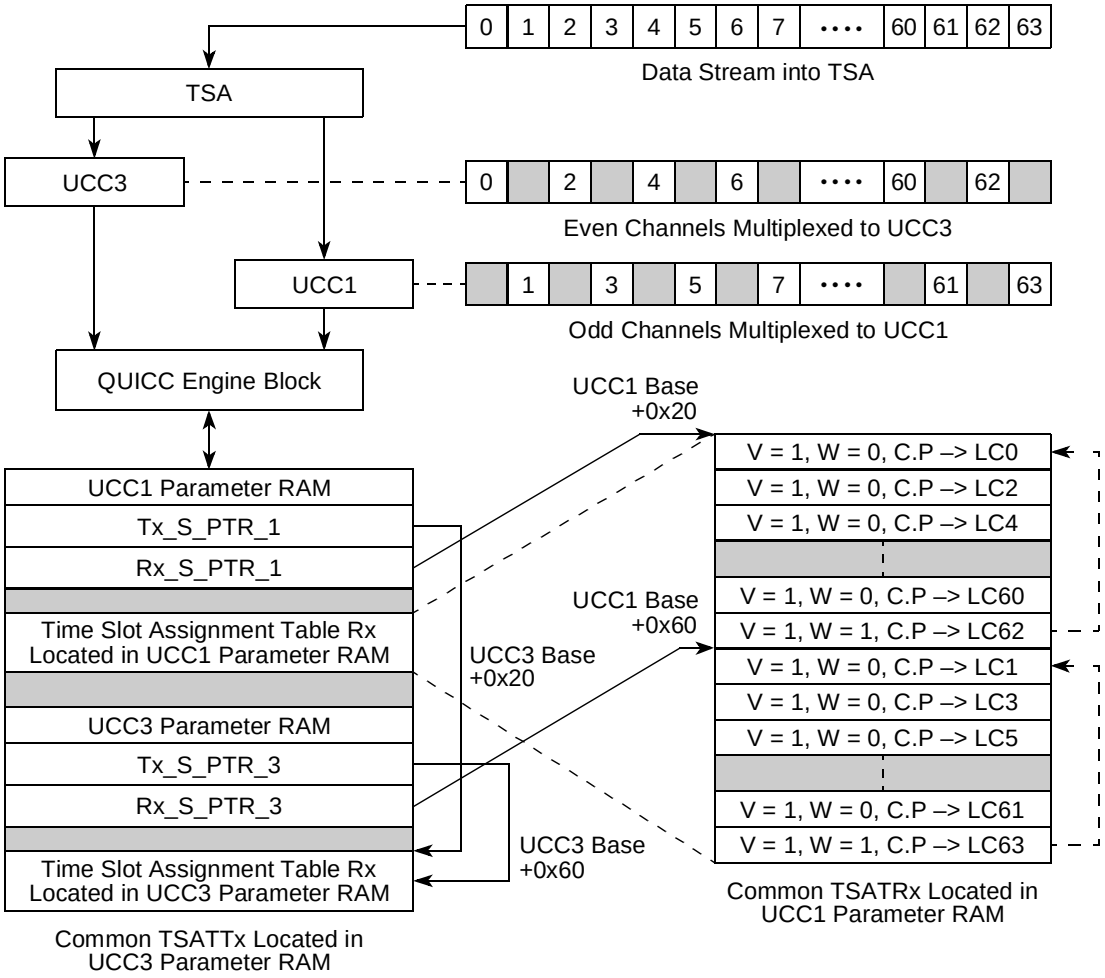

Figure 42-7. Time-Slot Assignment Tables for 64 Channels over 2 UCCs

A third scenario is depicted in Figure 42-8. A 16.384-Mbps TDM link (theoretical rate - 256 time slots of 64 Kbps) is conjugated by 4 different UCCs, each handling a group of 64 channels with its own memory space. Such a topology enables the user to apply different data contents to 256 different channels (and up to 512 in a topology with 8 UCCs).

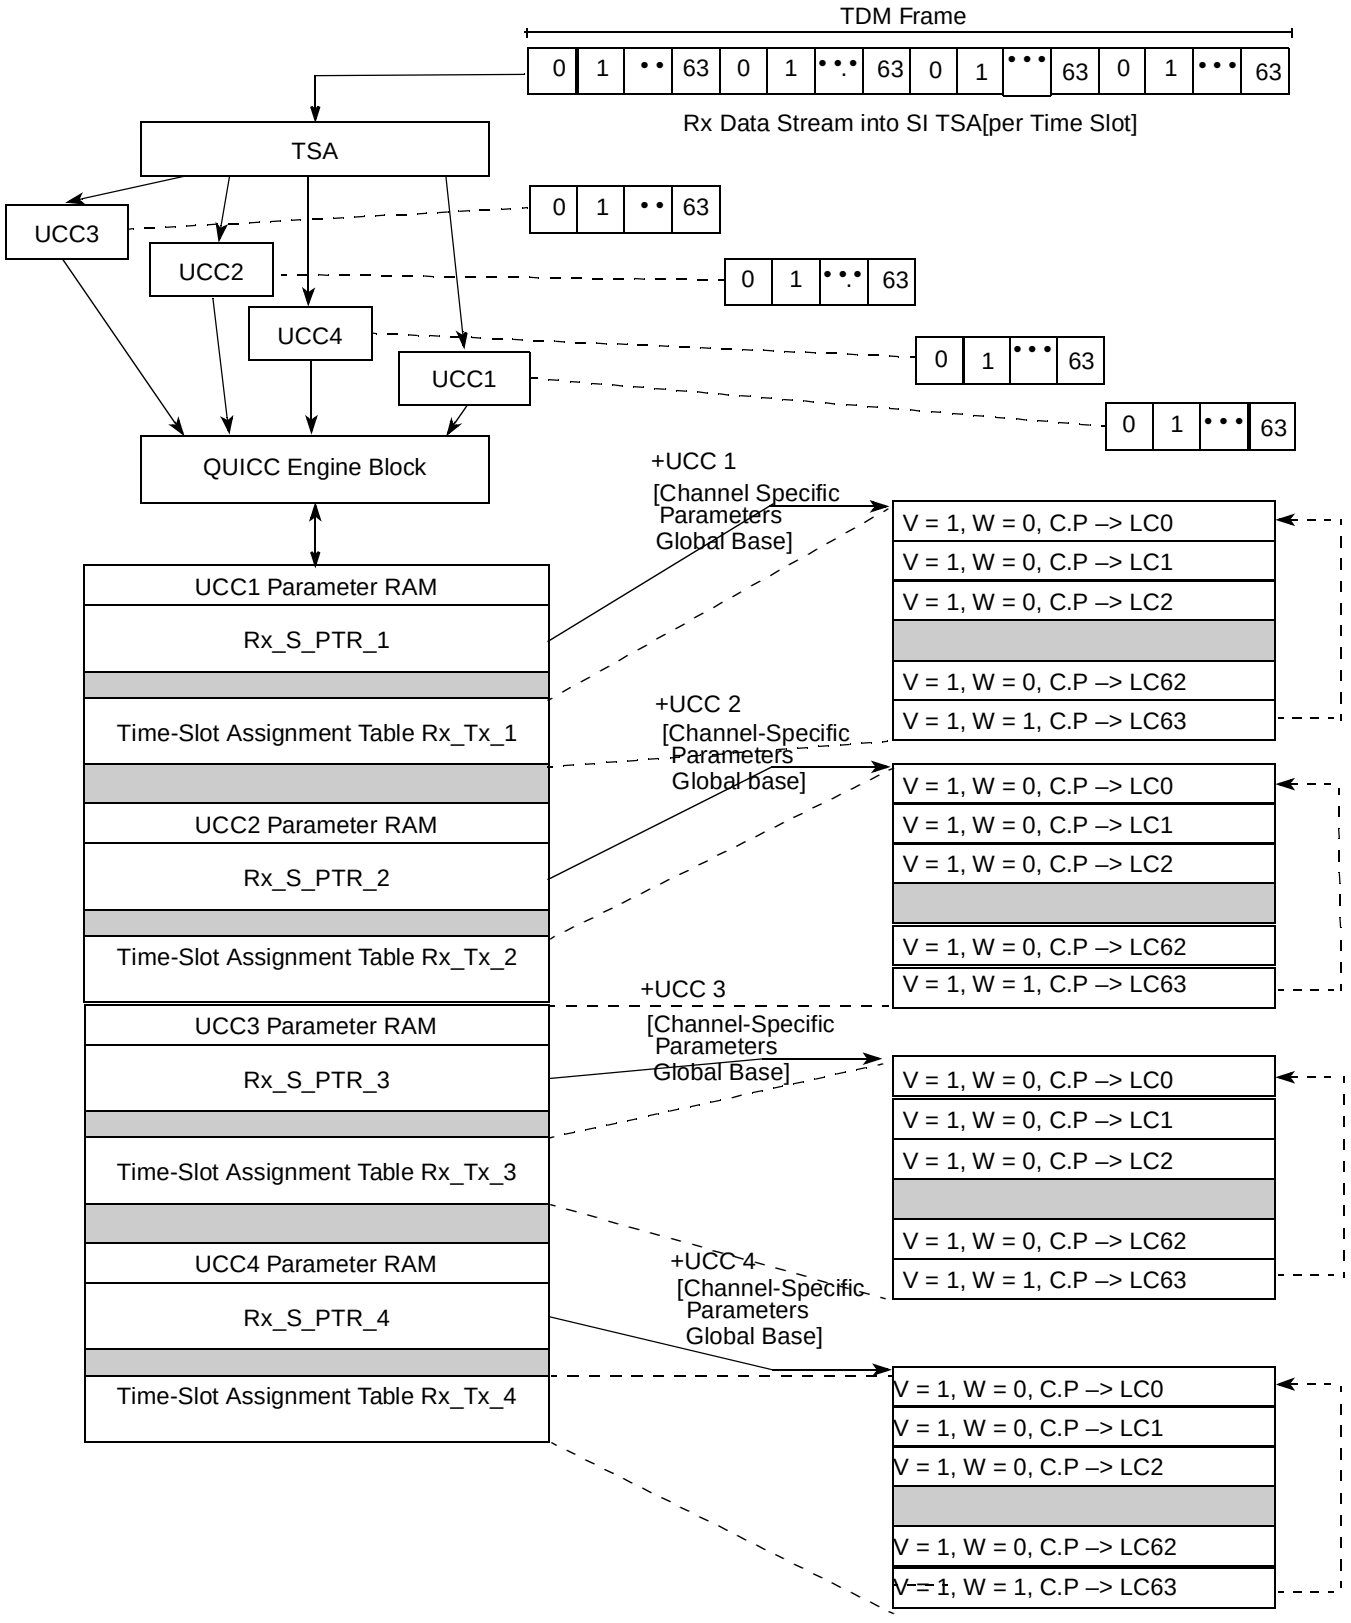

Figure 42-8. Time-Slot Assignment Tables for 256 Channels over 4 UCCs

42.3.4 Channel Specific Parameters

The channel-specific parameters are located in the lower part of the multi-user RAM. Each channel occupies 64 bytes of parameters. Physical time slots can be matched to logical channels in several combinations. Unused logical channels leave a hole in the channel-specific parameters that can be used for buffer descriptors for the other UCCs. The channel-specific area determines the operating mode—HDLC or transparent. Several entries take on different meanings depending on the protocol chosen.

42.3.4.1 Channel-Specific HDLC Parameters

Table 42-4 describes the channel-specific HDLC parameters. Boldfaced parameters must be initialized by the user.

Table 42-4. Channel-Specific HDLC Parameters

Offset	Name	Width (Bits)	Description
00	**TBASE**	16	Tx buffer descriptor base address—Offset of the channel's transmit buffer descriptor table relative to MCBASE, host-initialized. See Figure 42-2.
02	**CHAMR**	16	Channel mode register. See Section 42.3.4.1.1, "CHAMR—Channel Mode Register (HDLC)."
04	**TSTATE**	32	Tx internal state —TSTATE defines the internal Tx state. Initialize before enabling the channel. See Section 42.3.4.1.2, "TSTATE—Tx Internal State (HDLC)."
08	—	32	Tx internal data pointer—Points to current absolute address of channel.
0C	**TBPTR**	16	Tx buffer descriptor pointer (host-initialized to TBASE before enabling the channel or after a fatal error before reinitializing the channel again)—Offset of current BD relative to MCBASE. See Table 42-1. MCBASE + TBPTR gives the address for the BD in use.
0E	—	16	Tx internal byte count—Number of remaining bytes
10	TUPACK	32	(Tx Temp) Unpack 4 bytes from 1 long word
14	**ZISTATE**	32	Zero-insertion state (host-initialized to 0x0000_0200 for HDLC or transparent operation)—Contains the previous state of the zero-insertion state machine.
18	TCRC	32	Temp transmit CRC—Temp value of CRC calculation result
1C	**INTMSK**	16	Channel's interrupt mask flags—See Section 42.3.4.1.3, "INTMSK—Interrupt Mask (HDLC)."
1E	BDFlags	16	Temp
20	**RBASE**	16	Rx buffer descriptor offset (host-initialized)— Defines the offset of the channel's receive BD table relative to MCBASE (64-Kbyte table). See Figure 42-2.
22	**MFLR**	16	Maximum frame length register (host-initialized)—Defines the longest expectable frame for this channel. Its maximum value is 64 Kbytes. The remainder of a frame which is larger than MFLR is discarded and a flag in the last frame's BD is set (LG). An interrupt request (RXF and RXB) might be generated depending on the interrupt mask. The frame length is considered to be everything between flags, including CRC. MFLR is checked every long word, but the content may be on any number of bytes. If MFLR is set to 5 for example, checking is done when 8 bytes are received. At this point, the SDMA transfers the long word to memory, and all 8 bytes are in the receive buffer. Also, the MFLR violation (>5) is detected and the interrupt may be generated. No more data is written into this buffer when the MFLR violation is detected.

Table 42-4. Channel-Specific HDLC Parameters (continued)

Offset	Name	Width (Bits)	Description
24	**RSTATE**	32	Rx internal state. See Section 42.3.4.1.4, "RSTATE—Rx Internal State (HDLC)," for more information.
28	—	32	Rx internal data pointer—Points to current address of specific channel.
2C	**RBPTR**	16	Rx buffer descriptor pointer (host-initialized to RBASE prior to operation or due to a fatal error)—Contains the offset from MCBASE to the current receive buffer. See Table 42-1. MCBASE + RBPTR gives the address for the BD in use.
2E	—	16	Rx internal byte count—Per Channel: Number of remaining bytes in buffer
30	RPACK	32	(Rx Temp) Packs 4 bytes to 1 long word before writing to buffer. Should be initialized to 0x8000_0000.
34	**ZDSTATE**	32	Zero deletion machine state—(Host-initialized to 0x80FF_FFE0 in HDLC mode prior to operation and after a fatal Rx error (global overrun, busy) before channel initialization.)—Contains the previous state of zero deletion state machine. The middle 2 bytes, represented by zeros in the initialization value above, hold the received pattern during reception. A window of 16 bits shows the history of what is received on this logical channel. More information is given in the application note section.
38	RCRC	32	Temp receive CRC—Temp value of CRC calculation result
3C	MAX_cnt	16	Max_length counter—Count length remaining
3E	TMP_MB	16	Temp—Holds MIN(MAX_cnt, Rx internal byte count)

42.3.4.1.1 CHAMR—Channel Mode Register (HDLC)

CHAMR is a host-initialized register. Figure 42-9 shows the channel mode register for HDLC operation.

	0	1	2	3	4 6	7	8	9	10 11	12 15
Field	MODE	0	IDLM	ENT	Reserved	POL	CRC	0	Reserved	NOF
Reset	0000_0000_0000_0000									

Figure 42-9. CHAMR—Channel Mode Register (HDLC)

Table 42-5 describes the channel mode register's fields for HDLC operation. Boldfaced parameters must be initialized by the user.

Table 42-5. CHAMR Field Descriptions (HDLC)

Field	Name	Description
0	MODE	Mode. Each channel has a programmable option to use transparent mode or HDLC mode. 0 Transparent mode 1 HDLC mode
1	—	0

Table 42-5. CHAMR Field Descriptions (HDLC) (continued)

Field	Name	Description
2	**IDLM**	Idle mode 0 Idle mode is disabled. No idle patterns are transmitted between frames. After transmitting the NOF + 1 flags, the transmitter starts the data of the frame. If between frames and the frame buffer is not ready, the transmitter sends flags until it can start transmitting the data. The NOF shall be greater or equal to the PAD setting; see Section 42.6.2, "Transmit Buffer Descriptor." If NOF = 0, this is identical to flag sharing in HDLC mode. For a high QUICC Engine load or with long bus latencies, the QMC protocol may insert additional flags. 1 Idle mode enabled. At least one idle pattern is transmitted between adjacent frames. If between frames and the frame buffer is not ready, the transmitter sends idle characters. When data is ready, the NOF + 1 flags are sent followed by the data frame. If in IDLE mode and NOF = 1, the following sequence is transmitted: .....init value, FF, FF, flag, flag, data,..... The initial value before the idle is 1s. In this case, it is assumed the transmitter is uninitialized. An uninitialized UCC transmits 1s in every position.
3	**ENT**	Enable transmit 0 Disable transmitter. If this bit is cleared and the channel's transmitter is routed to a certain time slot (within TSATTx, see Figure 42-4) the transmitter sends 1's on this time slot. 1 The transmit portion of the channel is enabled and data is sent according to protocol and to other control settings. Note that there is no ENR bit in the QMC protocol. To enable the receiver, the ZDSTATE and RSTATE parameters shall be set to their initial values.
4–6	—	Reserved
7	**POL**	Enable polling. This bit enables the transmitter to poll the transmit buffer descriptors. 0 The QUICC Engine block does not check the ready bit (R) in the transmit buffer descriptor. 1 The QUICC Engine block checks the ready bit (R) in the transmit buffer descriptor. The user can use this bit to prevent unnecessary external bus cycles when checking the ready bit (R) in the buffer descriptor. This bit should always be set by the software at the beginning of a transmit sequence of one or more frames. This bit is cleared (0) by the RISC processor when no more buffers are ready in the transmit queue when it finds a buffer descriptor with the R bit cleared (0), that is, at the end of a frame or at the end of a multiframe transmission. In order to prevent deadlock the software should always prepare the new BD, or multiple BDs, and set (1) the ready bit in the BD, before setting (1) the POL bit. Note that as this bit is automatically cleared by the QUICC Engine block; the user should not attempt to clear this bit in software.
8	**CRC**	Selects the type of CRC when using the HDLC channel mode. 0 16-bit CCITT-CRC is selected for this channel. 1 32-bit CCITT-CRC is selected.
9	—	0
10–11	—	Reserved
12–15	**NOF**	Number of flags. Defines the minimum number of flags before frames. However, even if NOF = 0, at least one flag is transmitted before the first frame. See the description of the IDLM bit for more information.

42.3.4.1.2 TSTATE—Tx Internal State (HDLC)

TSTATE defines the internal transmitter state. Figure 42-10 shows the TSTATE register for HDLC operation.

	0	1	2	3	4	5	6	7
Field	—		GBL	BO		CETM	DTB	BDB
Reset	0000_0000_0000_0000							
R/W	R/W							

Figure 42-10. TSTATE—TX Internal State (HDLC)

Table 42-6 describes the TSTATE fields.

Table 42-6. TSTATE Field Descriptions (HDLC)

Bits	Name	Description
0–1	—	Reserved, should be cleared
2	**GBL**	Global 0 Snooping disabled 1 Snooping enabled To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
3–4	**BO**	Byte ordering. Set BO to select the required byte ordering for the buffer. 00, 01, 11Reserved 10 Big endian
5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1 and Section 5.4.3.7, "Debug Configuration."
6	DTB	Should be cleared
7	BDB	Should be cleared

42.3.4.1.3 INTMSK—Interrupt Mask (HDLC)

Each event defined in the interrupt circular queue entry maps directly to a bit in INTMSK, as shown in Figure 42-12. There is one mask bit for each event—NID (bit 2), IDL (bit 3), MRF (bit 10), UN (bit 11), RXF (bit 12), BSY (bit 13), TXB (bit 14) and RXB (bit 15). Bits that do not map to an event are reserved. Reserved bits must be cleared to zero. Refer to Section 42.5, "QMC Exceptions."

- 0 = No interrupt request is generated and no new entry is written in the circular interrupt table.
- 1 = Interrupts are enabled.

The host initializes this register prior to operation.

	0	1	2	3	4	9	10	11	12	13	14	15

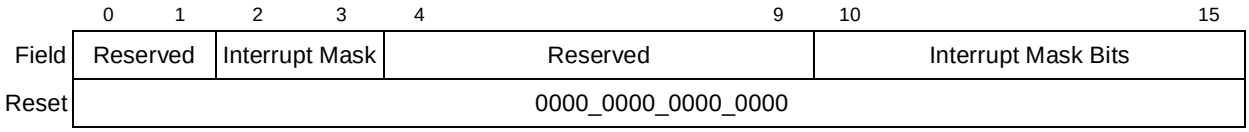

Figure 42-12. INTMSK (HDLC)

42.3.4.1.4 RSTATE—Rx Internal State (HDLC)

RSTATE is host-initialized before enabling the channel or after a fatal error (that is, global overrun, busy) or after a STOP Rx command. Figure 42-13 shows the RSTATE register for HDLC operation.

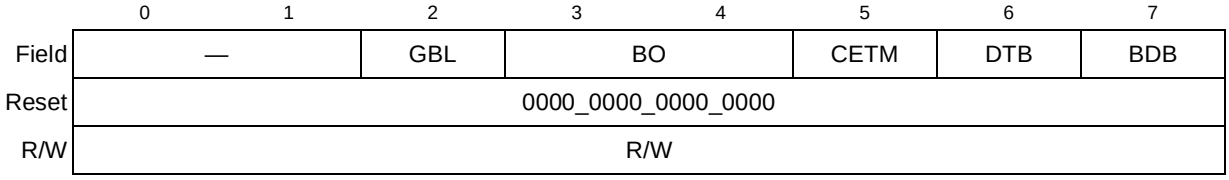

Figure 42-13. RSTATE—RX Internal State (HDLC)

Table 42-7 describes the RSTATE fields.

Table 42-7. RSTATE Field Descriptions (HDLC)

Bits	Name	Description
0–1	—	Reserved, should be cleared
2	**GBL**	Global 0 Snooping disabled 1 Snooping enabled To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”
3–4	**BO**	Byte ordering. Set BO to select the required byte ordering for the buffer. If BO is changed on-the-fly, it takes effect at the beginning of the next frame (Ethernet, HDLC, and transparent) or at the beginning of the next BD. 00, 01, 11Reserved 1x Big endian
5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes. See Figure 19-1 and Section 5.4.3.7, “Debug Configuration.”
6	DTB	Should be cleared
7	BDB	Should be cleared

42.3.4.2 Channel-Specific Transparent Parameters

Table 42-8 describes the channel-specific transparent parameters. Boldfaced parameters must be initialized by the user.

Table 42-8. Channel-Specific Transparent Parameters

Offset	Name	Width	Description
00	**TBASE**	16	Tx buffer descriptor base address—Defines the offset of the channel's transmit BD table relative to MCBASE, host-initialized. See Figure 42-2.
02	**CHAMR**	16	Channel mode register. See Section 42.3.4.2.1, "CHAMR—Channel Mode Register (Transparent Mode)."
04	**TSTATE**	32	Tx internal state —TSTATE defines the internal Tx state. Initialize before enabling the channel. See Section 42.3.4.2.2, "TSTATE—Tx Internal State (Transparent Mode)."
08		32	Tx internal data pointer—Points to current absolute address of channel.
0C	**TBPTR**	16	Tx buffer descriptor pointer (host-initialized to TBASE before enabling the channel or after a fatal error before reinitializing the channel)—Contains the offset of current BD relative to MCBASE. See Table 42-1. MCBASE + TBPTR gives the address for the BD in use.
0E		16	Tx internal byte count—Number of remaining bytes
10	TUPACK	32	(Tx temp) Unpack 4 bytes from 1 long word
14	**ZISTATE**	32	Zero-insertion machine state (host-initialized to 0x0000_0200)—Contains the previous state of the zero-insertion state machine.
18	RES	32	—
1C	**INTMSK**	16	Channel's interrupt mask flags. See Figure 42-17.
1E	BDFlags	16	Temp
20	**RBASE**	16	Receive buffer descriptor base offset—Defines the offset of the channel's 64-Kbyte receive BD table relative to MCBASE. Host-initialized. See also Figure 42-2.
22	**TMRBLR**	16	Transparent maximum receive buffer length (host-initialized entry)—Defines the maximum number of bytes written to a receive buffer before moving to the next buffer for this channel. Note that this value must be a multiple of 4 bytes as the QMC works on long-word alignment.
24	**RSTATE**	32	Rx internal state. See Section 42.3.4.2.5, "RSTATE—Rx Internal State (Transparent Mode)," for more information.
28		32	Rx internal data pointer—Points to current address of specific channel.
2C	**RBPTR**	16	Rx buffer descriptor pointer (host-initialized to RBASE, prior to operation or due to a fatal error)—Contains the offset from MCBASE to the current receive buffer. See Figure 42-2. MCBASE + RBPTR gives the address for the BD in use.
2E		16	Rx internal byte count—Per channel: Number of remaining bytes in buffer
30	RPACK	32	(Rx temp) Packs 4 bytes to 1 long word before writing to buffer. Should be initialized to 0x8000_0000.
34	**ZDSTATE**	32	Zero deletion machine state—(Host-initialized to 0x003F_FFE2 in transparent mode prior to operation and after a fatal Rx error (global overrun, busy) before channel initialization.)—Contains the previous state of the zero-deletion state machine. The middle 2 bytes, represented by zeros in the initialization value above, holds the received pattern during reception. A window of 16 bits shows the history of what is received on this logical channel.
38	RES	32	—

Table 42-8. Channel-Specific Transparent Parameters (continued)

Offset	Name	Width	Description
3C	**TRNSYNC**	16	Transparent synchronization—In transparent mode, this register controls synchronization for single time slots or superchannel applications. See Section 42.3.4.2.4, "TRNSYNC—Transparent Synchronization."
3E	RES	16	—

42.3.4.2.1 CHAMR—Channel Mode Register (Transparent Mode)

CHAMR is a host-initialized register. Figure 42-14 shows the channel mode register for transparent mode.

Table 42-9 describes the channel mode register fields for transparent operation. Boldfaced parameters must be initialized by the user.

Table 42-9. CHAMR Bit Settings (Transparent Mode)

Field	Name	Description
0	**MODE**	Mode. Each channel has a programmable option whether to use transparent mode or HDLC mode. 0 Transparent mode 1 HDLC mode
1	**RD**	Reverse data 0 The bit order is not reversed, transmitting/receiving the LSB of each octet first. 1 The bit order as seen on the channels is reversed, transmitting/receiving the MSB of each octet first.
2	—	1
3	**ENT**	Enable transmit 0 Disable transmitter. If this bit is cleared and the channel transmitter is routed to a certain time slot (within TSATTx, see Figure 42-4) the transmitter sends 1s on this time slot. 1 The transmit portion of the channel is enabled and data is sent according to protocol and to other control settings.
4	—	Reserved
5	**SYNC**	Synchronization. Controls synchronization of multichannel operation in transparent mode. 0 The first byte is put in the first available time slot or is read from the first available time slot to this logical channel. 1 The synchronization algorithm according to TRANSYNC is done.
6	RES	Reserved

Table 42-9. CHAMR Bit Settings (Transparent Mode) (continued)

Field	Name	Description
7	**POL**	Enable polling. Enables the transmitter to poll the transmit BDs. 0 The QUICC Engine block does not check the ready (R) bit in the transmit buffer descriptor. 1 The QUICC Engine block checks the ready (R) bit in the transmit buffer descriptor. The user can use this bit to prevent unnecessary external bus cycles when checking the ready bit (R) in the buffer descriptor. Software should always set POL at the beginning of a transmit sequence of one or more frames. The RISC processor clears POL when no more buffers are ready in the transmit queue when it finds a buffer descriptor with the R bit cleared, that is, at the end of a frame or at the end of a multiframe transmission. To prevent deadlock, software should prepare the new BD, or multiple BDs, and set the ready (R) bit in the BD before setting POL. Note that the QUICC Engine block automatically clears this bit; software should never try to clear this bit.
8–9	—	0
10–11	—	Reserved
12–15	—	0

42.3.4.4.2.2 TSTATE—Tx Internal State (Transparent Mode)

TSTATE defines the internal transmitter state. Figure 42-15 shows the TSTATE register for transparent mode.

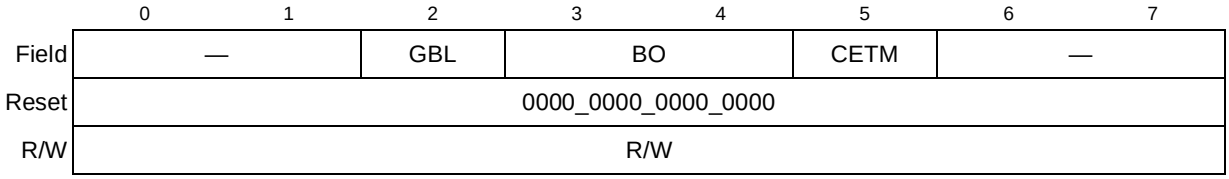

Figure 42-15. TSTATE—TX Internal State (Transparent Mode)

Table 42-10 describes the TSTATE fields.

Table 42-10. TSTATE Field Descriptions (Transparent Mode)

Bits	Name	Description
0–1	—	Reserved, should be cleared
2	**GBL**	Global 0 Snooping disabled 1 Snooping enabled To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”
3–4	**BO**	Byte ordering. Set BO to select the required byte ordering for the buffer. 00 , 01, 11 Reserved 10 Big endian
5	**CETM**	QUICC Engine Transaction Mark. The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block for debug purposes.See Figure 19-1 and Section 5.4.3.7, “Debug Configuration.”
6–7	—	Reserved, should be cleared

42.3.4.2.3 INTMSK—Interrupt Mask (Transparent Mode)

Each event defined in the interrupt circular queue entry maps directly to a bit in INTMSK as shown in Figure 42-17. There is one mask bit for each event—UN (bit 11), BSY (bit 13), TXB (bit 14) and RXB (bit 15). Bits that do not map to an event are reserved. Reserved bits must be cleared.

- 0 = No interrupt request is generated and no new entry is written in the circular interrupt table.
- 1 = Interrupts are enabled.

The host initializes this register before operation.

Figure 42-17. INTMSK (Transparent Mode)

42.3.4.2.4 TRNSYNC—Transparent Synchronization

In transparent mode, the TRNSYNC register controls the synchronization for single time slots or superchannel applications.

NOTE

This register has no meaning if the SYNC bit in the channel mode register (CHAMR) is cleared.

When a transparent message is sent over several time slots, the time slot in which the first byte of data appear is to appear must be known.

The TRNSYNC word-length register is divided into two parts with the high byte controlling the first received time slot and the low byte controlling the transmitter synchronization.

Take the example of a superchannel of several time slots:

TSn, TSn + 1, TSn + 2 ..... TSn + x

The algorithm for the receiver byte in decimal is:

$(TSn + 1) \times 2$

The algorithm for the transmit byte in decimal is:

$(TSn + x + 1) \times 2$

The result from these calculations is a decimal value programmed into TRNSYNC.

NOTE

TS*n* is not necessarily the first time slot in the frame. For example, if a superchannel is produced from TS2, TS4, and TS6, the message can be arranged with TS4 holding the first byte, then TS6, and the final byte held in TS2 of the following frame.

The following nine cases in Figure 42-18, named C1 to C9, show different scenarios ranging from a single time slot per logical channel to a superchannel using several time slots. In this application, 24 time slots are routed to this UCC from the SI RAM. After time slot 23, the frame starts with 0 again. The arrow in all the figures illustrates the starting position.

- C1 is for a single byte in TS7, so TSn = 7
  - Rx Byte:$(7+1) \times 2 = 16$
  - As x = 0, TSn + x = TSn = 7, so Tx Byte:$(7 + 1) \times 2 = 16$
- C2 is a single byte in TS23, so TSn = 23. Note that time slot after 23 is 0, so in the calculations below 23 + 1 = 0.
  - Rx Byte: $(23 + 1) \times 2 = 0$
  - As x = 0, TSn + x = TSn = 23, so Tx Byte:$(23 + 1) \times 2 = 0$
- C3 is a 2-byte pattern TS7, TS8, so TSn = 7
  - Rx Byte: $(7 + 1) \times 2 = 16$
  - As x = 1, TSn + x = 8, so Tx Byte:$(8 + 1) \times 2 = 18$
- C4 is a 2-byte pattern TS8, TS7, so TSn = 8
  - Rx Byte:$(8+1) \times 2 = 16$
  - As x = 1, TSn + x = 7, so Tx Byte:$(7 + 1) \times 2 = 16$
- C5 is a 2-byte pattern TS19, TS23, so TSn = 19
  - Rx Byte:$(19 + 1) \times 2 = 40$
  - As x = 1, TSn + x = 23, so Tx Byte:$(23 + 1) \times 2 = 0$
- C6 is a 2-byte pattern TS23, TS19, so TSn = 23
  - Rx Byte:$(23 + 1) \times 2 = 0$
  - As x = 1, TSn + x = 19, so Tx Byte:$(19 + 1) \times 2 = 40$
- C7 is a 4-byte pattern TS20, TS23, TS8, TS9, and TS19, so TSn = 20
  - Rx Byte:$(20 + 1) \times 2 = 42$
  - As x = 5, TSn + x = 19, so Tx Byte:$(19 + 1) \times 2 = 40$
- C8 is a 4-byte pattern TS8, TS9, TS19, TS20, and TS23, so TSn = 8
  - Rx Byte:$(8 + 1) \times 2 = 18$
  - As x = 5, TSn + x = 23, so Tx Byte:$(23 + 1) \times 2 = 0$
- C9 is a 4-byte pattern TS19, TS20, TS23, TS8, and TS9, so TSn = 19
  - Rx Byte:$(19 + 1) \times 2 = 40$
  - As x = 5, TSn + x = 9, so Tx Byte:$(9 + 1) \times 2 = 20$

NOTE

Case C1 and C2 can be used as described here. A more elegant solution for single time-slot applications is to have the SYNC bit cleared in the channel mode register. Both scenarios produce the same result.

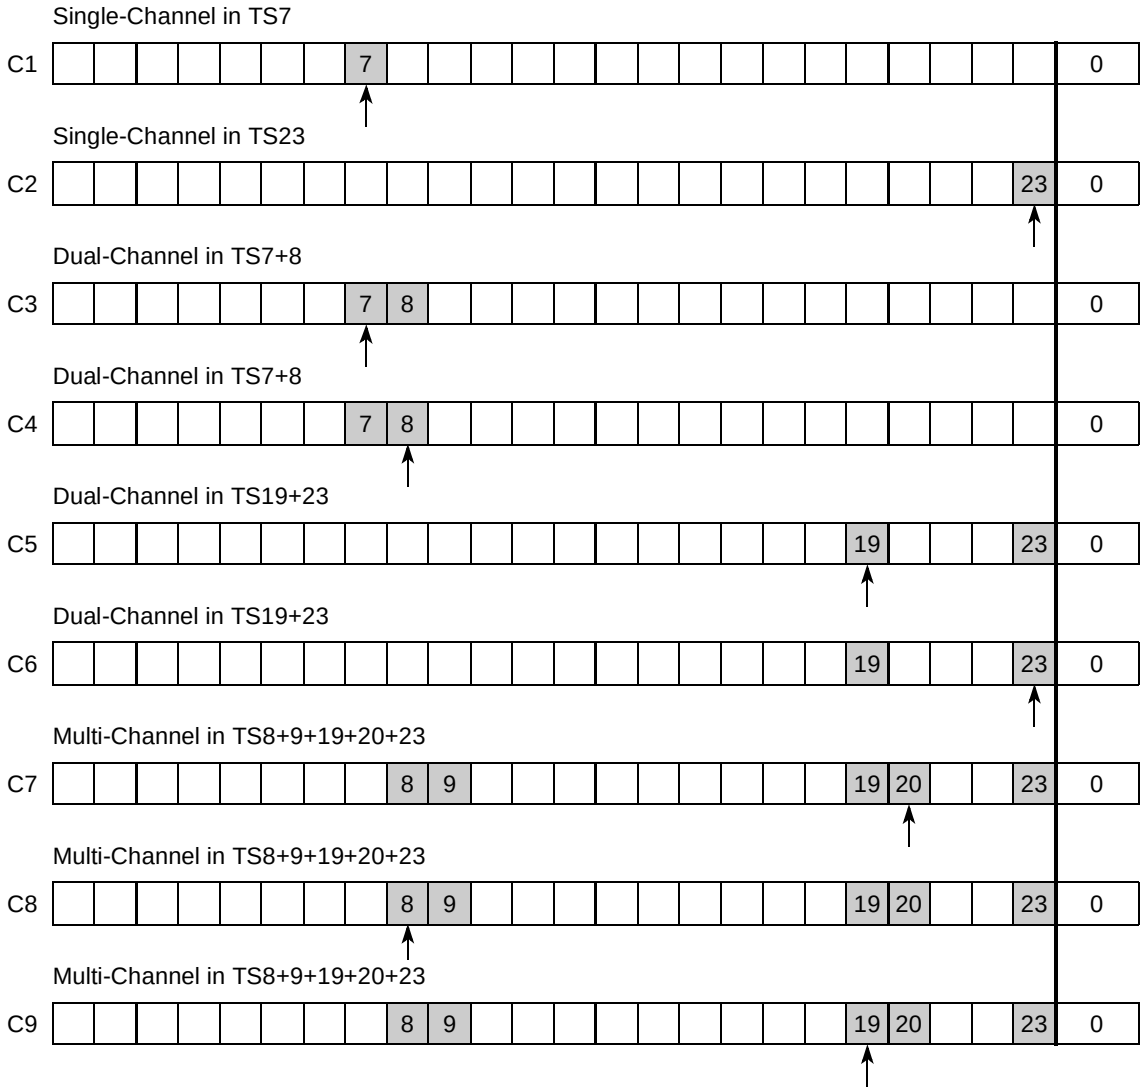

Figure 42-18. Examples of Different T1 Time Slot Allocation

42.3.4.2.5 RSTATE—Rx Internal State (Transparent Mode)

The RSTATE is host-initialized before enabling the channel or after a fatal error (that is, global overrun, busy) or after a STOP Rx command.

Figure 42-19 shows the RSTATE register for HDLC operation.

	0	1	2	3	4	5	6	7
Field	—		GBL	BO		CETM	—	
Reset	0000_0000_0000_0000							
R/W	R/W							

Figure 42-19. RSTATE—RX Internal State (Transparent)

Table 42-11 describes the RSTATE fields.

Table 42-11. RSTATE Field Descriptions (Transparent)

Bits	Name	Description
0–1	—	Reserved, should be cleared
2	**GBL**	Global 0 Snooping disabled 1 Snooping enabled To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, "Serial DMA Mode Register (SDMR)."
3–4	**BO**	Byte ordering. Set BO to select the required byte ordering for the buffer. 00, 01, 11 Reserved 10 Big endian
5	**CETM**	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine block, for debug purposes.See Figure 19-1 and Section 5.4.3.7, "Debug Configuration."
6–7	—	Reserved, should be cleared.

42.4 QMC Commands

The host issues commands to the QMC by writing to the command register (CECR); see Section 20.3.1, "QUICC Engine Command Register (CECR)."

42.4.1 Transmit Commands

The stop transmit command, shown as follows, disables the transmission of data on the selected channel and clears CHAMR[POL].

```
STOP TRANSMIT <channel>
```

When this command is issued in the middle of a frame, the RISC processor sends an ABORT indication (7F) on the selected channel followed by IDLEs or FLAGs, depending on the mode. If this command is issued between frames, the RISC processor continues sending IDLEs or FLAGs in this channel (depending on CHAMR[IDLM]). The Tx buffer descriptor pointer (TBPTR) is not advanced to the next buffer; see Table 42-4 and Section 42.3.2.8, "Global Multichannel Parameters."

Set the CHAMR[POL] bit t to start transmission or to continue after a stop command. Only after transmission starts for a deactivated channel, which is identified by a cleared V bit in the time-slot

assignment table or a cleared ENT bit, is it necessary to initialize ZISTATE and TSTATE before setting CHAMR[POL].

To deactivate a channel, clear both the V bit in the TSA table and CHAMR[ENT].

42.4.2 Receive Commands

The stop receive command, shown as follows, forces the receiver of the selected channel to stop receiving.

```
STOP RECEIVE<channel>
```

After this command is issued, the microcode does not change any receive parameters in the multi-user RAM. The command immediately stops activity on the channel. It does not wait for a frame reception to finish. Because the current buffer descriptor can remain open if a reception was in progress, errors may appear on this buffer when reception restarts. Initialize ZDSTATE and then RSTATE to their initial values to start reception or to continue receiving after a stop command.

NOTE

There is no command to start transmission and reception. This function is performed through the GSMR register.

42.5 QMC Exceptions

QMC interrupt handling involves two principle data structures—the UCC event register (UCCE) and the circular interrupt table. Figure 42-20 illustrates the circular interrupt table.

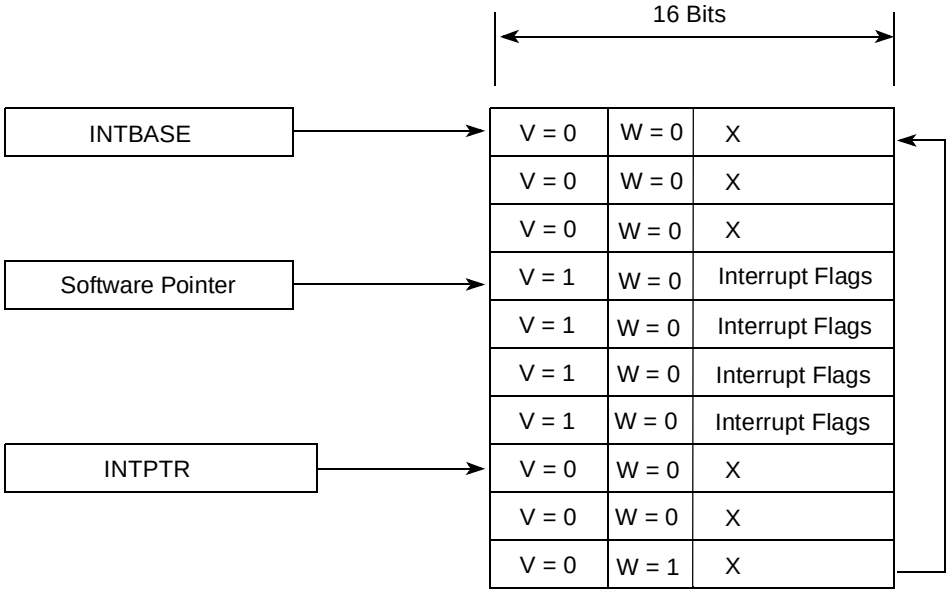

Figure 42-20. Circular Interrupt Table in External Memory

INTBASE (interrupt base) points to the starting location of the queue in external memory, and INTPTR (interrupt pointer) marks the current empty position available to the RISC processor. Both pointers are host-initialized global QMC parameters; see Table 42-1. The entry whose W (wrap) bit is set to 1 marks the end of the queue. When one of the QMC channels generates an interrupt request, the RISC processor

writes a new entry to the queue. In addition to the channel's number, this entry contains a description of the exception. The V (valid) bit is then set and INTPTR is incremented. When INTPTR reaches the entry with W = 1, INTPTR is reset to INTBASE.

An interrupt is written to the interrupt table only if it survives a mask with the INTMASK (interrupt mask) register. Following a write to the queue, the QMC protocol updates the UCC event register (UCCE) according to the type of exception.

Following a request that is not masked out by the INTMASK or the UCCM (UCC mask) register, an interrupt is generated to the host. The host reads the UCCE to determine the cause of interrupt. A dedicated UCCE bit (GINT) indicates that at least one new entry was added to the queue. After clearing GINT, the host starts processing the queue. The host then clears this entry's valid bit (V). The host follows this procedure until it reaches an entry with V = 0, indicating an invalid entry.

NOTE

It is very important that the user clear all bits but the wrap bit in a queue entry even though its valid bit may be cleared. Clearing only the interrupt bits confuse user software with incorrect channel interrupts.

42.5.1 Global Error Events

A global error affects the operation of the UCC. A global error can occur for two reasons— serial data rates being too high for the QUICC Engine block to handle, and QUICC Engine bus latency being too long for correct FIFO operation.

There are two global errors— global transmitting underrun (GUN) and global receiver overrun (GOV). GUN indicates that transmission has failed due to lack of data; and GOV indicates that the receiver has failed because the RISC processor did not write previous data to the receive buffer. In both cases, it is unknown which channel(s) are affected.

Nonglobal, individual channel errors are handled differently. See Section 42.5.3, "Interrupt Table Entry," for underrun and overrun in a specific channel.

The incoming data to the QUICC Engine block is governed by transfers between the UCC and the SI. Every transfer in either direction causes a request to the QUICC Engine state machine. If requests are received too quickly, the QUICC Engine block may lose track of the mapping of serial data to the QMC channels. If this happens, the QUICC Engine block has to cause a global error to halt activity on all QMC channels until user software intervenes. Note that this problem typically indicates a performance-related design problem. Also note that latency is very important.

The other error condition is bus latency. A receiving channel submits data to the FIFO for transfer to external memory as long as the channel operates normally. If the bus latency for the SDMA channels is too long and the receive FIFO is filled and overwritten, a receiver overflow occurs. The overwriting channels cannot be traced, affecting entire QMC operation.

A similar situation can occur during transmission when the SDMA cannot fill the FIFO from external memory because of bus latency. Again, it cannot be determined which channel is underrun, and the whole QMC operation is affected.

Global errors are unlikely to occur in normal system operation, if correct serial speed is used. The only area of concern is data movement between the FIFO and external memory. To avoid problems, the user must understand the bus arbitration mechanism of the QUICC and meet the latency requirements.

42.5.1.1 Global Underrun (GUN)

The QMC performs the following actions when it detects a GUN event:

- Transmits an abort sequence of minimum sixteen 1s in each time slot.
- Generates an interrupt request to the host (if enabled) and sets the GUN bit in the UCCE register.
- Stops reading data from buffer.
- Sends IDLEs or FLAGs in all time slots depending on channel mode settings until the host does the following:

  Host initializes all transmitting channels and time slots by preparing all buffer descriptors for transmission (R bits are set) and setting the POL bit. No other re-initialization is needed.

42.5.1.2 Global Overrun (GOV) in the FIFO

A global overrun affects all channels operating from an UCC. Following GOV, the QMC performs the following:

- Updates the RSTATE register to prevent further reception on this channel. Bit 20 in the RSTATE register indicates that the receiver is stopped.
- Generates an interrupt request to the host (if enabled) and sets the GOV bit in the UCCE.
- Stops writing data to all channels' buffers.
- Waits for host to initialize all the receiving channels by setting first the ZDSTATE followed by the RSTATE to their initial values.

42.5.1.3 Restart from a Global Error

The last two bullets in the above two sections describe the only steps necessary for re-initialization. The transmit and receive sections must be restarted individually for each separate logical channel.

For details about initialization, see Section 42.7, "QMC Initialization."

42.5.2 UCC Event Register (UCCE)

The QMC's UCCE is used to report events and generate interrupt requests. See Figure 42-21 and Table 42-12 for UCCE field descriptions. For each of its flags, a corresponding programmable mask/enable bit in the UCCM determines whether an interrupt request is generated. If a bit in the UCCM register is zero, the corresponding interrupt flag does not survive, and the QUICC Engine block does not proceed with its usual interrupt handling. If a bit in the UCCM is set, the corresponding interrupt flag in the UCCE survives, and the UCC event bit is set in the QUICC Engine interrupt-pending register. See Figure 42-22 for UCCM assignments.

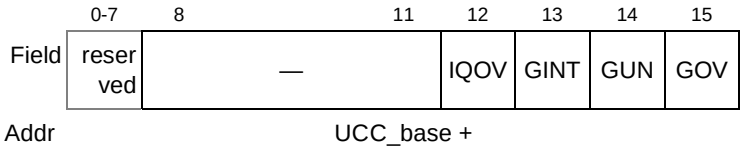

Figure 42-21. UCC Event Register

Table 42-12. UCC Event Register Field Descriptions

Field	Name	Description
0–11	—	Reserved
12	IQOV	Interrupt table (interrupt queue) overflow 0 No interrupt table overflow has occurred. 1 An overflow condition in the circular interrupt table occurs (and an interrupt request is generated). This condition occurs if the RISC processor attempts to write a new interrupt entry into an entry that was not handled by the host. Such an entry is identified by V = 1. This bit should be cleared immediately after reading the UCCE and recognizing this condition by writing a 1 to its location in the UCCE. If this condition occurs, the interrupt last received is lost. It does not overwrite the first entry that is still to be handled by the CPU.
13	GINT	Global interrupt 0 No global interrupt has occurred. 1 This flag indicates that at least one new entry in the circular interrupt table has been generated by the QMC. The host clears GINT by writing a 1 to its location in UCCE. After clearing it, the host reads the next entry from the circular interrupt table, and starts processing a specific channel's exception. The user must make sure that no more valid interrupts are pending in the interrupt table after clearing the GINT bit, before performing the RTE to avoid deadlock. This procedure ensures that no pending interrupts exist in the queue.
14	GUN	Global transmitter underrun 0 No global transmitter underrun has occurred. 1 This flag indicates that an underrun occurred in the UCC's transmitter FIFO. This error is fatal since it is unknown which channel(s) are affected. Following the assertion of the GUN bit in the UCCE, the QMC stops transmitting data on all channels. The TDM Tx line goes into idle mode. This error affects only the transmitter; the receiver continues to work. After initializing all the individual channels, the host may resume transmitting. If enabled in the UCCM, an interrupt request is generated when GUN is set. The host may clear GUN by writing 1 to its location in the UCCE.
15	GOV	Global receiver overrun 0 No global receiver overrun has occurred. 1 This flag indicates that an overrun occurred in the UCC's receiver FIFO. This error is fatal since it is unknown which channel(s) are affected. Following the assertion of the GOV bit in the UCCE, the QMC stops receiving data on all channels. Data is no longer written to memory. This error affects only the receiver; the transmitter continues to work. After initializing all the individual channels, the host may resume receiving. If enabled in UCCM, an interrupt request is generated when GOV is set. The host may clear GOV by writing 1 to its location in the UCCE.

Figure 42-22. UCCM Register

42.5.3 Interrupt Table Entry

The interrupt table contains information about channel-specific events. Its flags are shown in Figure 42-23. Note that some bits have no meaning when operating in transparent mode. For more detailed description on which bits are used in HDLC and transparent operation, refer to Section 42.3.4, "Channel Specific Parameters." Table 42-13 describes the fields of an interrupt table entry.

	0	1	2	3	4 — 9	10	11	12	13	14	15
Field	V	W	NID	IDL	Channel Number	MRF	UN	RXF	BSY	TXB	RXB
Reset	0000_0000_0000_0000										

Figure 42-23. Interrupt Table Entry

Table 42-13. Interrupt Table Entry Field Descriptions

Field	Name	Description
0	V	Valid bit 0 Entry is not valid 1 Valid entry containing interrupt information Upon generating a new entry, the RISC processor sets this bit. The V bit is cleared by the host immediately after it reads the interrupt flags in this entry (before processing the interrupt). The V bits in the queue are host-initialized. During the initialization procedure, the host must clear those bits in all queue entries.
1	W	Wrap bit 0 This is not the last entry in the circular interrupt table. 1 This is the last circular interrupt table entry. The next event's entry is written/read (by RISC/host) from the address contained in INTBASE. During initialization, the host must clear all W bits in the queue except the last one which must be set. The length of the queue is left to the user and can be a maximum of 64 Kbytes.
2	NID	Not idle 0 No NID event has occurred. 1 A pattern which is not an idle pattern was identified. NID interrupts are not generated in transparent mode.
3	IDL	Idle 0 No IDL event has occurred. 1 The channel's receiver has identified the first occurrence of HDLC idle (FFFE) after any non-idle pattern. IDL interrupts are not generated in transparent mode.
4–9	Channel number	Identifies the requesting logical channel index (0–31).

Table 42-13. Interrupt Table Entry Field Descriptions (continued)

Field	Name	Description
10	MRF	Maximum receive frame length violation—This interrupt occurs in HDLC mode when more than MFLR number bytes are received. As soon as MFLR is exceeded, this interrupt is generated and the remainder of the frame is discarded. At this point the receive buffer is not closed and the reception process continues. The receive buffer is closed upon detecting a flag. The length field written to this buffer descriptor is the entire number of bytes received between the two flags. MRF interrupts are not generated in transparent mode. **Note**: The MRF interrupt is generated directly when the MFLR value is a multiple of 4 bytes. The checking of this is done on a long-word boundary whenever the SDMA transfers 32 bits to memory. If MFLR is not aligned to 4x bytes, this interrupt may be 1- to 3-byte timings late for this channel. In any case, the violation can be checked to any number of bytes. The last entry in the data buffer is always a full long word.
11	UN	Tx no data 0 No UN event has occurred. 1 There is no valid data to send to the transmitter. The transmitter sends an abort indication consisting of 16 consecutive 1's and then sends idles or flags according to the protocol and the channel mode register setting. This error occurs when a transmit channel has no data buffer ready for a multibuffer transmission already in progress. Transmission of a frame is a continuous bit stream without gaps or interruption. When a buffer is not ready in the middle of this sequence, it is an error situation. This can be viewed as channel underrun. The transmitter for this channel is stopped. See Section 42.7.1, "Restarting the Transmitter," for recovery information.
12	RXF	Rx frame 0 No RXF event has occurred. 1 A complete HDLC frame is received. Data is stored in external memory and the buffer descriptor is updated. If during frame reception an abort sequence of at least seven 1's is detected, the buffer is closed and both RXB and RXF are reported along with the AB in the buffer descriptor. As a result of end-of-frame, the global frame counter GRFCNT is decremented for interrupt generation. This counter is decremented on RXF only, regardless if the RXF was caused by correct closing or due to an error. RXF interrupts are not generated in transparent mode.
13	BSY	Busy 0 No BSY event has occurred. 1 A frame was received but was discarded due to lack of buffers. This can be viewed as channel overrun. After a busy condition, the receiver for this channel is disabled and no more data is transferred to memory. Receiver restart is described in Section 42.7.2, "Restarting the Receiver."
14	TXB	Tx buffer 0 No TXB event has occurred. 1 A buffer has been completely transmitted. This bit is set (and an interrupt request is generated) as soon as the programmed number of PAD characters (or the closing flag, for PAD = 0) is written to the UCC's transmit FIFO. The number of PAD characters determines the timing of the TXB interrupt in relation to the closing flag sent out at TXD. See Section 42.6, "Buffer Descriptors," for an explanation of PAD characters and their use.
15	RXB	Rx buffer 0 No RXB event has occurred. 1 A buffer has been received on this channel.

42.5.4 Interrupt Handling

To handle interrupts by the QMC, first read the UCCE register. Write back immediately all the bits that you recognize and handle. This clears the respective interrupt events. It is, for example, incorrect to first handle all the new interrupt table entries and clear GINT afterwards. To avoid deadlocks in software, clear the recognized interrupt bits in the UCCE before actually handling the interrupt entries. Clear only the bits being handled. Never clear bits for events in the UCCE that are not handled. This facilitates debugging.

For a new GINT event, always handle all the new entries in the queue, not just a single one. After handling an entry, make sure that the entry is completely cleared out with the exception of the Wrap bit. Any entry that does not have the Valid bit set must be completely cleared out, including the channel number. If all the entries are not cleared out on startup or after handling them, these bits confuse the software when the entry is used again. QMC only ORs in new bits and numbers. It does not overwrite and clear previously set bits.

42.5.5 Channel Interrupt Processing Flow

Figure 42-24 illustrates the flow of a channel interrupt. Note that this does not describe the processing of the global interrupts GUN and GOV.

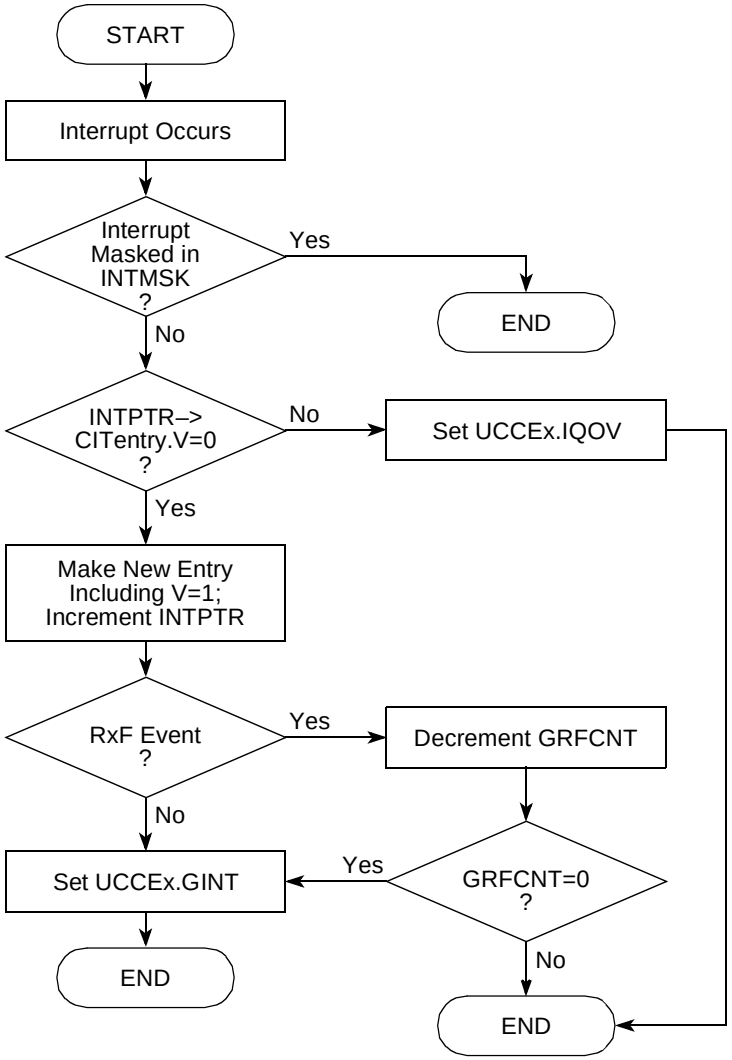

Figure 42-24. Channel Interrupt Flow

42.6 Buffer Descriptors

QMC buffer descriptors are located within 64 Kbytes in external memory; see Figure 42-2. Each buffer descriptor contains key information about the buffer it defines.

The first two sections describe the contents of the receive and transmit buffer descriptors for the QMC protocol.

The third section discusses the placement of QMC and non-QMC buffer descriptors in internal and external memory.

NOTE

The QUICC Engine block ORs the various status bits into the BD. Clear all the status bits generated by the QUICC Engine block before (re-)enabling the BD, or you may confuse your own software with leftover old status values.

42.6.1 Receive Buffer Descriptor

Figure 42-25 shows a receive buffer descriptor.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
OFFSET + 0	**E**	—	**W**	**I**	L	F	**CM**	—	UB	—	LG	NO	AB	CR	—	—
OFFSET + 2	DATA LENGTH															
OFFSET + 4	**Rx DATA BUFFER POINTER**															
OFFSET + 6																

Notes: Entries in boldface must be initialized by the user.

Figure 42-25. Receive Buffer Descriptor (RxBD)

Table 42-14 describes the individual fields of a receive buffer descriptor. Boldfaced entries must be initialized by the user.

Table 42-14. RxBD Field Descriptions

Bits	Name	Description
0	**E**	Empty 0 The data buffer associated with this BD has been filled with received data, or data reception has been aborted due to an error condition. The user is free to examine or write to any fields of this RxBD. The CP does not use this BD again while the empty bit remains zero. 1 The data buffer associated with this BD is empty, or reception is in progress. This RxBD and its associated receive buffer are in use by the CP. When E = 1, the user should not write any fields of this RxBD.
1	—	Reserved, should be cleared
2	**W**	Wrap (final BD in table) 0 This is not the last BD in the RxBD table. 1 This is the last BD in the RxBD table. After this buffer has been used, the CP receives incoming data into the first BD in the table (the BD pointed to by RBASE). The number of RxBDs in this table is programmable and is determined by the wrap bit.
3	**I**	Interrupt 0 The RXB bit is not set after this buffer has been used, but RXF operation remains unaffected. 1 The RXB or RXF bit in the HDLC interrupt circular table entry is set when this buffer has been used by the HDLC controller. These two bits may cause interrupts (if enabled).
4	L	Last in frame (only for HDLC mode of operation). The HDLC controller sets L = 1, when this buffer is the last in a frame. This implies the reception either of a closing flag or of an error, in which case one or more of the CD, OV, AB, and LG bits are set. The HDLC controller writes the number of frame octets to the data length field. 0 This buffer is not the last in a frame. 1 This buffer is the last in a frame.

Table 42-14. RxBD Field Descriptions (continued)

Bits	Name	Description
5	F	First in frame. The HDLC controller sets F = 1 for the first buffer in a frame. In transparent mode, F indicates that there was a synchronization before receiving data in this BD. 0 This is not the first buffer in a frame. 1 This is the first buffer in a frame.
6	**CM**	Continuous mode 0 Normal operation. (The empty bit (bit 0) is cleared by the CP after this BD is closed.) 1 The empty bit (bit 0) is not cleared by the CP after this BD is closed, allowing the associated data buffer to be overwritten automatically when the CP next accesses this BD. However, if an error occurs during reception, the empty bit is cleared regardless of the CM bit setting.
7	—	Reserved, should be cleared
8	**UB**	User bit. UB is a user-defined bit that the QUICC Engine block never sets nor clears. The user determines how this bit is used.
9	—	Reserved, should be cleared
10	LG	Rx frame length violation (HDLC mode only). Indicates that a frame length greater than the maximum value was received in this channel. Only the maximum-allowed number of bytes, MFLR rounded to the nearest higher word alignment, are written to the data buffer. This event is recognized as soon as the MFLR value is exceeded when data is word-aligned. When data is not word-aligned, this interrupt occurs when the SDMA writes 64 bits to memory. The worst-case latency from MFLR violation until detected is 7 bytes timing for this channel. When MFLR violation is detected, the receiver is still receiving even though the data is discarded. The buffer is closed upon detecting a flag, and this is considered to be the closing flag for this buffer. At this point, LG is set (1) and an interrupt may be generated. The length field for this buffer is everything between the opening flag and this last identifying flag.
11	NO	Rx nonoctet-aligned frame. A frame of bits not divisible exactly by eight was received. NO = 1 for any type of nonalignment regardless of frame length. The shortest frame that can be detected is of type FLAG-BIT-FLAG, which causes the buffer to be closed with NO error indicated. The Non Octet byte is not written into memory and the data length DL field is not updated with this count.
12	AB	Rx abort sequence. A minimum of seven consecutive 1s was received during frame reception. Abort is not detected between frames. The sequence Closing-Flag, data, CRC, AB, data, opening-flag... does not cause an abort error. If the abort is long enough to be an idle, an idle line interrupt may be generated. An abort within the frame is not reported by a unique interrupt but rather with a RXF interrupt and the user has to examine the BD.
13	CR	Rx CRC error. This frame contains a CRC error. The received CRC bytes are always written to the receive buffer.
14	—	Reserved, should be cleared
15	—	Reserved, should be cleared

NOTE: RxBD and MRBLR

When the length of a received frame is an exact multiple of MRBLR, the CP may not mark the BD that contains the last of the frame data as the last BD in the frame. The CP closes the BD, marks it with E = 0, sets the Data Length field to the length of the data in this buffer, but leaves L (bit 4) cleared. Then, the CP closes the next BD, erroneously marks it as containing data (E = 0), and marks it as the last BD in the frame (L = 1).

Figure 42-26 shows how non-octet alignment is reported and how data is stored. The two diagrams on the left show the reception of a single-buffer, 12-byte frame including the CRC. In the top case, the reception is correctly octet-aligned and the frame length indicates 12 bytes.

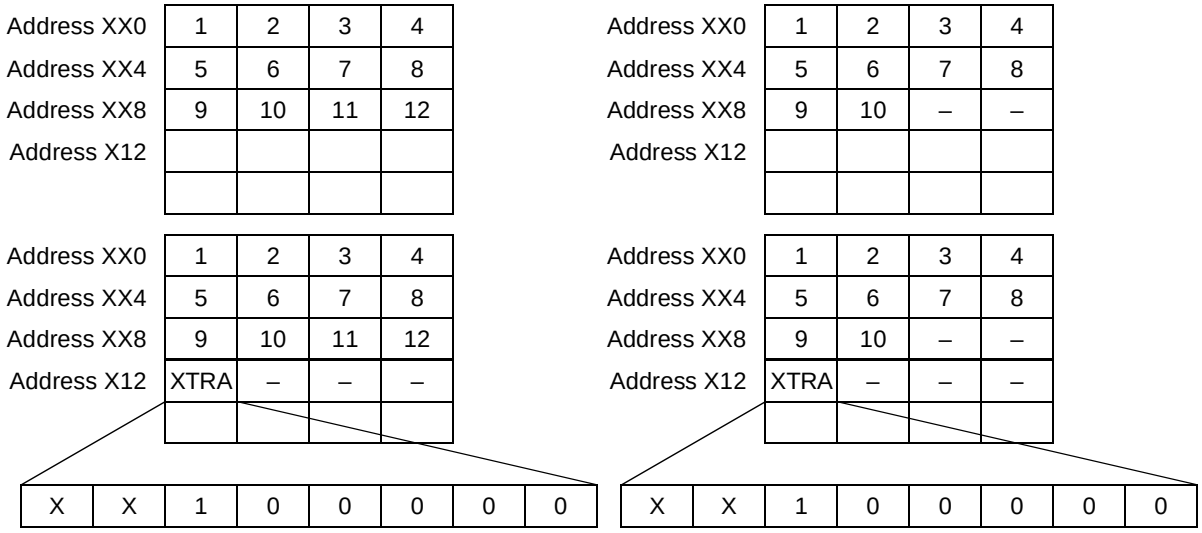

Figure 42-26. Nonoctet Alignment Data

In the bottom case, two more bits are received. The frame length is now 13 bytes, and the address positions X13 through X15 point to invalid data. Address position X12 contains information about the non-octet alignment. Valid information is written starting at the MSB position, shown as ‘x’ in the diagram. Starting from the LSB position, zeros are filled in followed by a ‘1’ immediately preceding the valid data.

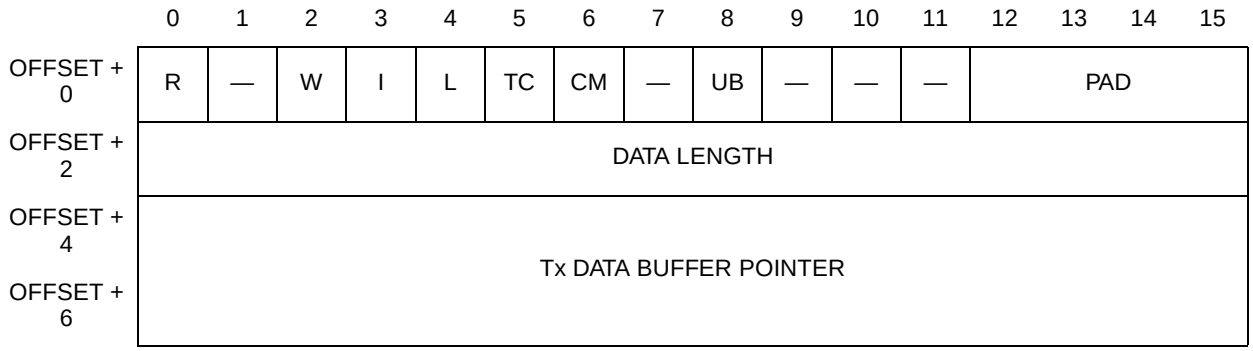
The two diagrams on the right show how the data and the extra information is stored for a frame length that is not a multiple of 4 bytes. The additional information is always on a long-word boundary. In the top case the frame length is 10 bytes and in the bottom case the length is 11 bytes.

For a minimum frame consisting of ‘flag, 1 bit, flag’ the frame length is 1. The only valid entry is at address XX0 with content of x1000000.

To accommodate the extra long word that may be written at the end of a frame and to avoid overwritten memory beyond the end of a buffer, it is recommended to reserve MRBLR + 8 bytes for each buffer area. The XTRA information shown in Figure 42-26 is written as 32-bit word. Under special, but quite possible circumstances the XTRA data is written four bytes further than indicated. Therefore, users must allocate MRBLR+8 bytes for each buffer area for QMC to avoid the risk of these memory areas being overwritten with XTRA info.

42.6.2 Transmit Buffer Descriptor

Figure 42-27 shows the transmit buffer descriptor.



Notes: Entries in boldface must be initialized by the user.

Figure 42-27. Transmit Buffer Descriptor (TxBD)

Table 42-15 describes the individual fields of a transmit buffer descriptor. Boldfaced entries must be initialized by the user.

Table 42-15. Transmit Buffer Descriptor (TxBD) Field Descriptions

Field	Name	Description
0	**R**	Ready 0 The data buffer associated with this buffer descriptor is not ready for transmission. The user can manipulate this buffer descriptor or its associated data buffer. The QUICC Engine block clears this bit after the buffer has been transmitted or after an error condition is encountered. 1 The data buffer, which has been prepared for transmission by the user, has not been transmitted or is being transmitted. If R = 1, the user cannot write to fields of this buffer descriptor.
1	—	—
2	**W**	Wrap (final buffer descriptor in table) 0 This is not the last buffer descriptor in the TxBD table. 1 This is the last descriptor in the Tx buffer descriptor table. After this buffer is used, the QUICC Engine block transmits data from the first buffer descriptor in the table (the buffer descriptor pointed to by TBASE). The number of TxBDs in this table is programmable and is determined only by the wrap bit and the overall space constraints of the multi-user RAM.
3	**I**	Interrupt 0 No interrupt is generated after this buffer has been serviced. 1 TXB in the circular interrupt table entry is set when the controller services this buffer. This bit can cause an interrupt (if enabled).
4	**L**	Last 0 This is not the last buffer in the frame. 1 This is the last buffer in the current frame.
5	**TC**	Tx CRC (HDLC mode only). This bit is valid only when L = 1; otherwise, it is ignored. 0 Transmit the closing flag after the last data byte. This setting can be used for testing purposes to send an erroneous CRC after the data. 1 Transmit the CRC sequence after the last data byte.

Table 42-15. Transmit Buffer Descriptor (TxBD) Field Descriptions (continued)

Field	Name	Description
6	**CM**	Continuous mode 0 Normal operation. 1 The R bit is not cleared by the QUICC Engine block after this buffer descriptor is closed, allowing the associated data buffer to be retransmitted automatically when the QUICC Engine block next accesses this buffer descriptor.
7	—	—
8	**UB**	User bit. The QUICC Engine block never touches, sets, or clears this user-defined bit. The user determines how this bit is used. For example, it can be used to signal between higher-level protocols whether a buffer has been processed by the CPU.
9–11	—	—
12–15	**PAD**	Padding bits. These four bits indicate the number of PAD characters (0x7E or 0xFF depending on IDLM mode in the CHAMR register) that the transmitter sends after the closing flag. The transmitter issues a TXB interrupt only after sending the programmed value of pads to the Tx FIFO. The user can use the PAD value to guarantee that a TXB interrupt occurs after the closing flag has been sent on the TXD line. PAD = 0 means the TXB interrupt is issued immediately after sending the closing flag to the Tx FIFO. The number of PAD characters depends on the FIFO size and the number of time slots in use. An example explains the calculation: In UCC1 the FIFO is 32 bytes. If 16 time slots are used in the link, the resulting number of PAD characters is 32/16 = 2, to append to this buffer to ensure that the TXB interrupt is not given before the closing flag has been transmitted through the TXD line. The number of PAD characters must not exceed the NOF characters, ensuring that the closing of one buffer (the interrupt generation) occurs before the start of the next frame (clearing of R-bit). After the sequence of a closing flag followed by (PAD + 1) flag characters, a TXB interrupt is generated; see Figure 42-28.
16–31	**DL**	Data length. The data length is the number of bytes the QUICC Engine block should transmit from this buffer descriptor's data buffer. It is never modified by the QUICC Engine block. This field should be greater than zero.
32–63	**TxBP**	Tx buffer pointer. The transmit buffer pointer, which contains the address of the associated data buffer, may be even or odd. The buffer may reside in either internal or external memory. This value is never modified by the QUICC Engine block.

Figure 42-28 shows a TXB interrupt generated after (PAD + 1) flag characters following the closing flag. Four flags (NOF = 3) precede the next data. To set up this sequence correctly, the PAD value must not exceed NOF.

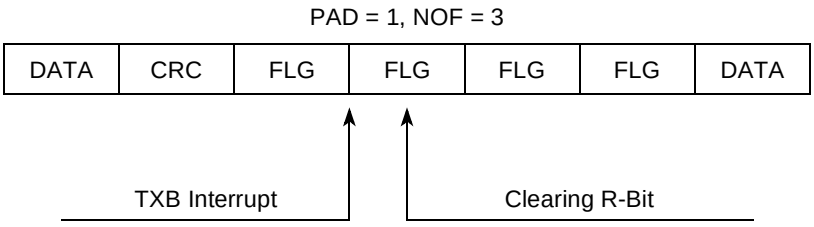


Figure 42-28. Relation between PAD and NOF

42.6.3 Placement of Buffer Descriptors

The internal multi-user RAM is used to store the buffer descriptors for all non-QMC operation. This solution causes minimum loading of the external bus. When starting any operation or switching between buffers during operations, several accesses must be made by the QUICC Engine block to find the actual data buffers and to read and write control and status information. This process is unseen by the user for internal accesses, and any external bus master or memory refresh control can occur uninterrupted.

42.6.3.1 Parameter RAM Usage for QMC over Several UCCs

There are two possible memory configurations for operating the QMC protocol on several UCCs. For each UCC in QMC protocol, a global parameter area is used, consuming at most 190 bytes if every global area contains the routing tables. The time-slot assignment tables (TSATRx and TSATTx) together occupy 128 bytes. The tables for each UCC in the parameter RAM can be duplicated, requiring 190 bytes per UCC.

Alternatively, multiple UCCs can use one set of common time slot assignment tables (TSATRx and TSATTx), as described in Section 42.3.2.1, “TSATRx/TSATTx Pointers and Time-Slot Assignment Table.” One UCC RAM page uses 190 bytes, 62 bytes for parameter fields and 128 bytes for the common time slot assignment tables, allowing the other UCCs to use only 62 bytes of parameter RAM for QMC protocol, freeing their 128 bytes of time-slot assignment table space.

42.6.3.2 Internal Memory Structure

For details about the internal memory, refer to Chapter 2, “Memory Map.”

To support 32 channels, only 2-Kbyte multi-user RAM is needed for channel-specific parameters. Each logical channel occupies 64 bytes; thus 32 channels require 2 Kbytes, leaving 2 Kbytes free in the multi-user RAM for buffer descriptors for other protocols.

To support 64 channels, 4-Kbyte multi-user RAM is required for channel-specific parameters. Each logical channel occupies 64 bytes, requiring 4 Kbytes for 64 channels.

Non-QMC protocol implementations may be constrained by these memory requirements since their buffer descriptors need to use internal memory space.

If fewer than 64 logical channels are used or if multiple time slots are concatenated to form super channels, using one QMC channel to manage those time slots, space is freed in the multi-user RAM. Each unused logical channel creates a 64-byte hole in the multi-user RAM. This area is free for buffer descriptors for any UCC. QMC channels can also use this space instead of external memory for buffer descriptors, reducing the load on the external bus.

42.7 QMC Initialization

The following are the general initialization steps necessary after a reset for QMC operation. Prior to completing these steps, ensure that the values of CECR[OPCODE], see Section 20.3.1, “QUICC Engine

Command Register (CECR)," and GUMR_L[MODE], see Section Figure 24-1., "GUMR_L—General UCC Mode Register Low Order," are set for QMC operation:

1. Initialize QMC global parameters, including all parameter fields, Tx and Rx time-slot assignment tables and framer tables.
2. Initialize channel-specific parameters.
3. Initialize TxBDs and corresponding Tx data buffers
4. Initialize RxBDs
5. Connect the UCC to the TDM interface through the appropriate UCC clock multiplexing register CMXUCR*x*
6. Initialize UCC registers, including enabling the UCC. Program GUMR_H[16] to a zero to select QMC mode, see Table 24-3.
7. Program RX and TX SIRAM to point appropriate time slots to the UCC used for QMC.
8. Initialize SI registers
9. Enable TDM

42.7.1 Restarting the Transmitter

A global underrun may require the UCC transmitter to be restarted. However, for channel-specific errors, only the affected channel need be restarted. The following steps are required to restart each channel:

1. Prepare buffer descriptors.
2. Set the POL bit in the channel mode register.

A stopped, but not deactivated channel is started as described above. A deactivated channel must first have the ZISTATE and TSTATE reinitialized to their correct values, followed by setting TSATTx[V] and CHAMR[ENT]. Lastly, set CHAMR[POL] if the buffers are ready.

42.7.2 Restarting the Receiver

A global receiver overrun may require the UCC receiver to be restarted. However, for channel-specific errors, only the affected channel need be restarted. The following steps are required to restart each channel:

1. Prepare buffer descriptors.
2. Reinitialize the ZDSTATE.
3. Reinitialize the RSTATE.

42.7.3 Disabling Receiver and Transmitter

A transmit channel can be stopped from sending any more data to the line with the STOP command described in Section 42.4.1, "Transmit Commands." The transmitter continues to send IDLEs or FLAGs according to the channel mode register setting. To deactivate a channel, the V bit has to be cleared in the time-slot assignment table and the ENT bit has to be cleared in the channel mode register.

To stop a channel while receiving, use the STOP command as described in Section 42.4.2, "Receive Commands," and perform a restart as described above.

Chapter 43
Inverse Multiplexing for ATM (IMA)

NOTE

ATM functionality is provided through an implementation of inverse multiplexing for ATM (IMA). This chapter provides a broad overview of the IMA specifications and the specific implementation.

43.1 Features

The IMA ATM Forum Specification defines the functions shown in Table 43-1.

Table 43-1. IMA Sublayer in Layer Reference Model

Layer	Sublayer	User Plane Functions	Layer Management Functions	Plane Management Functions
ATM	—	—	—	—
Physical	IMA Specific Transmission Convergence	• ATM cell stream splitting and reconstruction • ICP Cell Insertion & Removal • Cell Rate decoupling • IMA frame sync • Stuffing • Discarding bad-HEC cells	• IMA connectivity • ICP cell errors (OIF) • LIF/LODS/RDI-IMA defect processing • RDI-IMA alarm generation • Tx/Rx IMA link state report	• IMA group configuration • Link addition/removal • ATM cell rate change • IMA group failure notification • IMA statistics
	Interface Specific Transmission Convergence	• No cell discarding • No cell rate decoupling	—	—
		• Cell delineation • Cell scrambling & descrambling • Header error correction • HEC generation & verification	• HEC error indication • LCD-RDI alarm Generation	• LCD failure notification • TC statistics
	Physical Medium Dependent	• Bit timing • Line coding • Physical Medium	• Local alarm processing • RDI alarm generation	• Link failure notification • PMD state

This IMA microcode alone does not implement all of these functions. Software is responsible for managing the startup procedure, handling changes in group control, status, and maintaining the Link State Machine and Group State Machine. In general, this IMA microcode implements most of the IMA sublayer user plane functions and provides interrupts/statistics for the layer and plane management functions.

The key features of the IMA microcode are:

- Supports any UCC with multi-PHY UTOPIA capability
- Supports both IMA links and non-IMA links on the same UCC (on a per-PHY basis)

- Supports up to 8 IMA groups with one UCC
- Supports up to 31 links per IMA group using the internal microcoded TC layers (for an E1 configuration 2 IMA links can be supported per TDM interface)
- Supports up to 31 links per IMA group using an external TC layer device (Note that a maximum of 31 links can be supported per UCC)
- Performs the following IMA User Plane functions
  - ATM cell stream splitting and reconstruction
  - ICP cell insertion/removal – communication of control and framing information
  - Cell rate decoupling – insertion of ‘filler’ cells when ATM layer cells are unavailable
  - IMA frame synchronization – finding IMA frame boundaries within links
  - Stuffing--insertion of ‘stuff’ cells into fast links, in order to maintain an average data rate between links of a group
  - Discards cells with bad HECs
- Delay synchronization – correlating IMA frames among links of a group
- Maximum differential delay supported is user-programmable
- Provides interrupts on errors/state changes
- Maintains low-level statistic counters
  - Transmit stuff events
  - Receive stuff events
  - Receive ICP violations
  - Receive Out-of-IMA Frame anomalies

43.1.1 References

The features provided by the IMA microcode are driven by The ATM Forum’s IMA specification. The implementation of the IMA microcode is driven by the features, architecture, and resources available on the processor. In addition to published device errata, users should be familiar with the following (available at www.atmforum.com):

- The ATM Forum Technical Committee. Inverse Multiplexing for ATM (IMA) Specification Version 1.1 - AF-PHY-0086.001
- The ATM Forum Technical Committee. Inverse Multiplexing for ATM (IMA) Specification Version 1.0 - AF-PHY-0086.000

43.1.2 IMA Versions Supported

The IMA microcode supports IMA version 1.0 and version 1.1, with only minor configuration changes. These include the following:

- Programming the IMA version encoding in the OAM labels of the transmit ICP and Filler cell templates.
- Programming the validated OAM label field in the IMA group receive parameters.

43.1.3 PHY-Layer Devices Supported

The IMA microcode is primarily targeted at ATM's primary application (i.e. IMA over multiple DS1/E1). However, the IMA microcode supports any UTOPIA PHY device which (1) has a constant data rate and (2) can be programmed not to screen out HEC-errored cells. Most PHYs have this mode available for IMA also.

43.1.4 ATM Features Not Supported

The following ATM features are not available for IMA links only, but are available for non-IMA links:

- User-defined cells (UDC) (i.e. cells that are not 53 bytes and/or with customized headers)
- Internal rate mode for APC scheduling

43.2 IMA Protocol Overview

This section describes the IMA protocol, not this specific implementation of IMA microcode.

43.2.1 Introduction

Inverse multiplexing over ATM (IMA) is a cost-effective solution for carrying high speed connections such as T3/E3 and OC-3c/STM-1 links over already installed low speed connections such as T1/E1 links flexibly by dynamically adding/removing links depending on the bandwidth required. IMA transmits a stream of data over multiple low speed links and recombines the stream in the correct order at the end. IMA involves inverse multiplexing and de-multiplexing of ATM cells cyclically among links grouped to form a higher bandwidth logical link at a rate that approximates the sum of the link rates. Such groups of links are called IMA groups. Figure 43-1 illustrates the ATM inverse multiplexing technique in one direction. This technique applies in the opposite direction.

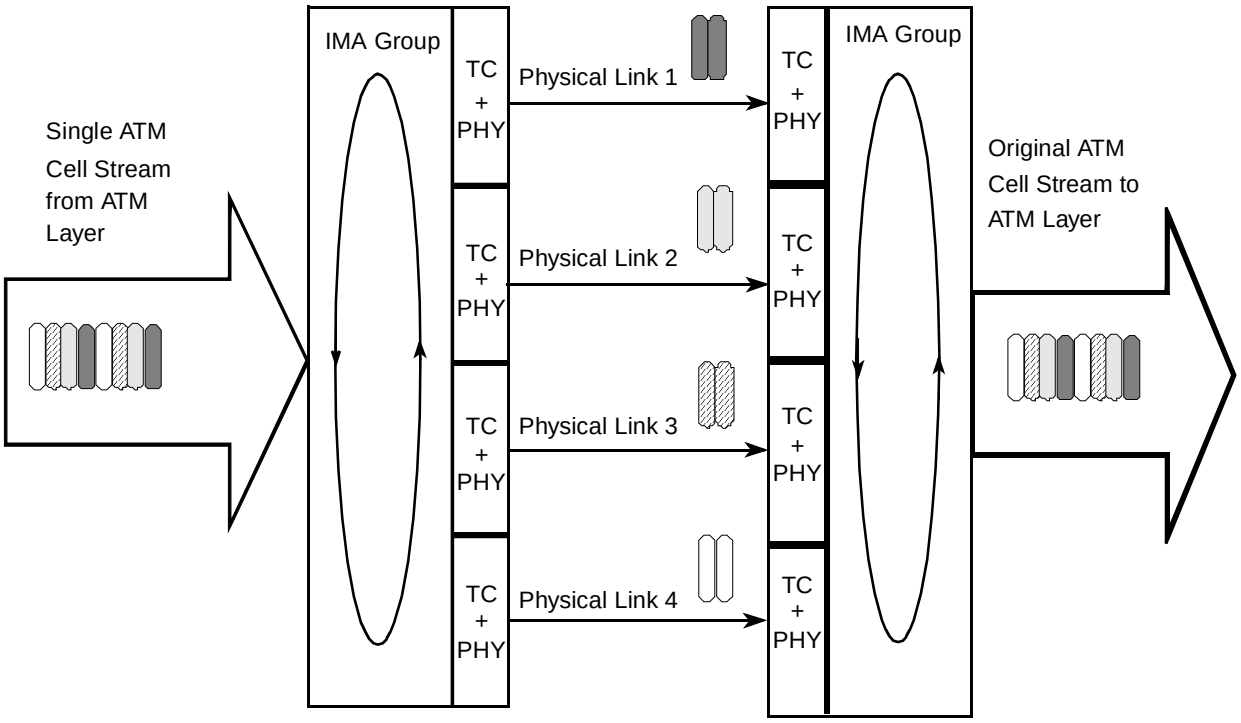

Figure 43-1. Basic Concept of IMA

In the transmit direction (near-end), the ATM cell stream received from the ATM layer is distributed, cell by cell, across the multiple links within the IMA group. At the far-end, the receiving IMA unit recombines the cells from each link, cell by cell, recreating the original ATM cell stream. The aggregate cell stream is then passed to the ATM layer. The IMA protocol enables the demultiplexing/deconstruction (transmit) of an ATM cell stream into multiple links. When receiving, the IMA protocol multiplexes/reconstructs incoming cells from multiple links into the original ATM cell stream. The IMA protocol must compensate for differences in clock rate and delay over the multiple links.

43.2.2 IMA Frame Overview

The IMA interface periodically transmits special cells that contain information to permit reconstruction of the ATM cell stream at the receiving end of the IMA virtual link. The receiver end reconstructs the ATM cell stream after accounting for the link differential delays, smoothing CDV introduced by the control cells, and so on. These cells, defined as IMA control protocol (ICP) cells, define an IMA frame. The transmitter must align the transmission of IMA frames on all links (shown in Figure 43-2) so that the receiver can adjust to differential link delays among the constituent physical links. Based on this required behavior, the receiver can detect the defensible delays by measuring the arrival times of the IMA frames on each link.

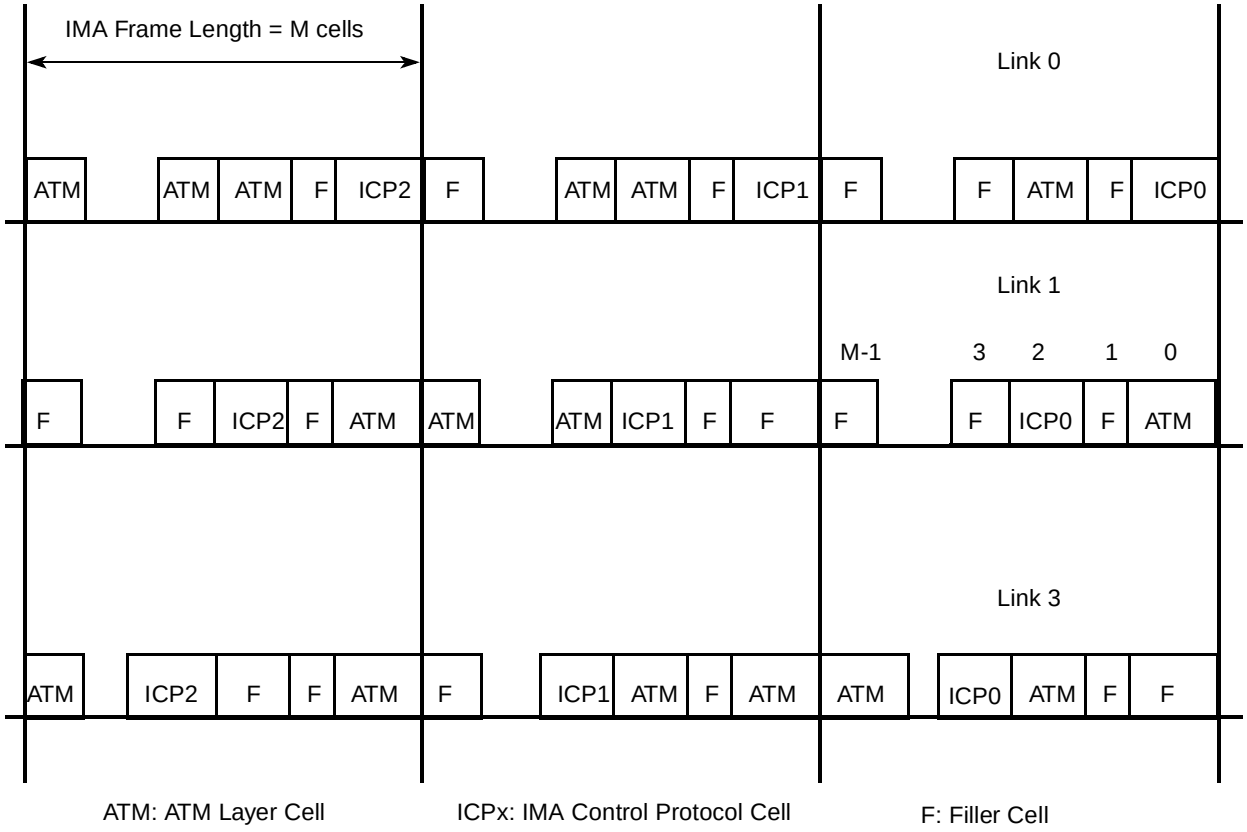

Figure 43-2. Illustration of IMA Frames

At the transmitting end, the cells are transmitted continuously. If there are no ATM layer cells to be sent between ICP cells within an IMA frame, the IMA transmitter sends filler cells to maintain a continuous stream of cells at the physical layer. The insertion of filler cells provides cell rate decoupling at the IMA sublayer. The IMA receiver should discard the filler cells. A new OAM cell is defined for use by the IMA protocol. The cell has codes that define it as an ICP or filler cell.

IMA data multiplexing is cell-based, where cells are distributed among the links in the IMA group in a round-robin cycle. To compensate for different clock rates, IMA must periodically insert ‘stuff’ cells into faster links to maintain a consistent average data rate over the links of the group. Furthermore, IMA must compensate for potential differences in delay between the links of the group. Per the IMA specification, the allowable delay differential for DS1/E1 links is 25ms, which at E1 rates is equivalent to approximately 118 cells. The IMA microcode allows the user to define the allowable delay differential through a delay compensation buffer of programmable length.

IMA accomplishes these goals by periodically inserting special OAM cells, which (among other things) define M-cell frame boundaries and provide frame sequence numbers and stuffing information. The receiver uses this framing information to correlate the received cell streams and extract cells in-order from the links of the IMA group, thereby reconstructing the original cell stream.

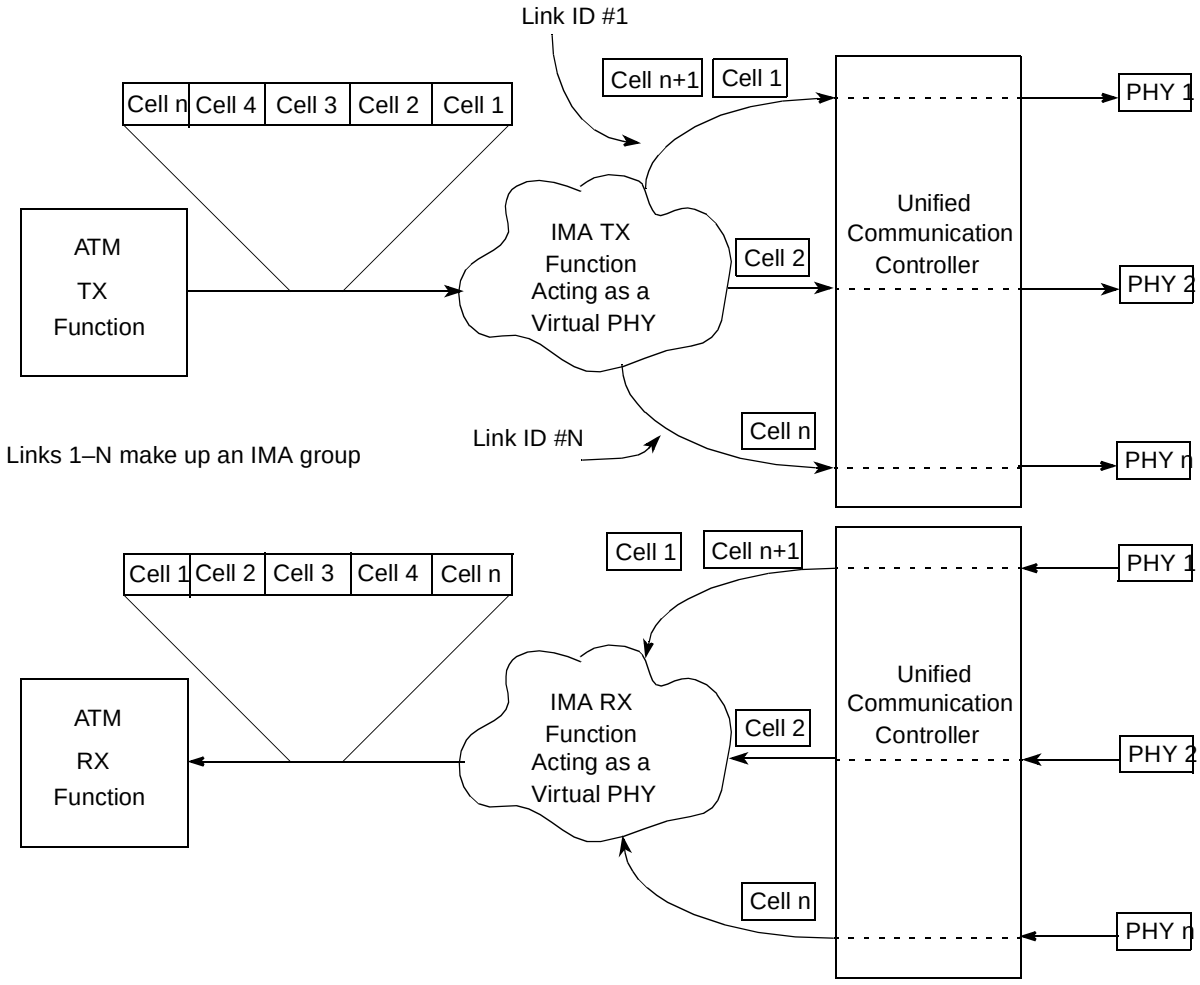

Figure 43-3. IMA Microcode Overview

43.2.3 Overview of IMA Cells

An IMA frame consists of M number of cells (M = 32, 64, 128, or 256 cells). Each frame consists of ATM data cells and IMA control cells. Two types of IMA control cells are defined and used by the IMA protocol: IMA control protocol (ICP) cells and filler cells.

43.2.3.1 IMA Control Cells

There is at least one IPC cell in each frame. An additional ICP cell may be included in a frame to compensate for timing differences between the links in an IMA group (for example, one link is slightly faster than the other). The insertion of additional ICP cells to compensate for timing differences between links is called a stuff event. The transmitter inserts stuff ICP (SICP) cells, and the receiver monitors for stuff indication and discards SICP cells. The location of the ICP cell in an IMA frame is determined during the IMA startup sequence.

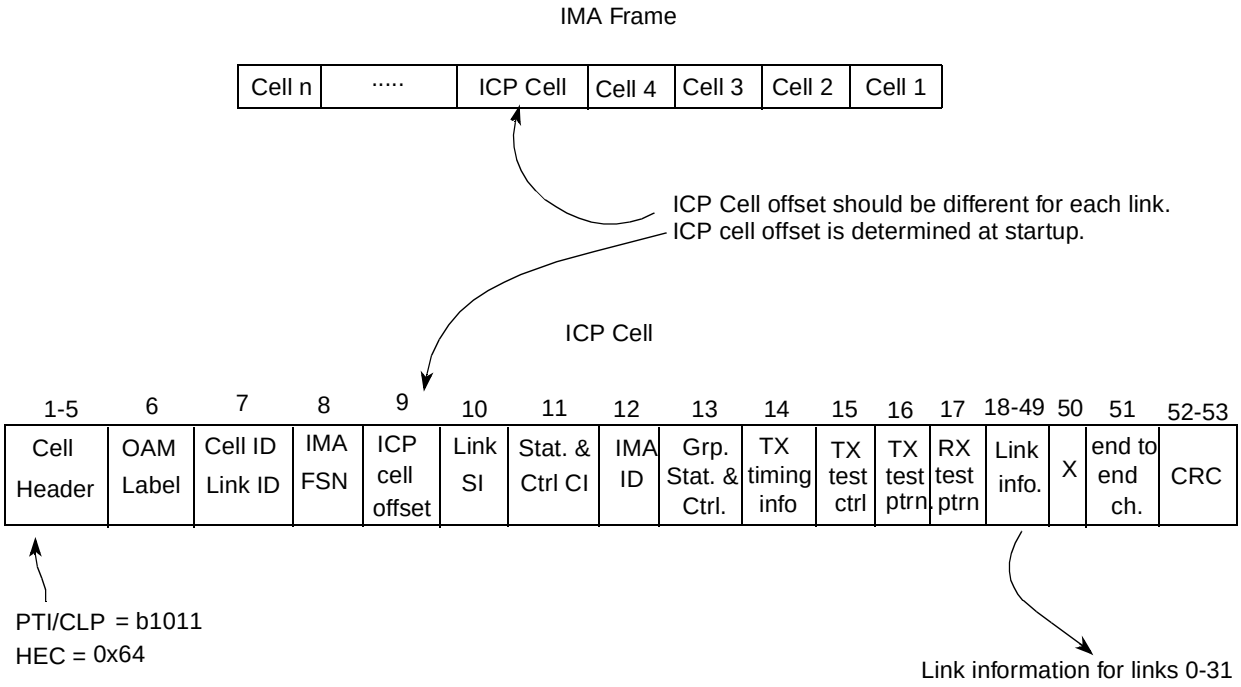

Figure 43-4. IMA Frame and ICP Cell Formats

The IMA protocol must compensate for potential differences in delay between the different links of the IMA group. The allowable delay differential for DS1/E1 links is 25ms, which at E1 rates is equivalent to approximately 118 cells.

43.2.3.2 IMA Filler Cells

At the transmitting end, cells are transmitted continuously. If there are no ATM layer cells to be sent between ICP cells within an IMA frame, then IMA transmitter sends filler cells to maintain a continuous stream of cells at the physical layer. The insertion of filler cells provides cell rate decoupling at the IMA sublayer. The IMA receiver should discard the filler cells.

43.3 IMA Microcode Architecture

This section explains the architecture of the receive and transmit IMA microcode tasks.

43.3.1 IMA Function Partitioning

The IMA microcode performs only functions with regular, critical real-time demands. The other functions of IMA, such as control and management, are the responsibility of host software. The IMA microcode corresponds primarily to the user plane functions defined in the IMA specification, and software must provide the layer management and plane management functionality. The IMA microcode provides interrupts when interaction with layer management and plane management is required.

43.3.1.1 User Plane Functions Performed by Microcode

- ATM cell stream splitting and reconstruction
- ICP cell insertion/removal
- Cell rate decoupling (that is, filler cell insertion/removal)
- IMA frame synchronization
- Stuffing
- Discards cells with bad HECs

43.3.1.2 Plane Management Functions Performed by Microcode

Although most plane management functions must be performed in software, certain statistics are intimately related to the lower-level user plane functions and are thus best provided by the microcode:

- ICP violations
- Transmit stuff events
- Receive stuff events

43.3.2 Transmit Architecture

This section discusses the behavior of the IMA microcode during transmission, focusing particularly on the independent transmit clock (ITC) mode of IMA. Differences in behavior when common transmit clock (CTC) mode is used are discussed at the end of this section.

Only one cell scheduler, known as the ATM pace controller or APC, is used per IMA group. This APC schedules transmission for the IMA group as a single aggregate channel. The APC hands these cells off to the IMA Tx microcode, which distributes these scheduled cells to each PHY in the IMA group. To compensate for clocking differences (jitter and average speed differential), the IMA Tx process distributes ATM cells into N jitter buffers with a depth of 5 cells. The IMA PHYs take cells from these jitter buffers and transmit them.

The cell scheduling is triggered by requests from the timing reference link (assertion of TxClav from the TRL PHY). Requests from non-TRL PHYs interact only with the jitter buffer and perform the stuffing function as needed (when the jitter buffer becomes too shallow). Therefore, the microcode tasks performed in response to TRL PHY requests and non-TRL PHY requests are different.

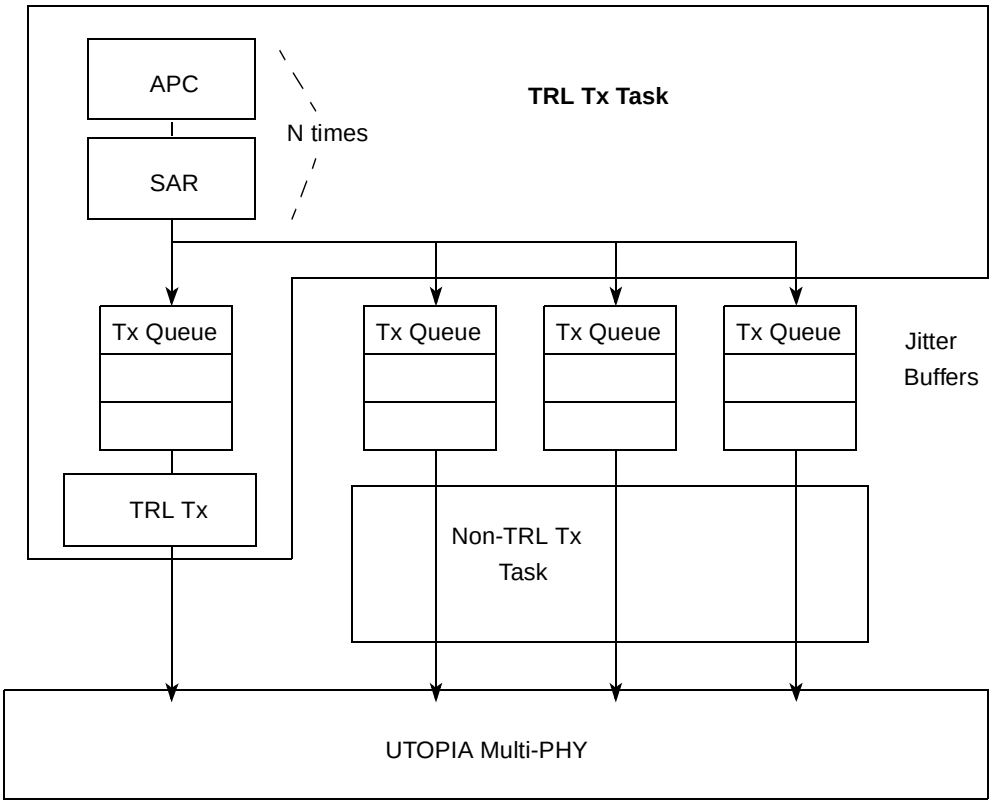

Figure 43-5. IMA Transmit Task Interaction

43.3.2.1 TRL Operation

A request from the TRL PHY triggers a complete round-robin process of cell scheduling and distribution, distributing one cell for each of the transmit queues of the N links in the IMA group. For each link, the microcode will:

1. Determine whether an ICP cell or a data/filler cell should be sent for the link:
   — If data/filler, determine whether link is in active or filler-only mode
   — If active, run the APC scheduling algorithm to find the next scheduled ATM channel
2. Distribute either:
   — An ICP cell
   — A filler cell (if ‘filler-only’ or ‘active’ with nothing scheduled in the APC)
   — A data cell (if a channel is scheduled in the APC, performing the appropriate segmentation task for the scheduled ATM channel, as determined by the channel’s AAL type)

The cells are distributed by writing the complete cells into circular transmit queues provided per link. These transmit queues function as jitter buffers to decouple the transmit rate of the TRL PHY from the transmit rate of the non-TRL PHYs in the group to allow for clocking differences between the PHYs.

At startup, the non-TRL links transmit filler cells until their transmit queues reach a minimum depth. To maintain less than the specified maximum +/-2.5 cell transmit timing differential (for cells within an IMA

frame), the TRL must exhibit the same behavior. Therefore, a 4-cell transmit buffer is also maintained for the timing reference link. The timing reference link begins to pass ATM layer cells to its PHY only after it has 3 cells in its buffer. Prior to this, it sends filler cells. This behavior is experienced only at group startup.

The TRL task also implements the standard amount of stuffing on the TRL link by maintaining a counter. When this task schedules (2048/ M) ICP cells for the TRL, a TRL stuff event is flagged and an indication of an upcoming stuff event is signaled in the ICP LSI field. If a TRL stuff event is flagged when the TRL task triggers, a stuff cell is sent to the TRL transmit queue. However, no cells are sent to the transmit queues of the non-TRL PHYs. This forces a standard amount of stuffing on the TRL, thereby reducing the effective data bit rate of the TRL to less than the minimum data clock rate allowed by the clock rate tolerance of the physical-layer standard. Therefore, this effective data bit rate is achievable by the non-TRL links; the non-TRL links can either stuff less if their data clock rate is slower than the TRL or stuff more if their data clock rate is faster than the TRL.

43.3.2.1.1 TRL Service Latency

NOTE

The functionality described in this section is available only with the latest RAM microcode package.

This optional feature allows the user to change the IMA APC behavior upon TRL request. When enabled the TRL request passes a programmable number of cells to the Tx queue of the links in an IMA group. This can be used to prevent the TRL from consuming a large amount of bandwidth before another cell is transmitted. The TRL request normally places a cell in a queue for N links where the group contains N links. Then a non_TRL link is free to pass a cell over the UTOPIA interface. The delay for the TRL can be long and in some cases the TC layer FIFO can underrun. This feature ensures that TRL and non-TRL requests are handled the same way, with 1 cell in and 1 cell out to the transmit queues. The non-TRL requests also trigger APC iterations when this feature is enabled. The depth of the TRL transmit queue must equal that of the non-TRL queues.

43.3.2.2 Non-TRL Operation

A request from a non-TRL PHY does not trigger any scheduling task. The cells for non-TRL links are already supplied (by the TRL task) in its associated transmit queue. The TRL simply read a cell out of its transmit queue and updates the queue pointers.

If the transmit queue becomes too shallow (because this link request rate is faster than the TRL), the link flags that a stuff event is imminent. The link signals an upcoming stuff event in the LSI field of its next ICP cell and then flags that a stuff event is due. The link continues sending cells from its queue as usual until it reaches its next ICP cell, upon which it indicates a stuff event in the ICP cell and transmits it but does not update the transmit queue pointers. When the link next requests a cell, the previous ICP cell is repeated (since the queue pointers were not updated). This process causes the transmit queue to deepen to the intended level.

At group startup, instead of accessing its transmit queue, the link sends filler cells to allow the transmit queues to reach their target steady-state depth. After the group startup flag is cleared, normal operation commences.

43.3.2.3 Transmit Queue Operation Examples (ITC mode)

The diagrams in this section demonstrate the different cases of queue operation and consequently justify the queue depth of 5 cells.

- The extraction pointer points to the queue entry currently supplied to the PHY. This cell must be entirely ready when the PHY requests it.
- The insertion pointer points to the queue entry to be filled next by the TRL process.

In the figures, note that the pointers and filled queue locations are just shown with respect to the overall queue depth available with the extraction pointer always shown at the bottom of the queue. This is done only for easy illustration. In reality, the transmit queues are circular queues in which the insertion and extraction pointers are continually rotating through the queue.

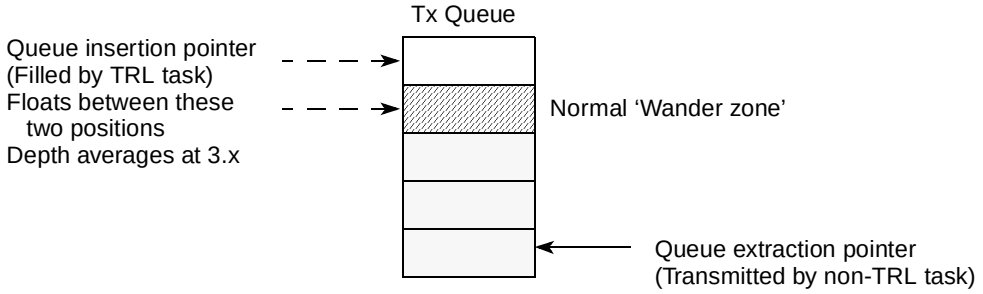

Figure 43-6. Transmit Queue Normal Operating State

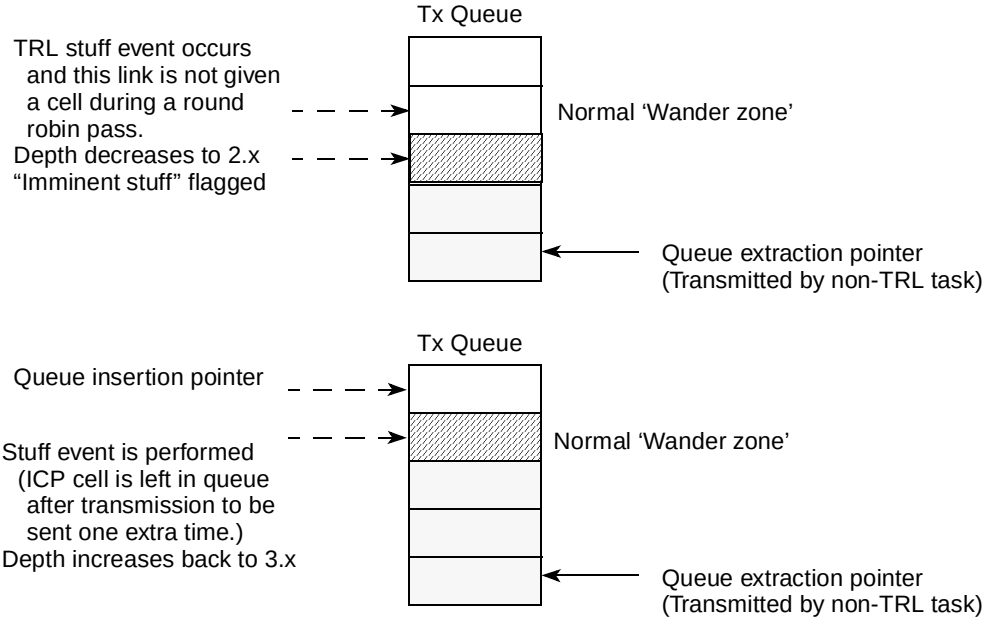

Figure 43-7. Transmit Queue Behavior: Link Clock Rate Same as TRL

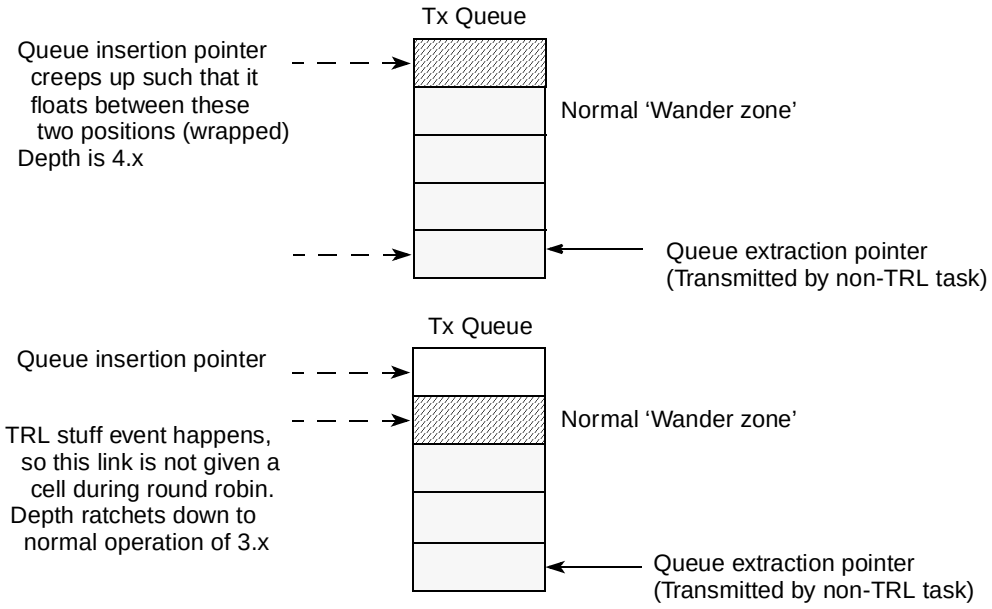

Figure 43-8. Transmit Queue Behavior: Link Clock Rate Slower Than TRL

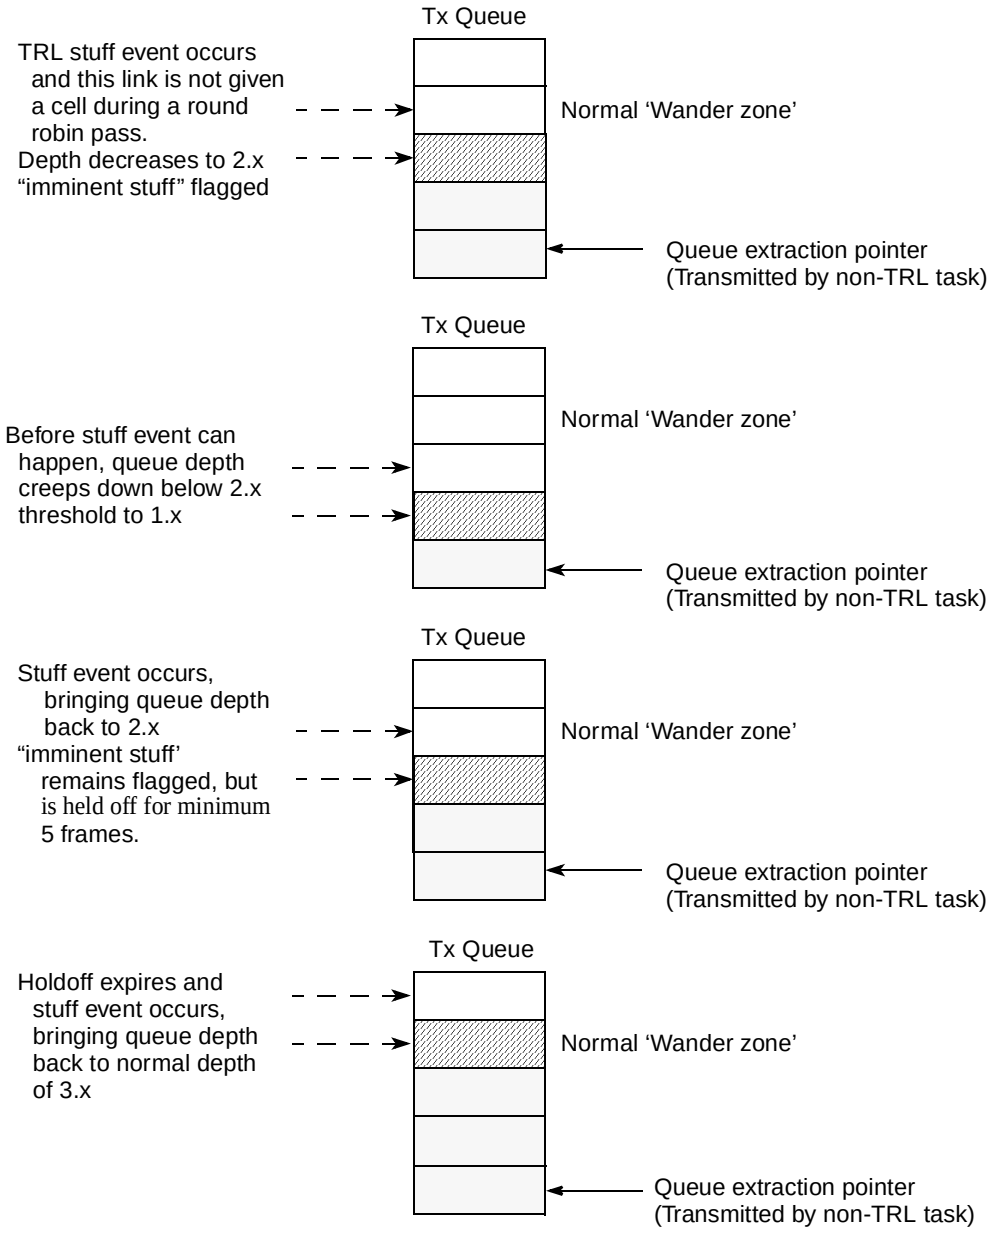

Figure 43-9. Transmit Queue Behavior: Link Clock Rate Faster Than TRL Worst-Case Event Sequence

43.3.2.4 Differences in CTC Operation

Overall, CTC operation is similar to ITC operation in task partitioning and structure. Differences are as follows:

- Transmit buffers are still maintained for the non-TRL links, but these buffers do not jitter because the transmit clocks are all the same. However, queue depths may vary slightly because PHY requests, while synchronous, do not necessarily come in simultaneously (may have constant offsets) and are definitely not serviced simultaneously.

- The non-TRL tasks do not determine when to perform stuffing on the non-TRL links. When the TRL flags imminent stuff on its own link, it flags imminent stuff on all the non-TRL links as well. Thus, the non-TRL links also stuff their links every 2048 cells.
- The non-TRL queue depths are the same as the TRL queue (4 cells).

43.3.3 Receive Architecture

The receive task consists of three parts:

- Cell reception from the link.
- Trigger for activating the cell processing task, including timing recovery if desired.
- Actual cell processing (passing cells to the ATM layer).

The cell reception task services requests from the links (through the UTOPIA multi-PHY interface and the UCC), maintains the link state, and (if the link and group state dictates) writes the received cells into the link delay compensation buffer in external memory. The cell processing activation function coordinates passing cells from the cell reception task on an on-demand basis. The cell processing task extracts cells from the delay compensation buffers and passes them to the ATM layer for processing.

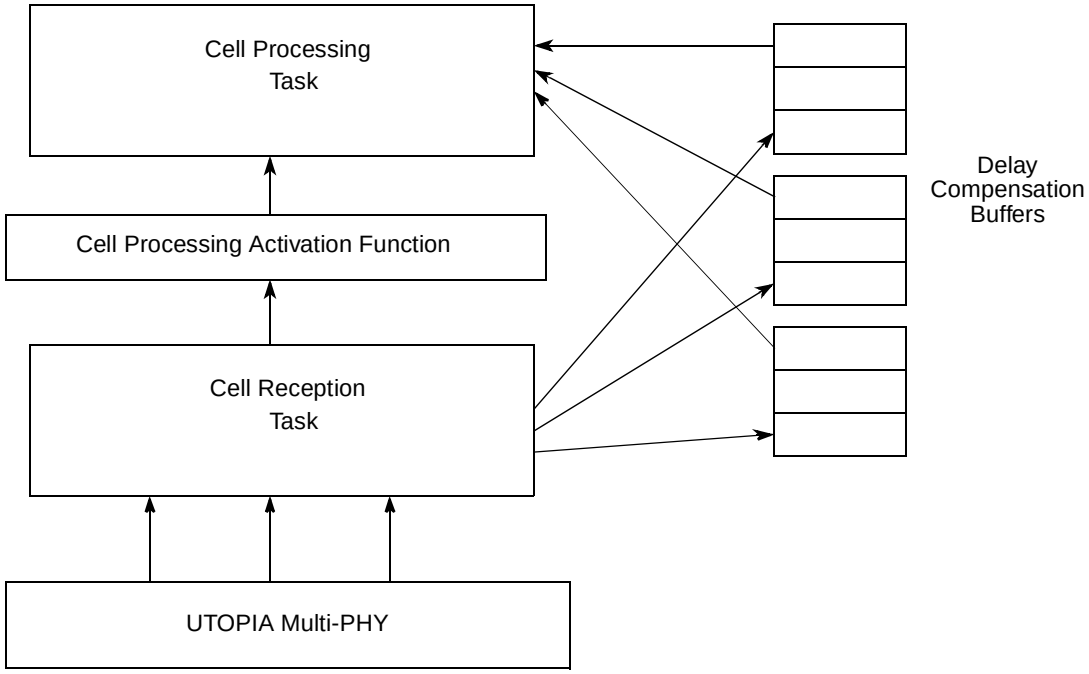

Figure 43-10. IMA Receive Task Interaction

43.3.3.1 Cell Reception Task

In the cell reception task, received ICP cells in which an SCCI change is noted, except for the first ICP received cell, are passed to a user-defined receive AAL0 channel to be processed by software. These received cells (and other event indications) are used by the software to initialize IMA links and groups, and to manage transitions between link and group states.

The cell reception task centers around a four-state link state machine. Microcode tasks are performed within each state, but transitions between states are managed by software. The processing of received cells (both ICP cells and data cells) is determined by the state of the link.

NOTES:
— Each IMA link follows a four-state machine.
— The driver processes each received ICP cell (AAL0-specific channel) to control the state machine.
— According to the link state, the microcode executes different tasks.

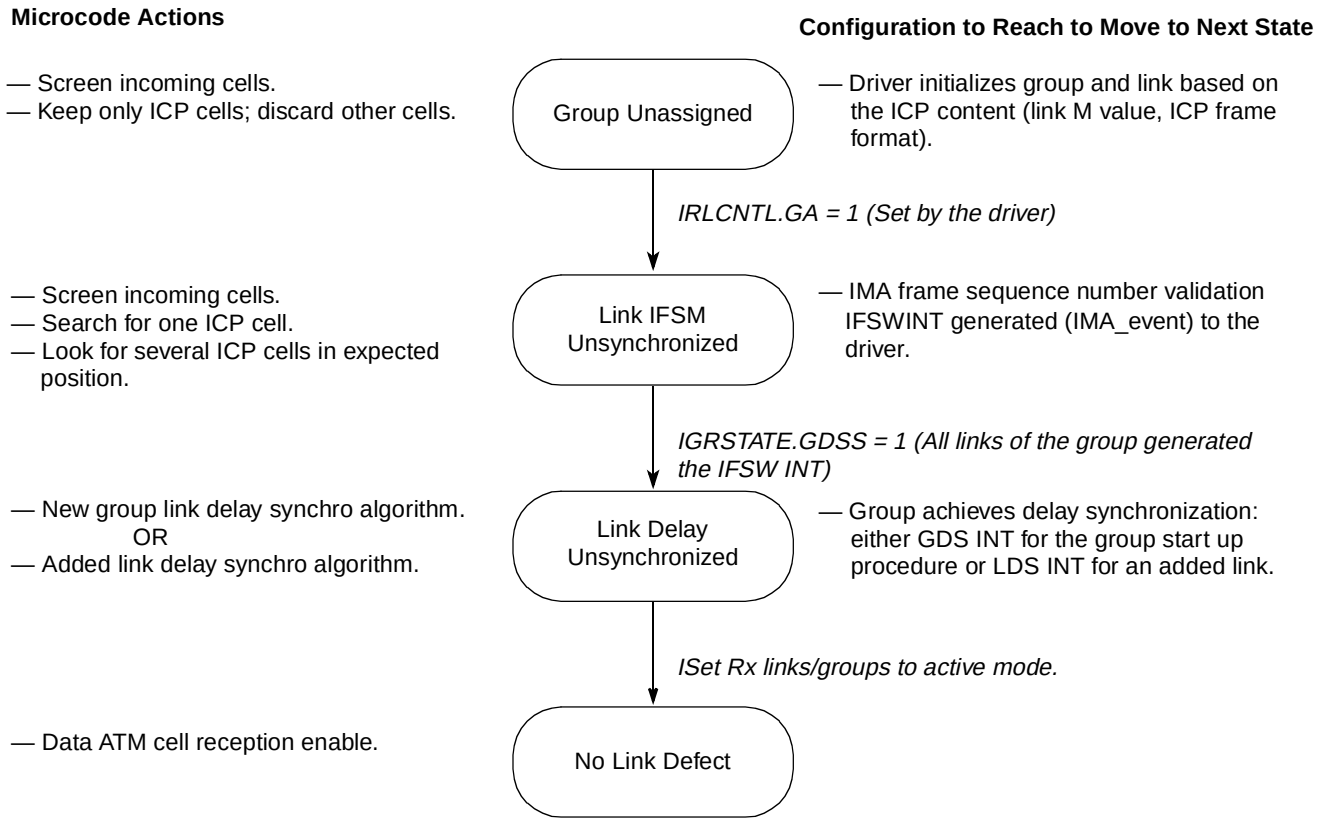

Figure 43-11. IMA Microcode: Receive Process

As Figure 43-11 shows, the states are as follows:

- Group Unassigned—Corresponds to a link that is known to be IMA but for which no information is known, such as IMA group number and IMA frame size. The receive task only screens the incoming cells for ICP cells and discards all others. ICP cells in which an SCCI change is noted are passed to a user-defined receive channel, where software must interpret their content to initialize the link and add it to the group. The link transitions to the ‘Link IFSM Unsynchronized’ state when software sets its Group Assigned flag.
- Link IFSM Unsynchronized—The link state machine has not yet found or validated the frame boundary for this link. Software initially enters this state after it defines the link M value and expected ICP cell format and then sets the Group Assigned flag. This state can be subsequently re-entered as the result of a link defect. The link searches for an ICP cell, then looks for ICP cells in the expected position of subsequent frames to validate frame synchronization. Cells other than ICP cells are discarded. When the IFSM becomes synchronized, an interrupt to the host is

generated. The link transitions to the Link Delay Unsynchronized state when software appropriately sets its group and link synchronization flags.

- Link Delay Unsynchronized—Contains two separate operations, depending on the state of the group to which the link belongs. If the link enters this state as the result of group startup, it performs the new-group link delay synchronization algorithm. If the link enters this state while the group is already activated per the link addition/slow recovery (LASR) procedure of the IMA standard, it performs the added-link delay synchronization algorithm. As the result of either algorithm, an interrupt is generated to the host when delay synchronization is achieved.
- No Link Defect—Normal receive operation after the link is established and the link-state is appropriately communicated to the far end. If the link is not inhibited at the group or link level, reception of ATM cells occurs. If the link or group is inhibited, non-ICP received cells are replaced with filler cells. Cells received (or their replacements) are written to the link delay compensation buffer. The link transitions out of this state only as the result of an error or a reset by host software.

43.3.3.2 Cell Processing Activation Function

The cell processing task is triggered directly by the cell reception task if a cell is written to a delay compensation buffer. Per the IMA specification, this is allowable under both of the following conditions:

- The IMA receiver is directly built into end equipment that directly terminates the ATM layer (that is, terminates all ATM connections).
- The system can carry only services that either do not require CDV control (some data services) or CDV control is handled in some other way, such as absorbed into a play-out buffer at the ATM layer connection termination.

This processor may qualify as such a system if it terminates all ATM connections that it receives. The buffer descriptors and external memory serve as a play-out buffer. Furthermore, a system that does not terminate cells but instead passes cells port-to-port can also use this mode of operation if either of the following conditions is met:

- All cell streams are switched at the VC level only, and the VC traffic type is supported by this APC. The APC can be programmed to reshape the VC appropriately at the egress port. Therefore, no cell delay variation (CDV) is introduced.
- Some (or all) cell streams are switched at the VP level, but the switched VPs carry only traffic for which cell delay variation (CDV) within the bounds of an IMA round-robin distribution is tolerable. For example, if the IMA group consists of 8 DS1 links, the maximum CDV introduced by this method would be 8 cell times, or approximately 2.2 ms

If the system meets these qualifications, this mode of operation is recommended because it is the simplest and yields overall better system performance. That is, this mode requires less QUICC Engine processing power.

43.3.3.3 Cell Processing Task

The cell processing activation function triggers the cell processing task. This task extracts cells in-order from the delay compensation buffers. These cells are processed per the processor standard ATM operation; that is, they are mapped into ATM channels and processed per the appropriate AAL or OAM function. If

the on-demand cell processing activation function is used and the cell processing task is triggered, it extracts cells in-order from the delay compensation buffers until either no more are available or four cells are extracted. The purpose of limiting the cell processing task to a maximum of four cells is to limit the maximum latency of servicing requests from the external PHYs. On the average, the receive process delivers one cell to the ATM layer per cell reception.

43.4 IMA Programming Model

43.4.1 Data Structure Organization

Figure 43-12 shows the organization of IMA data structures.

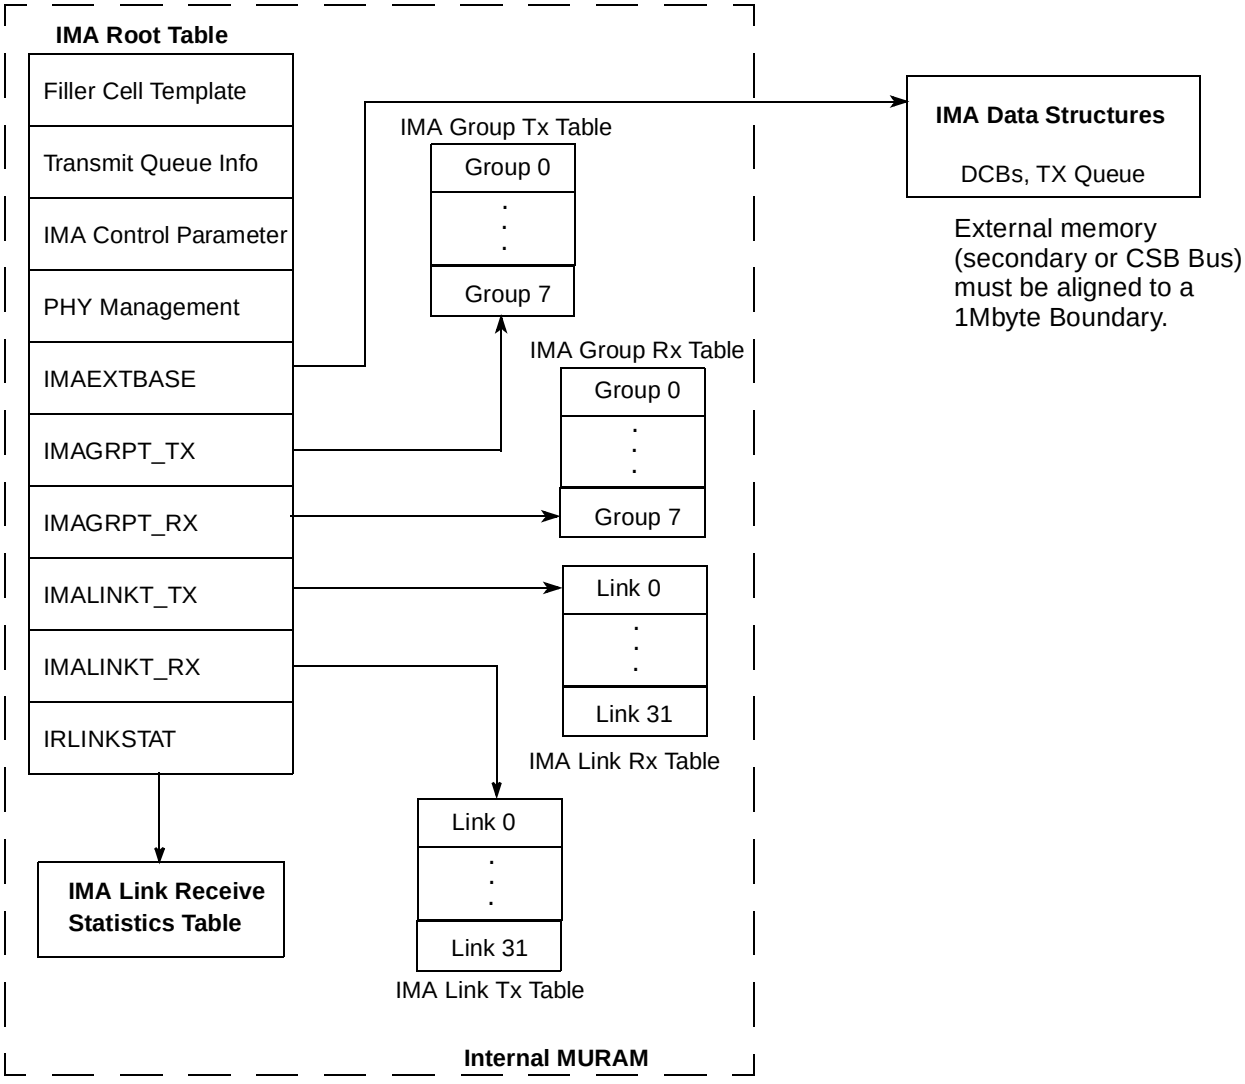

Figure 43-12. IMA Root Table Data Structures

The IMA data structures are organized as follows:

- Parameters at the UCC level determine common ATM parameters and location of the IMA root table.
- IMA root table includes parameters used by all IMA links of this UCC.
- IMA group receive table and IMA group transmit table entries include parameters that define the receive and transmit states and settings of the associated IMA group.
- IMA link receive table and IMA link transmit table entries include parameters that define the receive and transmit states and settings of the associated IMA link

43.4.2 IMA UCC Programming

43.4.2.1 UCC Registers

The UCC protocol-specific mode register (UPSMR) for ATM operation is described in Section 33.6.5.1, "UPDCx in ATM Protocol." Refer to that section for information pertaining to IMA.

For the UPC and therefore for an external TC layer of any PHY programmed in IMA mode (that is, the corresponding bit in IMA PHY is set), the corresponding UTIRRx must be programmed to disable the internal rate for this PHY. ALL IMA PHYs must operate in external rate mode. Refer to Section 33.3.3, "Transmit Internal/External Rate Modes." For Serial ATM based IMA PHYs the UPC must not be used.

43.4.2.2 UCC Parameters

User software must also configure the IMA_Temp parameter in the UCC distributor local parameter table. IMA functionality is enabled through the GMODE register. Refer to Section 32.3.2.5, "Global Mode Entry (GMODE)."

43.4.2.3 IMA-Specific UCC Parameters

The following parameter must be programmed in the UCC parameter RAM page in addition to the standard UCC parameters for ATM.

Table 43-2. UCC Parameter RAM Additions

Offset	Name	Width	Description
0x04	IMAROOT	Hword	Offset of IMA root table in multi-user RAM. The IMAROOT is offset from the UCC Sub-page0 Configuration Table. Must be 128-byte aligned.

43.4.2.4 Differences From CPM-Based IMA Implementation

The following text lists the differences of the IMA implementation for the QUICC Engine block versus the CPM:

- No alignment constraint on IMAROOT ending with 0x80; the IMA root can reside on any 128 byte aligned address.
- TXPHYEN and RXPHYEN bit arrays are removed from the IMA root.
- IMAPHY parameter no longer exists because the UTOPIA address is compressed to the range 0–31 per UCC using tables defined for Rx and Tx.

- Added the serial ATM enable bit to the IMACTL.
- No support for IDCR mode.

43.4.3 IMA Root Table

Table 43-3. IMA Root Table[1]

Offset	Name	Width	Description
-0x04	**IMAFILLERHD**[2]	4 Bytes	Filler cell template. Used by microcode in transmission of filler cells. The cell is formatted as byte-swapped, and additionally the header is bitswapped. [This is due to hardware implementation, and does not imply the order of the transmission of the cell. The transmission of the cell is per the ATM standard.] Content should be: 0xD0000000 (header) 0x6A6A0001 or 0x6A6A0003 (for IMA Version 1.0 or 1.1) 0x6A6A6A6A (padding) 0x6A6A6A6A (padding) 0x6A6A6A6A (padding) 0x6A6A6A6A (padding) 0x6A6A6A6A (padding) 0x6A6A6A6A (padding) 0x6A6A6A6A (padding) 0x6A6A6A6A (padding) 0x6A6A6A6A (padding) 0x6A6A6A6A (padding) 0xC6026A6A or 0xD9026A6A (for IMA Version 1.0 or 1.1)
0x00–0x2F	IMAFILLERPLD	48 Bytes	
0x30	FILLTAG	Byte	Tag indicating that the filler template is a filler cell. Program to zero.
0x31	**TQ_SIZE**	Byte	Transmit queue size. Recommended value is 0x18. Must be a multiple of 4. Refer to Section 43.4.6.1, “Transmit Queues” for more details
0x32	**TQ_TARGET**	Byte	Transmit queue target level. Recommended value is 0x0C. Must be a multiple of 4.
0x33	**TQ_THRESHOLD**	Byte	Transmit queue stuff threshold. Recommended value is 0x0C. Must be a multiple of 4.
0x34	RESERVED	Hword	Reserved.
0x36	**IMACNTL**	Byte	IMA control parameter. Controls functions shared by all IMA groups for this UCC.
0x37	TMP_PCNT	Byte	Microcode managed parameter (pass count).
0x38	**RXPHYEN_TSIZE**	Byte	Receive PHY Enable Table Size. Number of byte entries programmed in the receive table for IMA PHY number selection for IMA links on this UCCs UTOPIA bus. If the table consist of 1 entry program this parameter to 0, if it contains 2 entries program to 1 etc. See Section 43.4.3.2, “Utopia PHY Address Compression” for more details.
0x39	**RXPHYEN_TPTR**	3 Bytes	Receive PHY Enable Table Pointer. Pointer to table in the MURAM containing UTOPIA PHY addresses for the purpose of compression to the range 0-30. See Section 43.4.3.2, “Utopia PHY Address Compression” for more details.
0x3C	**TXPHYEN_TSIZE**	Byte	Transmit PHY Enable Table Size. Number of byte entries programmed in the transmit table for IMA PHY number selection for IMA links on this UCCs UTOPIA bus. If the table consist of 1 entry program this parameter to 0, if it contains 2 entries program to 1 etc. See Section 43.4.3.2, “Utopia PHY Address Compression” for more details.

Table 43-3. IMA Root Table[1] (continued)

Offset	Name	Width	Description
0x3D	**TXPHYEN_TPTR**	3 Bytes	Transmit PHY Enable Table Pointer. Pointer to table in the MURAM containing UTOPIA PHY addresses for the purpose of compression to the range 0-30. See Section 43.4.3.2, "Utopia PHY Address Compression" for more details.
0x40–0x43	—	—	Reserved. Must be programmed to zero during initialization.
0x44	**IMAEXTBASE**	Word	IMA external structure base pointer. Points to region in external memory where external IMA data structures are located. Must be aligned to a 1MB boundary (i.e. program bits 12-31 to zero).
0x48	**IMAGRPT_TX**	Hword	Offset of IMA group transmit table in multi-user RAM (MURAM). Must be 16-byte aligned.
0x4A	**IMAGRPT_RX**	Hword	Offset of IMA group receive table in MURAM. Must be 64-byte aligned.
0x4C	**IMALINKT_TX**	Hword	Offset of IMA link transmit table in MURAM. Must be 32-byte aligned.
0x4E	**IMALINKT_RX**	Hword	Offset of IMA link receive table in MURAM. Must be 32-byte aligned.
0x50	**IRLINKSTAT**	Hword	Offset of the optional IMA link receive statistics table in MURAM. Must be 8-byte aligned.
0x52	TMP_LPTR_RX	Hword	Microcode-managed parameter. Temporary storage of link table pointer.
0x54	TMP_LPTR_TX	Hword	Microcode-managed parameter. Temporary transmit table pointer.
0x56	TMP_GPTR_TX	Hword	Microcode-managed parameter. Temporary transmit group pointer.
0x58	TMP_GPORD_TX	Hword	Microcode-managed parameter. Temporary transmit group order pointer.
0x5A	TMP_GPTR_RX	Hword	Microcode-managed parameter. Temporary receive group pointer.
0X5C	TMP_RTRN_RX	Hword	Microcode-managed parameter. Temporary return pointer.
0x5E	TMP_GPTR2_RX	Hword	Microcode-managed parameter. Temporary receive group pointer 2.
0x60–0x6B	—	—	Reserved. Must be programmed to zero during initialization.
0x6C	**ITPGRPO**	Hword	Required for optional TRL Service Latency enhancement only. IMA Temp Group Order - Points to the base of a 2byte temp pointer storage per group. Software initialized before UCC is enabled. Microcode managed parameter.
0x6E–0x7F	—	—	Reserved. Must be programmed to zero during initialization.

1 **Boldfaced** entries in this table indicate parameters that must be initialized by the user. All other parameters are managed by the microcode and should be initialized to zero unless otherwise stated.

2 IMAFILLERHD is located at the word immediately preceding the 128-byte aligned region defined by IMAROOT. Thus it is located at offset 0x04 from the base o the f IMAROOT table.

43.4.3.1 IMA Control (IMACNTL)

The fields of the IMACNTL are shown in Figure 43-13.

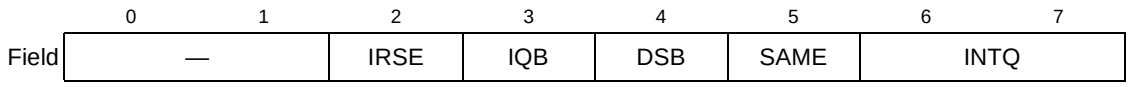

Figure 43-13. IMA Control (IMACNTL)

Table 43-4 describes the IMACNTL bit fields.

Table 43-4. IMACNTL Field Descriptions

Bits	Name	Description
0–1	—	Reserved
2	IRSE	IMA link receive statistics enable. If link receive statistics gathering is disabled, there is no need to initialize IRLINKSTAT or reserve space for the receive statistics table. 0 Link receive statistics gathering is disabled. 1 Link receive statistics gathering is enabled.
3	IQB	Interrupt queue bus. Defines the bus on which the IMA interrupt queue is located. 0 On the CSB bus. 1 On the secondary bus.
4	DSB	Data structure bus. Defines the bus on which the IMA external structure memory area is located. 0 On the CSB bus. 1 On the secondary bus.
5	SAME	Serial ATM Enable. 0 The TC layer is not SAM based 1 The TC layer is SAM based, that is, an MTC.
6–7	INTQ	Number of the ATM interrupt queue dedicated to IMA events. Note that these events do not include ICP cell reception events; the handling of ICP cell reception events is programmed in the RCT of the ICP channel defined by RICPCH.

43.4.3.2 Utopia PHY Address Compression

In IMA mode, the maximum number of IMA links supported per UCC is 31. The PHY address used by the IMA links must be in the range 0-30. As the UTOPIA address for a PHY is in the range 0-127 the IMA PHY address therefore must be compressed to the range 0-30. Figure 43-14 depicts the compression scheme.

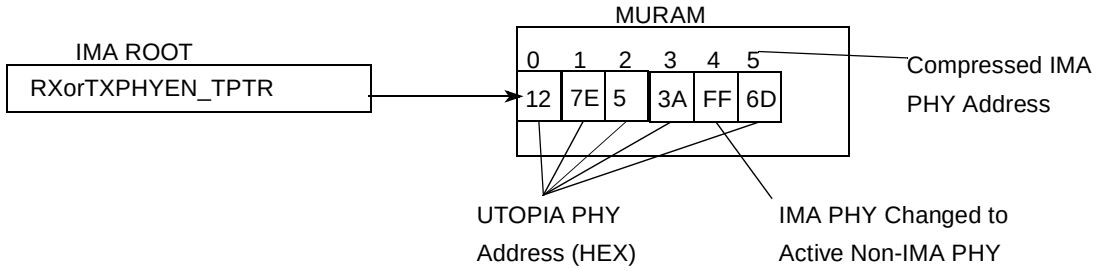

Figure 43-14. Utopia PHY Address Compression Tables

Each entry in the UTOPIA address compression table is 1 byte. The contents of a table entry is the UTOPIA PHY address for links that are IMA based on this UCC. The byte offset of a matched UTOPIA address from the table base (defined by RXPHYEN_TPTR or TXPHYEN_TPTR) is the IMA PHY address. For example in Figure 43-14 UTOPIA PHY address 0x7E is mapped to IMA link/PHY 0x1. Therefore, PHY address 0x7E uses link table 1 to define its IMA structures. The compressed address values must be used in the transmit and receive group order tables and not the UTOPIA PHY address.

There are two tables, one each for transmit and receive, but if the same UTOPIA PHY addresses are used on transmit and receive for IMA links, one compression table can be used, with RXPHYEN_TPTR and TXPHYEN_TPTR programmed to the same value.

If a link in an IMA group is then removed and therefore disabled at the TC level, the compression table must be updated before the link can become active again as a non-IMA PHY. Before re-enablement, the old link offset in the compression table must be programmed to a value that does not yield a match in the table. The suggested value is 0xFF. The link cannot be removed from the compression table by resizing because other links may still be in the IMA group and their offset within the table cannot be changed. The offset cannot be changed because it defines the link IMA PHY number, which is subsequently used to access the corresponding link table. If the link is added again as an IMA PHY, no compression table updates are required.

When links are added to an existing group, the table can be resized on the fly by first adding the new UTOPIA PHY address to the end of the compression table and then changing the xPHEN_TSIZE to reflect the new table size. Any already existing PHYs in the compression table must not have their relative offsets from the base of the compression table changed. Any added PHY must be placed either at the first entry at the end of the table or an entry beyond the first free entry. For example, consider an IMA group consisting of two links mapped as follows:

IMA PHY 0 = UTOPIA PHY ADDRESS 0x66

IMA PHY 1 = UTOPIA PHY ADDRESS 0x5A

If another PHY is to be added to the group (for example, 0x3F) and this PHY is required to be IMA PHY 3, the following table should be constructed:

0x66 | 0x5A | 0xFF | 0x3F

In the example, the xPHEN_TSIZE should be programmed to 3 (after the compression table is updated) to reflect a table size of four entries. The unused entry corresponding to IMA PHY 2 should be programmed to a value of 0xFF to pad the table so the UTOPIA PHY 0x3F is IMA PHY 3 after compression. At a later point, another link that uses IMA PHY 2 can be added to the group. In this case after the offset for IMA PHY 2 is overwritten in the compression table, there is no need to update the corresponding xPHEN_TSIZE parameter.

43.4.4 IMA Group Tables

The IMA group tables consist of multiple IMA group structures indexed by group number, which ranges from 0–7. The transmit and receive parameters are located in separate tables. The IMA group transmit table entries are 16 bytes long. The IMA group receive table entries are 64 bytes long. However, there is no need to reserve memory space in MURAM for 8 receive IMA groups if less than 8 IMA groups are required. To conserve memory space used by these tables, it is best to add groups starting from group zero. Note that group number is independent of the assignment of IMA ID.

43.4.4.1 IMA Group Transmit Table Entry

Table 43-5. IMA Group Transmit Table Entry [1]

Offset	Name	Width	Description
0x00	**IGTCNTL**	Byte	IMA group transmit control parameters.
0x01	IGTSTATE	Byte	IMA group transmit state. Microcode-managed parameter. Must be initialized to zero at group startup.
0x02	**TGRPORDER**	Hword	Offset of transmit group order table in MURAM. Can be changed on the fly.
0x04	**TVPHYNUM**	Byte	Transmit Virtual PHY number. Maps this IMA transmit group to a virtual PHY number for the purpose of selecting an ATM pace controller (APC) table number for this IMA group. Note that this parameter must be unique; it must not conflict with the PHY number of any non-IMA PHYs or with the TVPHYNUM of any other IMA group. If there are any PHY numbers which will never be used in a system (i.e. the actual PHY with the address does not exist), then TVPHYNUM should be selected from one of these PHYs. If no such PHY numbers are available (i.e. the multi-PHY interface consists of the full 31 PHYs), then select TVPHYNUM from one of the PHY numbers of the PHYs within this IMA group.
0x05	TIFSN	Byte	Transmit IMA Frame Sequence Number (IFSN). Microcode-managed parameter. Increments each time an IMA frame is transmitted, cycling from 0 through 255. Should be initialized to zero at group startup.
0x06	TMCTR	Byte	Transmit IMA M counter. Microcode-managed parameter. Tracks IMA frame boundaries. Increments once per round-robin distribution of cells to the transmit queues, cycling from 0 through M. Initialize to zero at group startup.
0x07	TRLSTFCNT	Byte	TRL stuff frame counter. Microcode-managed parameter. Controls required stuffing on the TRL. Decrements each time an ICP cell is sent on the TRL, cycling from TRLSTFN through 0. A TRL stuff event occurs when it reaches zero. Initialize to the value of TRLSTFN at group startup.
0x08	**TICPPTR**	Hword	Offset of transmit ICP cell payload template area in MURAM. Must be 64-byte aligned. This parameter and the associated template area may only be changed when IGCNTL[ICPC]=IGTSTATE[ICPCA]. After changing TICPPTR, IGCNTL[ICPC] must be toggled.
0x0A	**TM**	Byte	Transmit IMA frame size. Program to 31, 63, 127, or 255 for frame sizes (M) of 32, 64, 128, or 256, respectively.
0x0B	**TRLSTFN**	Byte	TRL stuff frame number. Defines the number of IMA frames sent between TRL stuff events. For ITC operation IGTCNT[CTC] = 0, program TRLSTFN = 2048/M. For CTC operation IGTCNT[CTC] = 1, program TRLSTFN = (2048/M) – 1. Refer to Section 43.4.4.1.1, “IMA Group Transmit Control (IGTCNTL).”
0x0C	**TNUMLINKS**	Byte	Number of transmit links in the IMA group that are in the active state (ILTCNTL[TXSC]=01). Used by the APC to scale the rescheduling parameters appropriately when rescheduling channels.
0x0D	RTSTPCNT	Byte	Real time-stamp subcounter. Microcode-managed parameter, used by the APC. Initialize to zero at group startup.

Table 43-5. IMA Group Transmit Table Entry (continued)[1]

Offset	Name	Width	Description
0x0E	**IASNCCtr**	Byte	Required for optional TRL Service Latency enhancement only. IMA APC Scheduled Number of Cells Counter - Number of cells passed to the groups links upon request. Initialize to IASNC.
0x0F	**IASNC**	Byte	Required for optional TRL Service Latency enhancement only. IMA APC Scheduled Number of Cells - reset for IASNCtr. Number of cells passed to the groups links upon request. Recommended value is 1.

1 **Boldfaced** entries must be initialized by the user. All other parameters initialize to zero.

43.4.4.1.1 IMA Group Transmit Control (IGTCNTL)

The fields of the IGTCNTL register are shown in Figure 43-15.

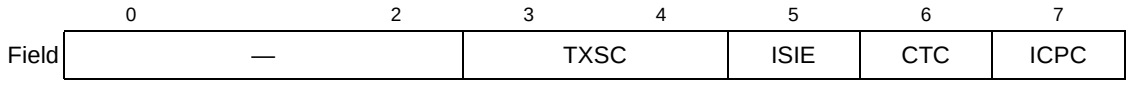

Figure 43-15. IMA Group Transmit Control (IGTCNTL)

Table 43-6 describes the IGTCNTL bit fields.

Table 43-6. IGTCNTL Field Descriptions

Bits	Name	Description
0–2	—	Reserved
3–4	TXSC	Transmit status/control. Sets the transmit mode of the IMA group. 00 Filler mode. The IMA group transmits only ICP and filler cells, no data cells. 01 Active mode. The IMA group is capable of sending data cells. 1X Reserved.
5	ISIE	IMA Scheduler Split Iterations Enable 0 APC is not split, TRL completes round robin distribution of cells. 1 APC split, both TRL and non-TRL requests distribute cells to the transmit queues. Required for optional TRL Service Latency. This option is valid for a 1 IMA Tx group configuration per UCC. If more than 1 IMA group is used per UCC then clear ISIE.
6	CTC[1]	Transmit clock mode for this IMA group. 0 Independent transmit clock (ITC) mode. 1 Common transmit clock (CTC) mode.
7	ICPC	ICP change flag. Maintains at least the minimum 2-frame spacing of ICP cell control/status changes. Initialize to zero at group startup. Must be toggled by software whenever TICPPTR is changed. After two subsequent IMA frames are transmitted, the IGTSTATE[ICPCA] field will be changed to match IGTCNTL[ICPC]. When IGTCNTL[ICPC] equals IGTSTATE[ICPCA], changes to TICPPTR are allowed.

[1]Ensure transmit clock mode is not changed during IMA group startup to avoid erratic behavior.

43.4.4.1.2 IMA Group Transmit State (IGTSTATE)

The fields of the IGTSTATE register are shown in Figure 43-16.

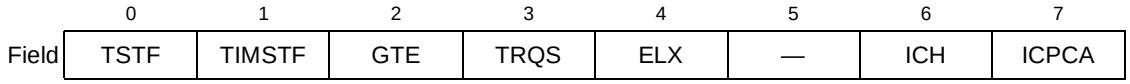

Figure 43-16. IMA Group Transmit State (IGTSTATE)

Table 43-7 describes the IGTSTATE bit fields.

Table 43-7. IGTSTATE Field Descriptions

Bits	Name	Description
0	TSTF	TRL stuff flag. Microcode-managed parameter. Indicates that the next ICP cell on the TRL will be part of a stuff event. Initialize to zero at group startup.
1	TIMSTF	TRL imminent stuff flag. Microcode-managed parameter. Indicates that an upcoming stuff event will be signaled in the next ICP of the TRL (via LSI=001). Initialize to zero at group startup.
2	GTE	Go to end flag - TRL has requested 2 time before round robin distribution has completed or link will underrun and is still due cell from round robin distribution. Microcode managed parameter initialize to 0. Used for optional TRL Service Latency enhancement only.
3	TRQS	TRL Request - TRL has requested therefore 1 round robin distribution of cells is yet to be completed. Microcode managed parameter initialize to 0. Used for optional TRL Service Latency enhancement only.
4	ELX	Early exit flag. Microcode-managed parameter. Initialize to zero at group startup.
5	—	Reserved
6	ICH	ICP change holdoff. Microcode-managed parameter. Initialize to zero at group startup.
7	ICPCA	ICP change allowed flag. Microcode-managed parameter. See description of IGTCNTL[ICPC].

43.4.4.1.3 Transmit Group Order Table

The transmit group order table defines the order of the links in the round-robin distribution of cells to the links of the IMA group. The table consists of an array of bytes ordered from first link to last link, with each byte providing the PHY address of its associated link. The end of the table is indicated by an entry programmed to 0x1F.

This table alone defines the order of cell distribution. It is the responsibility of software to program the LID of the links in the IMA Link Table entries, and to program the group order table such that its order corresponds to the order of increasing LIDs within the group.

The format of a transmit group order table entry is shown in Figure 43-17.

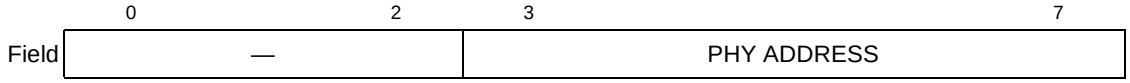

Figure 43-17. Transmit Group Order Table Entry

Table 43-8 describes the format of a transmit group order table entry.

Table 43-8. Transmit Group Order Table Entry Field Descriptions

Bits	Name	Description
0–2	—	Reserved
3–7	PHY ADDRESS	PHY address (Up to 31 PHYs[0–30]) of the link transmitting in this position in the round-robin. A value of 0x1F in this field indicates the end of the group order table. The value programmed must be the compressed value after Utopia Address Compression see Section 43.4.3.2, "Utopia PHY Address Compression."

43.4.4.1.4 ICP Cell Templates

The ICP cell templates are areas of memory provided by software to the microcode for construction of ICP cells for transmission. Software prepares the fields which are common to the group (i.e. class B, C, D, and E parameters). The other (class A) parameters will be written to the appropriate fields by the microcode. The template is 64 bytes long and must be aligned on a 64-byte boundary.

Table 43-9 describes the format of a group order table entry. The ICP cell template is formatted as byte-swapped, and additionally the ICP cell header is bitswapped. [This is due to hardware implementation, and does not imply the order of transmission of the cell. The transmission of the cell is per the ATM standard.] Reflecting this byte-swap, the offset column gives the offset in MURAM from the ICP template base.

Table 43-9. ICP Cell Template [1]

Offset	Name	Width	Description
0x00	**ICP CELL HEADER**	Word	ICP cell header. Program to 0xD0000000.
0x04	ICP Cell Offset	Byte	Microcode-managed area. Microcode will program this field dynamically.
0x05	IMA Frame Sequence Number	Byte	Microcode-managed area. Microcode will program this field dynamically.
0x06	Cell ID and Link ID	Byte	Microcode-managed area. Microcode will program this field dynamically.
0x07	**OAM LABEL**	Byte	IMA Version value. 1 IMA Version 1.0 3 IMA Version 1.1

Table 43-9. ICP Cell Template (continued)[1]

Offset	Name	Width	Description
0x08	**GROUP STATUS AND CONTROL**	Byte	Bits 7-4: Group State 0000 = Start-up, 0001 = Start-up-Ack, 0010 = Config-Aborted - Unsupported M, 0011 = Config-Aborted - Incompatible Group Symmetry, 0100 = Config-Aborted - Unsupported IMA Version, 0101, 0110 = Reserved for other Config-Aborted reasons in a future version of the IMA specification, 0111 = Config-Aborted - Other reasons, 1000 = Insufficient-Links, 1001 = Blocked, 1010 = Operational, Others: Reserved for later use in a future version of the IMA specification. Bits 3-2: Group Symmetry Mode 00 = Symmetrical configuration and operation, 01 = Symmetrical configuration and asymmetrical operation (optional), 10 = Asymmetrical configuration and asymmetrical operation (optional), 11 = Reserved Bits 1-0: IMA Frame Length (00: M=32, 01: M=64, 10: M=128, 11: M=256)
0x09	**IMA ID**	Byte	Bits 7-0: IMA ID
0x0A	**STATUS AND CONTROL CHANGE INDICATION (SCCI)**	Byte	Software must increment this field in the new ICP template whenever a new ICP template is created.
0x0B	Link Stuff Indication	Byte	Microcode-managed area. Microcode will program this field dynamically.
0x0C	**RX TEST PATTERN**	Byte	Bits 7-0: Rx Test Pattern (value from 0 to 255)
0x0D	**TX TEST PATTERN**	Byte	Bits 7-0: Tx Test Pattern (value from 0 to 255)
0x0E	**TX TEST CONTROL**	Byte	Bits 7-6: Unused and set to 0 Bit 5: Test Link Command (0: inactive, I: active) Bits 4-0: Tx LID of test link (0 to 31)
0x0F	**TRANSMIT TIMING INFORMATION**	Byte	Bits 7-6: Unused and set to 0 Bit 5: Transmit Clock Mode: (0: ITC mode, 1: CTC mode) Bits 4-0: Tx LID of the timing reference (0 to 31)
0x10	**LINK 3 INFO**	Byte	Status and control of link with LID = 3
0x11	**LINK 2 INFO**	Byte	Status and control of link with LID = 2
0x12	**LINK 1 INFO**	Byte	Status and control of link with LID = 1
0x13	**LINK 0 INFO**	Byte	Status and control of link with LID = 0
0x14	**LINK 7 INFO**	Byte	Status and control of link with LID = 7
0x15	**LINK 6 INFO**	Byte	Status and control of link with LID = 6
0x16	**LINK 5 INFO**	Byte	Status and control of link with LID = 5
0x17	**LINK 4 INFO**	Byte	Status and control of link with LID = 4
0x18	**LINK 11 INFO**	Byte	Status and control of link with LID = 11
0x19	**LINK 10 INFO**	Byte	Status and control of link with LID = 10

Table 43-9. ICP Cell Template (continued)[1]

Offset	Name	Width	Description
0x1A	**LINK 9 INFO**	Byte	Status and control of link with LID = 9
0x1B	**LINK 8 INFO**	Byte	Status and control of link with LID = 8
0x1C	**LINK 15 INFO**	Byte	Status and control of link with LID = 15
0x1D	**LINK 14 INFO**	Byte	Status and control of link with LID = 14
0x1E	**LINK 13 INFO**	Byte	Status and control of link with LID = 13
0x1F	**LINK 12 INFO**	Byte	Status and control of link with LID = 12
0x20	**LINK 19 INFO**	Byte	Status and control of link with LID = 19
0x21	**LINK 18 INFO**	Byte	Status and control of link with LID = 18
0x22	**LINK 17 INFO**	Byte	Status and control of link with LID = 17
0x23	**LINK 16 INFO**	Byte	Status and control of link with LID = 16
0x24	**LINK 23 INFO**	Byte	Status and control of link with LID = 23
0x25	**LINK 22 INFO**	Byte	Status and control of link with LID = 22
0x26	**LINK 21 INFO**	Byte	Status and control of link with LID = 21
0x27	**LINK 20 INFO**	Byte	Status and control of link with LID = 20
0x28	**LINK 27 INFO**	Byte	Status and control of link with LID = 27
0x29	**LINK 26 INFO**	Byte	Status and control of link with LID = 26
0x2A	**LINK 25 INFO**	Byte	Status and control of link with LID = 25
0x2B	**LINK 24 INFO**	Byte	Status and control of link with LID = 24
0x2C	**LINK 31 INFO**	Byte	Program to 0x00.
0x2D	**LINK 30 INFO**	Byte	Status and control of link with LID = 30
0x2E	**LINK 29 INFO**	Byte	Status and control of link with LID = 29
0x2F	**LINK 28 INFO**	Byte	Status and control of link with LID = 28
0x30	CRC10	Hword	Microcode-managed area. Microcode will program this field dynamically.
0x32	**END-TO-END CHANNEL**	Byte	Program to any value desired for end-to-end implementation-dependent signaling, or program to 0x00 if unused.
0x33	**UNUSED**	Byte	Program to 0x6A.
0x34	**TAG**	Byte	Internally-used tag value indicating that this is an ICP cell. Program to 0x80.
0x35	**Reserved**	11 Bytes	Initialize to 0.

[1] **Boldfaced** entries in the above table indicate parameters which must be initialized by the user. All other parameters are managed by the microcode and should be initialized to zero unless otherwise stated.

43.4.4.2 IMA Group Receive Table Entry

Table 43-10. IMA Group Receive Table Entry [1]

Offset	Name	Width	Description
0x00	**IGRCNTL**	Byte	IMA group receive control parameters.
0x01	IGRSTATE	Byte	IMA group receive state. Microcode-managed parameter. Initialize to zero at group startup.
0x02	**RIMAID**	Byte	Receive IMA ID. Program to the validated receive IMA ID value.
0x03	**IMAVER**	Byte	IMA version. Program to the validated IMA version value. 1 IMA Version 1.0 3 IMA Version 1.1
0x04	**RM**	Byte	Receive IMA frame size. Program to 31, 63, 127, or 255 for frame sizes of 32, 64, 128, or 256, respectively.
0x05	**RNUMLINKS**	Byte	Number of receive links in the IMA group that are in the active state (ILRCNTL[RXSC]=01.
0x06	DCB_RM	Byte	Current cell (x out of RM cells in a Frame) being processed by the reconstruction routine. Microcode-managed parameter. Initialize to zero at group startup.
0x07	RSCCI	Byte	Receive IMA SCCI field. Microcode-managed parameter. Holds the SCCI value of the last ICP cell received by this group.
0x08	**DCBLNK**	Hword	Pointer to link entry in group order table currently in use. Microcode-managed parameter. Initialize to value of RGRPORDER0 at group startup.
0x0A	DCBX	Hword	Delay-compensation buffer extraction pointer. Microcode-managed parameter. Initialize to zero at group startup.
0x0C	STALL_COUNT	Byte	Number of On-demand requests made for which there were no cells available in a link's DCB. Microcode managed parameter. Initialize to zero at group startup.
0x0D	REF_IFSN	Byte	Identifies the IFSN of the frame being processed by the "reconstruction" routine. Microcode managed parameter.
0x0E	GFP	Hword	Pointer to the start of the current frame being processed by the "reconstruction" routine. Microcode managed parameter. Initialize to zero at group startup.
0x10	**RGRPORDER0**	Hword	Offset of receive group order table 0 in MURAM.
0x12	**RGRPORDER1**	Hword	Offset of receive group order table 1 in MURAM.
0x14	**ALPHABETA**	Byte	Alpha and beta parameters for IMA frame synchronization mechanism (IFSM). Bits 0-3: Alpha. Allowable range is 1-2; typical value is 2. Bits 4-7: Beta. Allowable range is 1-5; typical value is 2.
0x15	**GAMMA**	Byte	Gamma parameter for IMA frame synchronization mechanism (IFSM). Allowable range is 1-5; typical value is 1.
0x16–0x17	—	Hword	Reserved. Must be initialized to zero at group startup.
0x18	**REF_LINK**	Word	Bit array identifying which of the links (i.e., PHY) in this group are enabled. Bit 0 corresponds to PHY 0, bit 30 corresponds to PHY 30. Software must set the corresponding bits to 1 so that the delay compensation process for the link(s) is started.

Table 43-10. IMA Group Receive Table Entry (continued)[1]

Offset	Name	Width	Description
0x1C	LINK_ICP	Word	Bit array identifying which of the links in this group has received an ICP cell. A “1” in the corresponding link’s bit position indicates that an ICP cell has been received. Microcode-managed parameter. Initialize to zero at group startup.
0x20	LINK_DCB	Word	Bit array identifying which of the links in this group has started storing cells to its corresponding DCB. A “1” in the corresponding link’s bit position indicates that cells have been stored in the DCB. Microcode-managed parameter. Initialize to zero at group startup.
0x24	LINK_LD	Word	Bit array identifying which of the “added” links in this group has a Longer propagation Delay (LD) than any of the existing links. A “1” in the corresponding link’s bit position indicates that it has a longer propagation delay. Microcode-managed parameter. Initialize to zero at group startup.
0x28	—	Byte	Reserved. Must be initialized to zero at group startup.
0x29	**RVPHYNUM**	Byte	Receive Virtual PHY number. Maps this IMA receive group to a virtual PHY number for the purpose of address mapping of received cells. Note that this parameter must be unique; it must not conflict with the PHY number of any non-IMA PHYs or with the RVPHYNUM of any other IMA group. If there are any PHY numbers which will never be used in a system (i.e. the actual PHY with the address does not exist), then RVPHYNUM should be selected from one of these PHYs. If no such PHY numbers are available (i.e. the multi-PHY interface consists of the full 31 PHYs), then select RVPHYNUM from one of the PHY numbers of the PHYs within this IMA group.
0x2A	**STALL_THR**	Byte	Stall threshold. Used to detect stalled links when performing round-robin cell extraction from the delay compensation buffers (Dcbz). This is the number of cells which may be received without advancing the cell extraction pointer. The value is application-dependent and must be tuned by the user to the “expected worst case.” Its value depends on the depth of queues and FIFOs in the complete transmit/receive path, and the ‘burstiness’ of the behavior of the FIFOs. Assuming very bursty FIFOs, it is approximately: STALL_THR = 2 x RNUMLINKS x (3 + RX_FIFO) where: a) RNUMLINKS is the number of links in the receive group order structure (regardless of link status). b) RX_FIFO is the depth of the receive FIFOs of the TC layer. c) 3 is the rounded value of the allowed transmit skew between links of a group (2.5, per the IMA standard). An optimal value for STALL_THR will be great enough to produce no link stall events in normal operation, but low enough to detect a failed link as quickly as possible.
0x2B	**IRGFS**	Byte	IMA Receive Group Frame Size Bits 0-5: Reserved Bits 6-7 - GSC_M: Value of received ICP cell Group Status Contl field (Bits 1:0) which determine the IMA frame size. This field must be programmed before links in the group are assigned
0x2C	—	Word	Reserved. Must be initialized to zero at group startups.

Table 43-10. IMA Group Receive Table Entry (continued)[1]

Offset	Name	Width	Description
0x30	LINK_DCBO	Word	Link DCB overflow interrupt indication. Bit array identifying which links have issued a link DCB overflow (DCBO) interrupt. This parameter ensures that only one DCBO interrupt is generated per event. Microcode managed parameter. Initialize to zero at group startup.
0x34–0x3F	—	3 Words	Reserved. Must be initialized to zero at group startups.

1 **Boldfaced** entries indicate parameters that must be initialized by the user. All other parameters are managed by the microcode and should be initialized to zero unless otherwise stated.

43.4.4.2.1 IMA Group Receive Control (IGRCNTL)

The fields of the IGRCNTL register are shown in Figure 43-18.

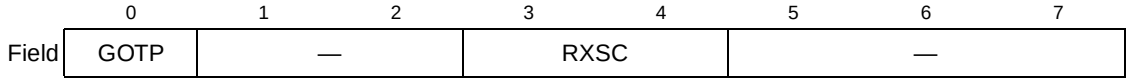

Figure 43-18. IMA Group Receive Control (IGRCNTL)

Table 43-11 describes the IGRCNTL bit fields.

Table 43-11. IGRCNTL Field Descriptions

Bits	Name	Description
0	GOTP	Group order table pointer. Defines which group order table pointer (RGRPORDER0 or RGRPORDER1) will be used for the cell extraction round-robin. Initialize to zero at group startup, i.e., when programming RGRPORDER0 table, which must be used for the GDS process.
1–2	—	Reserved, initialize to zero.
3–4	RXSC	Receive status/control. Sets the receive mode of the IMA group. 00 Filler mode. The IMA group processes only ICP cells. Data cells are replaced with filler cells. 01 Active mode. The IMA group is capable of receiving data cells. 1X Reserved. Defaults to Filler Mode.
5–7	—	Reserved, initialize to zero.

43.4.4.2.2 IMA Group Receive State (IGRSTATE)

The fields of the IGRSTATE register are shown in Figure 43-19.

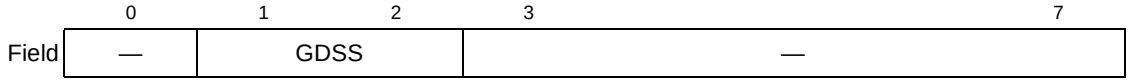

Figure 43-19. IMA Group Receive State (IGRSTATE)

Table 43-12 describes the IGRSTATE bit fields.

Table 43-12. IGRSTATE Field Descriptions

Bits	Name	Description
0	—	Reserved, initialize to zero.
1–2	GDSS	Group delay synchronization state. Initialize to zero at group startup. Must be changed by software to 01 after sufficient links have achieved frame synchronization. Subsequently managed by microcode. 00 Group delay synchronization process inhibited. 01 Group delay synchronization process enabled. 10 Group delay synchronization process in progress. 11 Group delay synchronized. Refer to Section 43.5.3.10, “Receive Event Response Procedures.”
3–7	—	Reserved, initialize to zero.

43.4.4.2.3 IMA Receive Group Frame Size

The fields of the IRGFS register are shown in Figure 43-20.

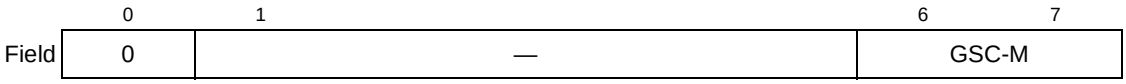

Figure 43-20. IMA Receive Group Frame Size (IGRSTATE)

Table 43-13 describes the IRGFS bit fields.

Table 43-13. IRGFS Field Descriptions

Bits	Name	Description
0	0	Reserved, initialize to zero.
1–5	—	Reserved, initialize to zero.
6–7	GSC-M	IMA Receive Group Frame Size Bits 0-5: Reserved Bits 6-7 - GSC_M: Value of received ICP cell Group Status Contl field (Bits 1:0) which determine the IMA frame size. This field must be programmed before links in the group are assigned

43.4.4.2.4 Receive Group Order Tables

The receive group order tables define the order of the links in the round-robin extraction of cells to the links of the IMA group. The table consists of an array of bytes ordered from first link to last link, with each byte providing the PHY address of its associated link. The end of the table is indicated by an entry programmed to 0x1F.

Two group order tables are used in order to allow for on-the-fly changes (i.e. to add or remove links), while making certain that the changes only occur at the end of a round-robin cycle. IGRCNTL[GOTP] indicates which group order table pointer (and therefore, group table) is currently in use. Changes should be made to the group order table not in use, and then IGRCNTL[GOTP] should be toggled. When the current round-robin cell extraction process completes, the next process will use the new table.

This table alone defines the order of cell extraction from the delay compensation buffers. It is the responsibility of software to read the LIDs of the links in the group from the received ICP cells during group startup, and to program the group order table such that its order corresponds to the order of increasing LIDs within the group.

The format of a receive group order table entry is shown in Figure 43-21.

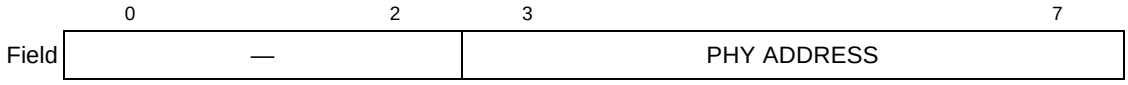

Figure 43-21. Receive Group Order Table Entry

Table 43-14 describes the format of a receive group order table entry.

Table 43-14. Receive Group Order Table Entry Field Descriptions

Bits	Name	Description
0–2	—	Reserved, initialize to zero.
3–7	PHY ADDRESS	PHY address (up to 31 PHYs[0–30]) of the link transmitting in this position in the round-robin. A value of 0x1F in this field indicates the end of the group order table. The value programmed must be the compressed value after Utopia Address Compression see Section 43.4.3.2, “Utopia PHY Address Compression.”

43.4.5 IMA Link Tables

The IMA link tables consist of multiple IMA group structures indexed by the PHY address of their corresponding PHYs. The transmit and receive parameters are located in separate tables. The IMA group transmit and receive table entries are each 32 bytes long. To conserve memory space consumed by these tables, it is best to group the addresses of the PHYs that are assigned as IMA. For example, if out of eight total links only four are IMA, then optimally these would be links 0–3.

43.4.5.1 IMA Link Transmit Table Entry

Table 43-15. IMA Link Transmit Table Entry [1]

Offset	Name	Width	Description
0x00	**ILTCNTL**	Byte	IMA link transmit control parameters.
0x01	ILTSTATE	Byte	IMA link transmit state. Microcode-managed parameter. Initialize to zero at link startup.
0x02	**LICPOS**	Byte	Link ICP offset. Determines the position of the ICP cell within the IMA frame. Program in the range 0 to M-1. See the IMA specification for recommended methods for programming this field.
0x03	**ILID**	Byte	IMA link ID. Formatted per the Cell ID and Link ID field of an ICP cell. Bit 0: 1 (indicating ICP cell) Bits 1-2: Not Used, set to zero Bits 3-7: Program to software-assigned LID. [Note: This value is only used by microcode to format ICP cells for this link, it is not used to determine round-robin transmission order. That function is performed by the group order table.]

Table 43-15. IMA Link Transmit Table Entry (continued)[1]

Offset	Name	Width	Description
0x04	ITSEC	Word	IMA transmit stuff event counter. While ILTCNTL[SES]=0, increments each time a stuff event is performed on this link. Initialize to zero at link startup.
0x08	**ITQSP**	Hword	IMA link transmit queue start pointer. This parameter forms bits 12-27 of the pointer; bits 0-11 are from IMAEXTBASE, and bits 28-31 are zero. Refer to Section 43.4.6.1, “Transmit Queues.”
0x0A	**ITQEP**	Hword	IMA link transmit queue end pointer. This parameter forms bits 12-27 of the pointer; bits 0-11 are from IMAEXTBASE, and bits 28-31 are zero. Points to the last cell in the transmit queue. Program this parameter to ITQSP+TQ_SIZE-4. Refer to Section 43.4.6.1, “Transmit Queues.”
0x0C	**ITQFP**	Hword	IMA link transmit queue fill pointer. This parameter forms bits 12-27 of the pointer; bits 0-11 are from IMAEXTBASE, and bits 28-31 are zero. Initialize this to the value of ITQSP. Refer to Section 43.4.6.1, “Transmit Queues.”
0x0E	**ITQXP**	Hword	IMA link transmit queue extract pointer. This parameter forms bits 12-27 of the pointer; bits 0-11 are from IMAEXTBASE, and bits 28-31 are zero. Initialize this to the value of ITQSP. Refer to Section 43.4.6.1, “Transmit Queues.”
0x10	**ITINTMSK**	Byte	IMA transmit interrupt mask. Has the same format as the upper byte of the IMA interrupt queue entry. Setting a bit enables the associated interrupt; clearing a bit masks it. For group-related events, only the mask register for the TRL is referenced.
0x11	ITINTSTAT	Byte	IMA transmit interrupt status. Indicates the status of transmit interrupt events.
0x12	LSHC	Byte	Stuff holdoff counter. Maintains the minimum five-frame spacing between stuff events for non-TRL links. Must be initialized to zero. Set to 4 by the microcode after a stuff event, and decrements after each ICP cell is sent (saturating at zero). Signaling of ‘imminent stuff’ (and subsequent stuff events) will not occur while this counter is non-zero.

[1] **Boldfaced** entries indicate parameters that must be initialized by the user. All other parameters are managed by the microcode and should be initialized to zero unless otherwise stated.

43.4.5.1.1 IMA Link Transmit Control (ILTCNTL)

The fields of the ILTCNTL register are shown in Figure 43-22.

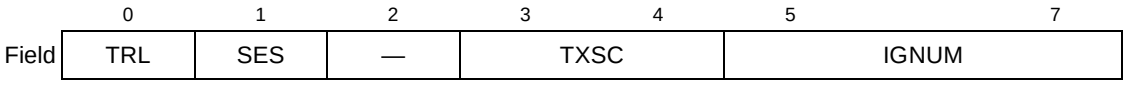

Figure 43-22. IMA Link Transmit Control (ILTCNTL)

Table 43-16 describes the ILTCNTL bit fields.

Table 43-16. ILTCNTL Field Descriptions

Bits	Name	Description
0	TRL	Defines this link as the timing reference link (TRL) of the group. 0 This link is not the TRL. 1 This link is the TRL. Note: One and only one link of the group must be programmed as the TRL. If zero or more than one links are defined as TRL, erratic operation will occur.
1	SES	Severely errorred seconds. Set by software when a severely errorred second indication is detected. When set, causes the transmit stuff event counter to stop counting.
2	—	Reserved, initialize to zero.
3–4	TXSC	Transmit status/control. Sets the transmit mode of the IMA link. 00 Filler mode. The IMA link transmits only ICP and filler cells, no data cells. 01 Active mode. The IMA link is capable of sending data cells. 1X Reserved.
5–7	IGNUM	Determines to which IMA group this link belongs. Contains the number of the link's associated IMA Group Table entry. Note: This value need not be the same as the group's IMA ID; the IMA ID is programmed separately in the group's ICP cell template.

43.4.5.1.2 IMA Link Transmit State (ILTSTATE)

The fields of the ILTSTATE register are shown in Figure 43-23

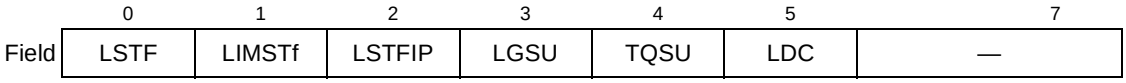

Figure 43-23. IMA Link Transmit State (ILTSTATE)

Table 43-17 describes the ILTSTATE bit fields.

Table 43-17. ILTSTATE Field Descriptions

Bits	Name	Description
0	LSTF	Link stuff flag. Microcode-managed parameter. Indicates that the next ICP cell on this link will be part of a stuff event. Initialize to zero at link startup.
1	LIMSTF	Link imminent stuff flag. Microcode-managed parameter. Indicates that an upcoming stuff event will be signaled in the next ICP of this link (via LSI=001). Initialize to zero at link startup.
2	LSTFIP	Link stuff-in-progress flag. Microcode-managed parameter. Indicates that the next cell on this link will be the second cell of a stuff event. Initialize to zero at link startup.
3	LGSU	Link/group startup flag. Microcode-managed parameter. Will be set by the microcode after the link's transmit queue has reached target average depth of 3 cells. While this bit is cleared, the link will transmit only filler cells. Initialize to zero at link startup.
4	TQSU	Transmit queue startup flag. Microcode-managed parameter. Will be set by the microcode after the first cell has been sent to the transmit queue. Initialize to zero at link startup.

Table 43-17. ILTSTATE Field Descriptions (continued)

Bits	Name	Description
5	LDC	Link Due Cell - Link is due cell from round robin distribution. Microcode managed parameter initialize to 0. Used for optional TRL Service Latency enhancement only.
6–7	—	Reserved, initialize to zero.

43.4.5.1.3 IMA Transmit Interrupt Status (ITINTSTAT)

The fields of the ITINTSTAT register are shown in Figure 43-24.

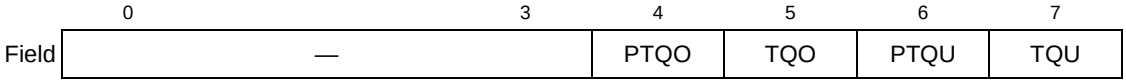

Figure 43-24. IMA Transmit Interrupt Status (ITINTSTAT)

Table 43-18 describes the ITINTSTAT bit fields.

Table 43-18. ITINTSTAT Field Descriptions

Bits	Name	Description
0–3	—	Reserved, initialize to zero.
4	PTQO	Persistent transmit queue overflow. Set when a transmit queue overflow occurs for two cells in a row. Further transmit queue overflow events are masked when this bit is set, in order to avoid a ‘flood’ of interrupts. This bit can be used to distinguish a temporary overflow condition (which could be caused by a rate differential between the TRL and non-TRL link which was out of compensatable range), or a persistent overflow condition (which could be caused by a more permanent condition, such as a failure of this link’s PHY device). Initialize to zero at link startup.
5	TQO	Transmit queue overflow. Set when a transmit queue overflow occurs; cleared when a cell is successfully transmitted. As this bit is set or cleared on a cell-by-cell basis, it may no longer be set when software reads it if the overflow condition was only temporary. PTQO should be used instead to distinguish between persistent or temporary underrun conditions.
6	PTQU	Persistent transmit queue underrun. Set when a transmit queue underrun occurs for two cells in a row. Further transmit queue underrun events are masked when this bit is set, in order to avoid a ‘flood’ of interrupts. This bit can be used to distinguish a temporary underrun condition (which could be caused by a rate differential between the TRL and non-TRL link which was out of compensatable range), or a persistent underrun condition (which could be caused by a more permanent condition, such as a TRL failure). Initialize to zero at link startup.
7	TQU	Transmit queue underrun. Set when a transmit queue underrun occurs; cleared when a cell is successfully transmitted. As this bit is set or cleared on a cell-by-cell basis, it may no longer be set when software reads it if the underrun condition was only temporary. PTQU should be used instead to distinguish between persistent or temporary underrun conditions. Initialize to zero at link startup.

43.4.5.2 IMA Link Receive Table Entry

Table 43-19. IMA Link Receive Table Entry[1]

Offset	Name	Width	Description
0x00	**ILRCNTL**	Hword	IMA link receive control parameters.
0x02	ILRSTATE	Hword	IMA link receive state. Microcode-managed parameter. Initialize to 0x0040 at link startup.
0x04	**ILID**	Byte	IMA link ID. Formatted per the Cell ID and Link ID field of an ICP cell. Bit 0: 1 (indicating ICP cell) Bits 1-2: Program to zero Bits 3-7: Program to validated LID for this link [Note: This value is only used by microcode to validate incoming ICP cells for this link, it is not used to determine round-robin transmission order. That function is performed by the group order table.]
0x05	RMCTR	Byte	Receive M counter. Microcode-managed parameter.
0x06	LRIFSN	Byte	Receive IFSN counter. Microcode-managed parameter.
0x07	DFC	Byte	Number of frames to discard on a this link until it is caught up with the other links in this group (long propagation delay). Microcode-managed parameter.
0x08	**DCBSP**	Hword	IMA link delay compensation buffer start pointer. This parameter forms bits 12-27 of the pointer; bits 0-11 are from IMAEXTBASE, and bits 28-31 are zero. Refer to Section 43.4.6.2, “Delay Compensation Buffers (DCB)” for more details.
0x0A	**DCBEP**	Hword	IMA link delay compensation buffer end pointer. This parameter forms bits 12-27 of the pointer; bits 0-11 are from IMAEXTBASE, and bits 28-31 are zero. Refer to Section 43.4.6.2, “Delay Compensation Buffers (DCB)” for more details.
0x0C	**DCBFP**	Hword	IMA link delay compensation buffer fill pointer. Microcode-managed parameter. This parameter forms bits 12-27 of the pointer; bits 0-11 are from IMAEXTBASE, and bits 28-31 are zero. Initialize to DCBSP at link startup.
0x0E	**DCBRP**	Hword	IMA link delay compensation buffer read pointer. Only used during group delay synchronization and link addition. Microcode-managed parameter. This parameter forms bits 12-27 of the pointer; bits 0-11 are from IMAEXTBASE, and bits 28-31 are zero.
0x10	**RICPCH**	Hword	Receive ICP channel number. ATM receive channel number to which received ICP cells are sent.
0x12	**IRINTMSK**	Byte	IMA receive interrupt mask. Has the same format as the IMA interrupt queue entry.; however, only receive-related bits are relevant. Setting a bit enables the associated interrupt; clearing a bit masks it. For group-related events, only the mask register for the TRL is referenced.
0x13	**LICPOS**	Byte	Link ICP offset. Program to the ICP offset validated for this link.
0x14	IRSEC	Word	IMA receive stuff event counter. Increments each time a stuff event is received on this ink. Initialize to zero at link startup.
0x18	ANOMALY_CTR	Byte	Anomaly counter. Microcode-managed parameter. Initialize to zero at link startup.

Table 43-19. IMA Link Receive Table Entry[1] (continued)

Offset	Name	Width	Description
0x19	ALPHABETA_CTR	Byte	Alpha/beta counter. Microcode-managed parameter. Initialize to zero at link startup.
0x1A	GAMMA_CTR	Byte	Gamma counter. Microcode-managed parameter. Initialize to zero at link startup.
0x1B	—	Byte	Reserved. Must be initialized to zero.
0x1C	DEFECT_CTR	Hword	Defect counter. This counter is active while the link is in the Loss-of-IMA-Frame (LIF) state and is used to ensure IFSD interrupts are generated for every GAMMA+2 frames. Software can use the period interrupt issued by this counter in order to determine if the link is taking too long to synchronize. The DEFECT_CTR is active before IFSM reaches SYNC. It starts counting from the first cell received and will count from 0 to (GAMMA+2) x M. When it reaches (GAMMA+2) x M an IFSD interrupt is generated and the counter is reset. Upon reception of the next cell it starts to count again and subsequent interrupts are generated. Microcode managed parameter. Initialize to zero at link startup.
0x1E	—	Hword	Reserved. Must be initialized to zero.

1 **Boldfaced** entries indicate parameters that must be initialized by the user. All other parameters are managed by the microcode and should be initialized to zero unless otherwise stated.

43.4.5.2.1 IMA Link Receive Control (ILRCNTL)

The fields of the ILRCNTL register are shown in Figure 43-25

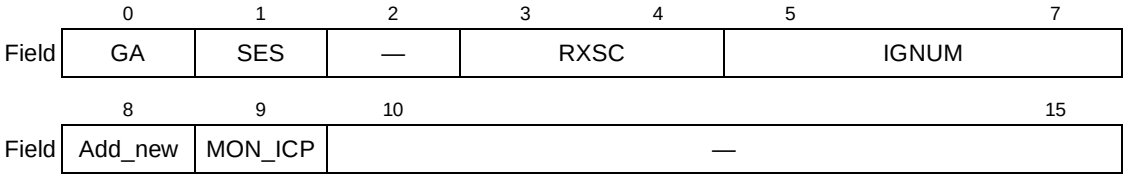

Figure 43-25. IMA Link Receive Control (ILRCNTL)

Table 43-20 describes the ILRCNTL bit fields.

Table 43-20. ILRCNTL Field Descriptions

Bits	Name	Description
0	GA	Group assigned flag. Set by software after group parameters have been validated. 0 Group unassigned. 1 Group assigned.
1	SES	Severely errorred seconds. Set by software when a severely errorred second indication is detected. When set, causes the receive stuff event counter and ICP violation counter to stop counting.
2	—	Reserved, initialize to zero.

Table 43-20. ILRCNTL Field Descriptions (continued)

Bits	Name	Description
3–4	RXSC	Receive status/control. Sets the receive mode of the IMA link. 00 Filler mode. The IMA link processes only ICP cells. Data cells are replaced with filler cells. 01 Active mode. The IMA link is capable of receiving data cells. 10 Dropped. Must be set by the user during the process of dropping the link. Dropped links are treated filler mode until they are switched out of the receive round-robin (i.e. data cells are replaced with filler cells). 11 Reserved.
5–7	IGNUM	Determines to which IMA group this link belongs. Contains the number of the link's associated IMA Group Table entry. Note: This value need not be the same as the group's IMA ID; the IMA ID is programmed separately in the receive group's RIMAID field.
8	ADD_NEW	Identifies this link as a new/added link to a group. Software must flip (0 to 1 or 1 to 0) this bit ONLY when adding a link to an existing group that is operational. If ADD_NEW = ILRSTATE[ADD_NEW_M] = 0, set ADD_NEW to 1 to indicate this is an added link. If ADD_NEW = ILRSTATE[ADD_NEW_M] = 1, set ADD_NEW to 0 to indicate this is an added link. Initialize to zero.
9	MON_ICP	Setting this bit will allow changed ICP cells received on this link to be passed on to the ATM layer (defined channel). The user must monitor at least one link in order for ICP cells to be passed on to the ATM layer.
10–15	—	Reserved, initialize to zero.

43.4.5.2.2 IMA Link Receive State (ILRSTATE)

The fields of the ILRSTATE register are shown in Figure 43-26

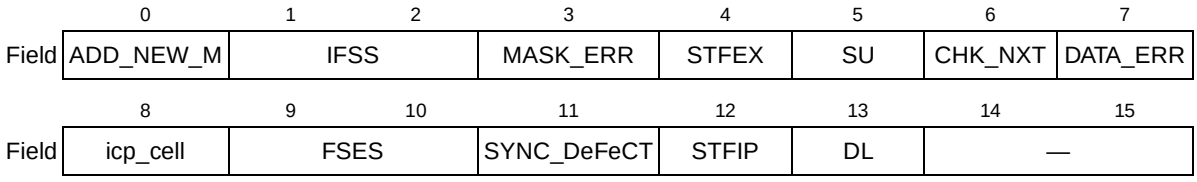

Figure 43-26. IMA Link Receive State (ILRSTATE)

Table 43-21 describes the ILRSTATE bit fields.

Table 43-21. ILRSTATE Field Descriptions

Bits	Name	Description
0	ADD_NEW_M	'New Link' shadow bit. Microcode managed parameter. Initialize to zero at link startup.
1–2	IFSS[1]	IMA frame synchronization state. Microcode-managed parameter. Initialize to zero at link startup. 00 IMA hunt. 01 IMA presync. 1x IMA sync.
3	MASK_ERR	Mask Error. Microcode managed parameter. Initialize to zero at link startup.
4	STFEX	Stuff cell expected. Microcode-managed parameter. Initialize to zero at link startup.
5	SU	Start Up. Microcode-managed parameter. Initialize to zero at link startup.

Table 43-21. ILRSTATE Field Descriptions (continued)

Bits	Name	Description
6	CHK_NXT	Check Next. Microcode-managed parameter. Initialize to zero at link startup.
7	DATA_ERR	Data Error - Parity/CRC. Microcode-managed parameter. Initialize to zero at link startup.
8	ICP_CELL	Current Cell is an ICP Cell. Microcode-managed parameter. Initialize to zero at link startup.
9–10	FSES[1]	Frame Synchronization Error State. Microcode-managed parameter. Initialize to 10 at link startup. 00 IMA working. 01 Out-of-IMA frame anomaly. 1x Loss-of-IMA frame defect.
11	SYNC_DEFECT	Synchronization Defect. Microcode-managed parameter. Initialize to zero at link startup.
12	STFIP	Stuff In-Progress flag. Microcode-managed parameter. Initialize to zero at link startup.
13	DL	Dropped link. Microcode-managed parameter. Initialize to zero at link startup.
14–15	—	Reserved, initialize to zero.

[1]Enable these parameters to their default values during IMA initialization to avoid spurious IMA events in the IMA interrupt queues.

43.4.5.3 IMA Link Receive Statistics Table

The IMA link receive statistics table is optional. It is enabled globally for this UCC via IMACNTL[IRSE]. The base of this table is determined by IRLINKSTAT. Entries in the table are indexed by the link number of the associated link. The format for the IMA link receive statistic table entries is shown in Table 43-22

Table 43-22. IMA Link Receive Statistics Table Entry

Offset	Name	Width	Description
0x00	ICPVIOL	Word	IMA receive ICP violation event counter. While ILRCNTL[SES]=0, increments each time an errorred, invalid, or missing ICP cell is received on this link. Initialize to zero at link startup.
0x04	OIF	Word	Out-of-IMA frame counter. While ILRCNTL[SES]=0, increments each time an Out-of-IMA Frame anomaly occurs on this link. Initialize to zero at link startup.

43.4.6 Structures in External Memory

The IMA microcode requires supporting queue structures in external memory. These are used for the jitter buffers (on transmission) and the delay compensation buffers (on reception). These structures reside in a 1 megabyte memory region defined by IMAEXTBASE, and may reside on either the CSB bus or the secondary bus, as defined by IMACNTL[DSB].

43.4.6.1 Transmit Queues

Transmit queues are allocated on a per-link basis. They are circular queues of 64-byte buffers, defined by their start and end pointers. For the transmit queue of the timing reference link (TRL), the queue must consist of a minimum of four buffers (although it may consist of five buffers, if consistency of data structures is desired). For the transmit queues of non-TRL links, the queues must consist of five buffers.

Queue fill and extract pointers must be initialized by software to the start of the queue; thereafter, these pointers are managed by the microcode. The queue pointers must be on a 64-byte aligned boundary.

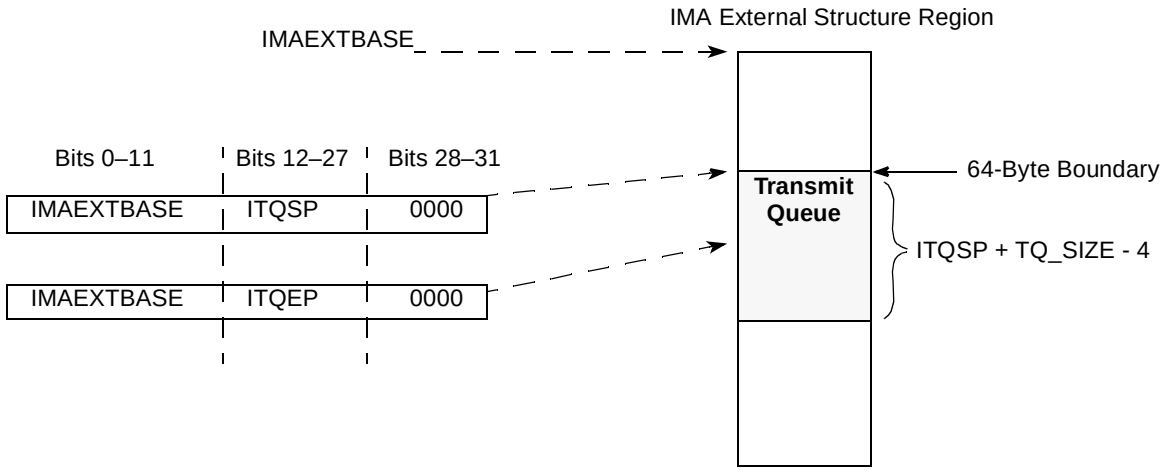

Figure 43-27. IMA Transmit Queue

43.4.6.2 Delay Compensation Buffers (DCB)

Cells received on a link are initially stored in a delay compensation buffer (DCB). DCBs are allocated on a per-link basis. They are of user-definable length and provide a programmable maximum synchronizable delay. DCBs of links within a group must all have the same size. DCBs consist of a circular queue of 64-byte cell buffers that contain the received cell followed by 12 bytes of header/status information.

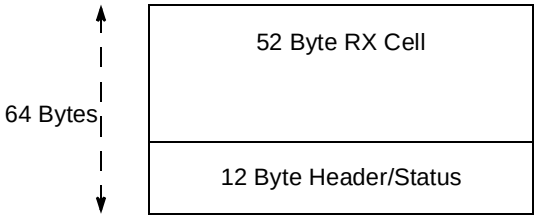

Figure 43-28. Cell Buffer in Delay Compensation Buffer

The length of a DCB is defined by the link DCBSP and DCBEP parameters. The length of the DCB (defined by (DCBEP–DCBSP) x 16) must be an integer multiple of the IMA frame length in bytes, M x 64. Furthermore, the DCBSP must be aligned on a M x 64-byte boundary. For example, if M = 64, DCBSP must be on a 4 Kbyte boundary. To ensure group delay synchronization, the minimum length of the DCB should be $2(M \times 64)$. The DCB memory area must be initialized to zero at link startup.

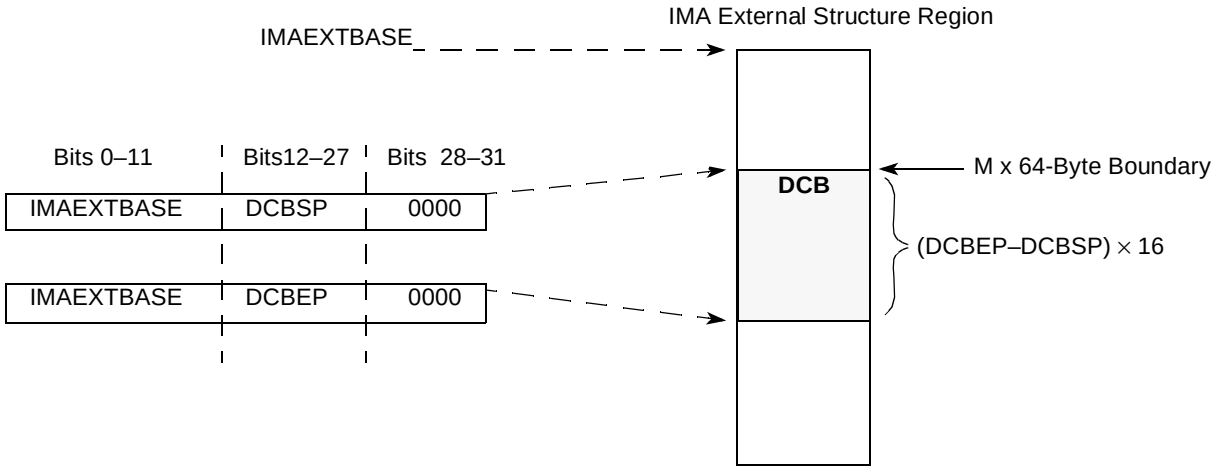

Figure 43-29. IMA Delay Compensation Buffer

43.4.7 IMA Events

One of the four ATM interrupt queues must be dedicated to IMA events. This requirement enables minimum latency in dealing with the IMA state machines and ensures that IMA events are not confused with other events. The IMA interrupt queue is defined in the IMACNTL[INTQ] parameter. IMA events sent to this queue include only those described in this section. ICP receive events are treated as normal receive events, and should therefore go to the interrupt queue allocated for receive events.

43.4.7.1 IMA Interrupt Queue Entry

The format for the IMA interrupt queue entries is shown in Figure 43-30

	0	1	2	3–5	6	7	8	9	10	11	12	13	14	15
OFFSET + 0	V	—	W	—	TQU	TQO	—	DSL	LS	DCBO	LDS	GDS	IFSD	IFSW
OFFSET + 2	L/G	NUM												

Figure 43-30. IMA Interrupt Queue Entry

Table 43-23 describes the IMA interrupt queue entry bit fields.

Table 43-23. IMA Interrupt Queue Entry Field Descriptions

Offset	Bits	Name	Description
Offset + 0	0	V	Valid interrupt entry. 0 This interrupt queue entry is free and can be used by the CP. 1 This interrupt queue entry is valid. The host should read this interrupt and clear this bit.
	1	—	Reserved.
	2	W	Wrap bit.When set, this is the last interrupt circular table entry. During initialization, the host must clear all W bits in the table except the last one, which must be set.
	3–4	—	Reserved
	5	—	Reserved
	6	TQU	Transmit queue underrun. Indicates that the corresponding PHY for this link requested a cell for transmission, but the transmit queue was empty.
	7	TQO	Transmit queue overflow. Indicates that the TRL attempted to send a cell to this link's transmit queue, but no space was available.
	8	—	Reserved
	9	DSL	DCB synchronization lost. This interrupt is issued when a link in a group with IGRSTATE[GDSS] = 11 loses synchronization and the link enters HUNT state at the IFSM.
	10	LS	Link stalled. A link in the round-robin cell extraction process has excessively stalled and been deactivated (i.e. switched to filler mode by the microcode).
	11	DCBO	Link out of delay synchronization. Set when the link's DCB overflows, indicating that delay synchronization for this link is not possible.
	12	LDS	Link delay synchronized. Set when delay synchronization is achieved for a link that has been added to an existing group.
	13	GDS	Group delay synchronized. Set when a group achieves delay synchronization as part of the group startup procedure.
	14	IFSD	IMA frame synchronization status = defect. Set when the associated link goes into the Loss of IMA Frame Defect state of the Error/Maintenance State Machine.
	15	IFSW	IMA frame synchronization status = working. Set when the associated link goes into the IMA Working state of the Error/Maintenance State Machine.
Offset + 2	0	L/G	Link/group indicator. Indicates whether this interrupt is associated with a link or a group, and thus if the NUM field is a link number or group number. 0 This interrupt is associated with a link. 1 This interrupt is associated with a group.
	1–15	NUM	Link or group number associated with this interrupt.

43.4.7.2 ICP Cell Reception Events

ICP cells are received as AAL0 in the channel defined in RICPCH. Receive interrupts are provided for this channel if enabled in its associated RCT.

43.4.8 APC Programming for IMA

Dynamically adding and dropping links from a group changes the overall bandwidth of the group. The bandwidth of a particular ATM channel is programmed as a percentage of the overall bandwidth, up to 100 percent for an APC pace of 1. For IMA, it is desirable to allow for the dynamic addition and deletion of links without changing the bandwidth of individual ATM channels so that ATM traffic contracts are not violated. To do this without requiring updates of the APC parameters of all of the ATM channels, the APC algorithm must be modified to consider the number of links in the group.

To accomplish this for channels to be used with IMA groups, the APC parameters should be programmed to define the bandwidth of a channel as a percentage of one link of the IMA group. The APC pace can be greater than 100 percent if a channel uses more bandwidth than a single link can provide. The APC pace is scaled automatically by the IMA group transmit parameter TNUMLINKS. After scaling, if the pace required of the group is still greater than 100 percent of the group bandwidth, the channel is rescheduled at 100 percent of the group bandwidth. Refer to the examples in Table 43-24.

Table 43-24. Examples of APC Programming for IMA

Example	Description
1	The simplest case. For an IMA group consisting of one 2Mbps link, with one CBR channel consuming the full bandwidth of that link (2 Mbps), TNUMLINKS for the group should be programmed to 1 and the APC pace of the channel should be programmed to 1 (PCR=1, PCR_Fraction=0).
2	Another 2 Mbps link is added to the IMA group in Example 1. The overall bandwidth of the group is now 4 Mbps. However, TNUMLINKS is now 2, and therefore the programmed PCR will be scaled by 2. [Note that the scaling is done automatically internally; the PCR programmed into the channels transmit connection table entry is not modified.] A scaled PCR of 2 indicates that the channel uses 50% of the bandwidth of the group, or 2Mbps. Comparing to example 1 above, we see that the bandwidth of the channel has not changed, even though the bandwidth of the group has changed.
3	Consider an IMA group consisting of five 2 Mbps links over which a 6 Mbps CBR channel is to be sent. 6 Mbps is 300 percent of what a single 2 Mbps link can provide, so its pace should be programmed as 1/3 (PCR=0, PCR_Fraction=85). Scaling the pace by TNUMLINKS results in 5/3 (PCR=1, PCR_Fraction=169), which indicates that the channel uses 60 percent of the bandwidth of the group, or 6 Mbps.
4	Suppose one link is dropped from the IMA group in Example 4. The overall bandwidth of the group is now 8 Mbps, and TNUMLINKS becomes 4. Therefore, the pace for the 6 Mbps CBR channel scales to 4/3 (PCR=1, PCR_Fraction=84), indicating that the channel uses 75 percent of the bandwidth of the group, which is still 6 Mbps.
5	Suppose two more links are dropped from the IMA group in Example 4. The overall bandwidth of the group is now 4 Mbps, and TNUMLINKS becomes 2. Therefore, the pace for the 6 Mbps CBR channel scales to 2/3 (PCR=0, PCR_Fraction=170). This is less than 1, which is not possible to support, so it is rounded up to 1. The channel originally programmed for 6 Mbps now consumes 100 percent of the 4 Mbps IMA group.

Per the above explanation and examples, TNUMLINKS is the only parameter that software must modify when a link is added or dropped from an IMA group. All other APC parameters need not be modified. However, if links are dropped so that the total scheduled bandwidth of the ATM channels is greater than 100 percent of the IMA group bandwidth, the eventual result is APC overruns, which should therefore be corrected and/or avoided.

NOTE

Software should ensure that the length of the APC scheduling table is increased if links are added to the IMA group. When incrementing the number of links in an IMA group, the user might exceed the length of the APC scheduling table; if this happens, the ATM channel is mapped outside of the APC scheduling table and the channel stops.

43.4.8.1 Programming for CBR, UBR, VBR, and UBR+

All APC parameters for CBR, UBR, VBR, and UBR+ channels to be transmitted over IMA groups should be scaled by the intended steady-state value of TNUMLINKS. Their values should be divided by TNUMLINKS because they will be scaled by TNUMLINKS when the pacing algorithms are performed. The parameters that must be scaled include: PCR, SCR, OOBR, BT, MCR, and MDA.

43.4.9 Changing IMA Version

A CECR command added to the IMA microcode changes the IMA version on-the-fly without software intervention. Use the following procedure:

1. Before issuing the command, initialize the COMM_INFO fields in the parameter RAM as shown in Figure 43-31.
2. To issue this UCC command, refer to Section 20.3.1.1, “QUICC Engine Commands.” Use opcode 001101(0x0D).

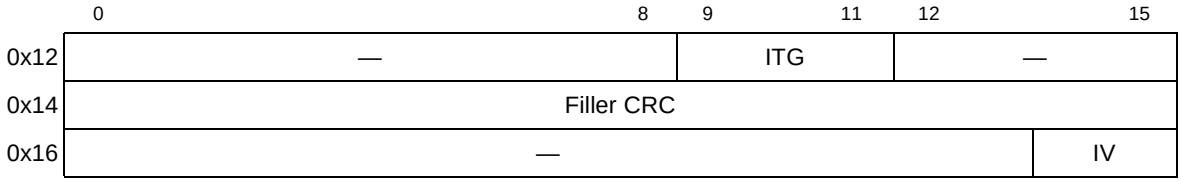

Figure 43-31. COMM_INFO Field

Table 43-25. COMM_INFO Field Descriptions

Offset	Bits	Name	Description
0x12	0–8	—	Reserved, should be cleared.
	9–11	ITG	IMA transmit group. Program to the IMA group number [0–7] multiplied by 16 bytes. For example, if the IMA group number = 3, program ITG to 0x30.
	12–15	—	Reserved, should be cleared.
0x14	0–15	Filler CRC	Filler cell CRC. Set to 0xC602 (for IMA version 1.0) or 0xD902 (for IMA version 1.1)
0x16	0–13	—	Reserved, should be cleared.
	14–15	IV	IMA version 00 Reserved 01 IMA version 1.0 10 Reserved 11 IMA version 1.1

3. Wait for the QUICC Engine block to clear the CECR[FLG] before issuing a new CP command. Refer to Section 20.3.1.1, “QUICC Engine Commands.”

43.5 IMA Software Interface and Requirements

The IMA microcode facilitates the implementation of the lower levels of an IMA system. Host software, which from here on is code running on the G2 core, initializes the processor IMA data structures, establishes and tears down connections, handles alarms, keeps statistics, and controls protocol state machines. The IMA microcode interfaces to the software-implemented (layer management and plane management) functions by providing received ICP cells and by interrupts. The software-implemented functions control the microcode and the system through the IMA root, group, and link parameters and by providing an ICP cell template to the microcode for ICP cell transmission.

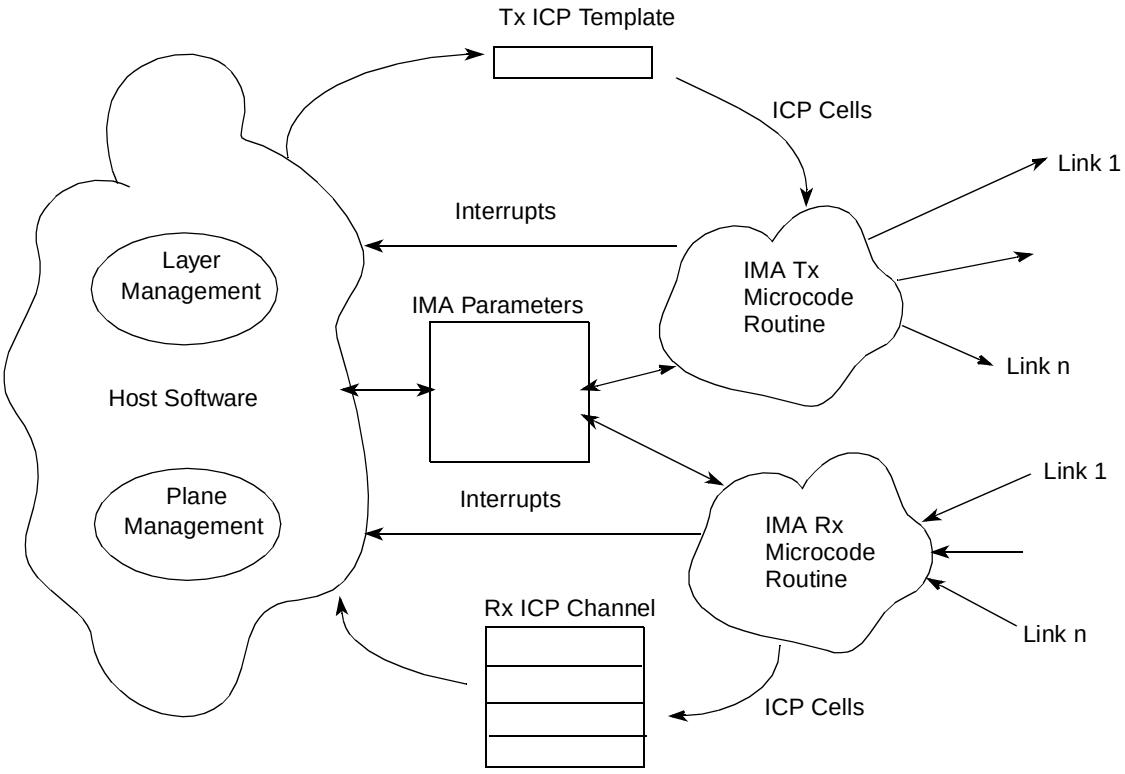

Figure 43-32. IMA Microcode/Software Interaction

43.5.1 Initialization Procedure

1. Program the UCC registers/parameters for ATM operation with UTOPIA multi-PHY (excluding APC parameters for IMA PHYs).
2. Program the IMA UCC and root parameters.
3. Enable the UCC through the GFMRx[ENR,ENT] bits.

Aside from IMA state machine control and IMA-specific error events, subsequent interaction with the ATM channels is the same as for non-IMA operation (e.g. host commands, RCT/TCT parameters, buffer descriptors, interrupts).

43.5.2 Software Responsibilities

Table 43-26 lists functions that are the responsibility of the host software, which must complement the IMA microcode to provide a complete IMA solution.

Table 43-26. Host Software Functions

Function	Action
System definition	Define the P(Rx) and P(Tx) software variables to determine sufficient links.
General Operation	React to received ICP cells. ICP cells are received only when their SCCI field changes, except the first received ICP cell.
	Report any NE and FE timing mode mismatches (ITC versus CTC) to the unit management.
Receive link state machine control	Set up unassigned links, awaiting ICP cells: • Define either as standard multi-PHY or as unassigned IMA link. • Set up receive channel for ICP OAM cells for this link only.
	Create and initialize the delay compensation buffer.
	Respond to received ICP cells. Extract and validate link/group parameters: • IMA ID • Link ID • Link ICP offset • IMA frame size (M)
	After establishing the group, change the receive channel for ICP OAM cells so that all links in the group point to the same channel.
	Control link operation (through ILRCTNL[RXSC]) in coordination with link and group states.
Receive group state machine control	Coordinate receive links using received ICP cells to identify a proposed group.
	Establish and validate group parameters in conjunction with the received link states and parameters • IMA version • IMA ID • Group order table
	Enable delay synchronization for the group, and react to its completion.
	Control group operation (through IGRCNTL[RXSC]) in coordination with group state.
	Signal receive group state through ICP cells of corresponding transmit group.
Transmit link state machine control	Define the IMA link • Define link parameters (e.g. IMA ID, Link ID, IMA frame size (M)) in coordination with IMA group definition • Assign ICP offset • Create and initialize transmit queue
	Control link operation (through ILTCNTL[TXSC]) in coordination with link and group states.

Table 43-26. Host Software Functions (continued)

Function	Action
Transmit group state machine control	Define the IMA group(s) • Assign IMA ID • Assign Link IDs and the transmit group order table • Assign TRL • Assign IMA frame size (M) • Signal group parameters via ICP cells • Define ATM pace controller (APC) parameters for this transmit group
	Signal transmit group state through ICP cells.
	Negotiate transmit group parameters with the far end.
	Check status of links in group to make ‘Sufficient Links’ determination.
	Control group operation (through IGTCNTL[TXSC]) in coordination with group state.
	Coordinate link state transitions with group state transitions during group startup and link addition.
Group symmetry control	Support for all types of group symmetry (operation and configuration) is facilitated by the ability to enable/disable links independently and to control link and group states through independent link and group transmit and receive parameters.
ICP end-to-end channel transmission	Can send information on end-to-end channel by updating field in Tx ICP.
	No Rx support is provided for end-to-end channel.
Link addition and slow recovery (LASR) procedure	Coordinate addition of links for both receive and transmit, including the following: • Establishing their parameters • Checking for defects • On-the-fly insertion into data structures
Failure alarms	React to errors signaled in received ICP cells.
	React to physical layer errors.
	Monitor persistence of errors to determine alarm condition.
	Report receive defects within 2M cells of entering defect state.
	Signal upper-layer software.
Test pattern control	Initiate transmit test patterns in the group’s transmit ICP cells (through TXTC and TXTP) and monitor the response in the receive ICP cells of the associated receive group.
	Respond to test patterns by: • Recognizing test pattern activity in the received ICP cells • Locating the Tx Test Pattern field in the ICP cell of the test link. (Because the SCCI field changes as part of the test pattern generation by the far end, the cell will necessarily be among the received ICP cells. Locate the latest ICP cell with a LID matching the Tx LID of the test link). • Signaling back via the transmit ICP cells of the associated transmit group, by modifying the transmit ICP cell template appropriately
Performance parameter measurement and reporting	Establish timers to correlate errors with time intervals (e.g. to determine severely errored seconds (SES) or unusable seconds (UUS))
	Maintain statistics.

Table 43-26. Host Software Functions (continued)

Function	Action
	Enable/disable receive and transmit event counters according to severely errored seconds (SES) condition through ILRCNTL[SES] and ILTCNTL[SES].
SNMP MIBs	Control interface and statistics information should be provided per the SNMP MIB definition for IMA.

43.5.3 IMA Software Procedures

Procedures must be followed to assure the synchronization of changes between the link state machines and the group state machine. Issues to be considered are order of changes to the ICP cell and pointer, group order structure and pointer, IMA PHY assignment structure, and group/link Tx control fields.

43.5.3.1 Transmit ICP Cell Signaling

1. Copy the transmit ICP cell template currently in use (as indicated by TICPPTR) to the ICP cell template area not in use.
2. In the new template, change the ICP cell template fields as appropriate.
3. Verify that the IGTCNTL[ICPC] equals IGTSTATE[ICPCA]. If not, wait until it does.
4. Change TICPPTR to point to the “changed/altered” (see step 1) ICP cell template.
5. Toggle IGTCNTL[ICPC].

43.5.3.2 Transmit Group Initialization

1. Initialize all IMA parameters, this must include the Transmit Group Order Tables for the link
2. Enable the corresponding TC layer to request cells, basically stage 1 should be complete before the TC layer requests cells to be delivered. A request for cells is an assertion of TxClav by the TC layer when using an external TC layer on the UTOPIA bus. When using the SAM a request for cells would be setting MTC_MODE[TXEN]. The TRL link should be enabled last.

43.5.3.3 Receive Link Startup Procedure

Before links and group can be activated, ICP cells must be received and processed by the management software. Software must configure all IMA links to group unassigned mode. Reception of ICP cells requires that the corresponding PHYs (that is, links) be enabled and the corresponding connection table entry/entries initialized (see RXPHYEN_TPTR and RICPH). In group unassigned mode, the first received ICP cell is always reported to the corresponding channel’s buffer (RICPCH) and subsequently every time there is a change in the Status and Control Change Indication (SCCI) field of the ICP cell.

- Clear ILRCNTL[GA].

Clearing GA (group unassigned) allows only ICP cells to be processed; all other cells are dropped. The management software analyzes the ICP cells and programs the corresponding IMA link receive table parameters:

- IMA Link ID (ILID)

- Link ICP offset (LICPOS)
- Select link as the Timing Reference Link (only one link can be TRL). ILRCNTL[TRL] = 1.
- Assign the link to a group. ILRCNTL[IGNUM] = x.
- Verify that the size of frame (M) is the expected value.

The software must have built-in knowledge of the mapping between physical links and their corresponding channel number (for example, PHY 0 uses channel 2 (RICPH = 2)). After a group is established, the user can have all links in a group report changed ICP cells to a single channel either by changing RICPCH for all the links to be the same or by clearing the MON_ICP bit:

- ILRCNTL[MON_ICP] = 0. At least 1 link in the group must have this bit set.

43.5.3.4 Group Startup Procedure

The IMA frame synchronization mechanism (IFSM) is initiated when a link is switched to group assigned. Management software must already have programmed the group parameters based upon the received/negotiated values in ICP cells:

- IMA ID (RIMAID)
- IMA Version (IMAVER)
- IMA Frame Size (RM)

Other parameters do not depend on ICP information for programmability. Therefore, they should be initialized before the start of the IFSM. Start the IFSM by setting each link in the group to “Group Assigned”:

- Set ILRCNTL[GA].

Management software must wait until each link in the group achieves IMA frame synchronization. For each link in the group that is “group assigned,” an IMA frame synchronization working (IFSW) event is generated. Having achieved frame synchronization, software can enable the group delay synchronization (GDS) mechanism; that is, finding the link with shortest delay and buffering accordingly through DCB.

- Configure the group order table with the ascending link order (round-robin distribution) to be used in reconstructing the ATM stream.
- Set the corresponding PHY bits in REF_LINK.
- Set IGRSTATE[GDSS] to 1 (one) to enable GDS.

After group delay synchronization is achieved, a GDS event is generated and ATM stream reconstruction can take place. For stream reconstruction to be performed by the processor, the user must switch all links and corresponding group (both directions) to active mode for receiving data cells. Set RX to active first to prevent the transmitter from generating a data stream when the opposite end is not ready:

- Set ILRCNTL[RXSC] to enable reception of data cells at the link level.
- Set IGRCNTL[RXSC] to enable reception of data cells at the group level.
- Set ILTCNTL[TXSC] to enable transmission of data cells at the link level.
- Set IGTCNTL[TXSC] to enable reception of data cells at the group level.

43.5.3.4.1 Initiator (Tx) Actions

Most of the actions required when a system initiates the establishment of a group with X links involve the exchange of ICP cells between the near end (initiator) and the far end (responder). Both ends must start with a group of X potential links configured to filler mode. One and only one of the links in the group must be designated as TRL.

- Set ILTCNTL[TXSC] to 0 (zero)—link is in filler mode.
- Set IGTCNTL[TXSC] to 0 (zero)—group is in filler mode.

The actions at both ends mirror each other. That is, the near end initiates the establishment of a group with X links by sending ICP cells to the FE and *vise versa*. The normal ICP state changes, driven by the state machine software, are (on a per-link basis):

- Not In Group
- Unusable
- Usable
- Active

Refer to Section 43.5.3.1, “Transmit ICP Cell Signaling” for details on how to modify and transmit an updated ICP cell. It is the responsibility of the GSM/LSM (group/Link State Machine software) to initialize the IMA ID (i.e. group ID) in the ICP cell template and link ID in the corresponding TX IMA Link Transmit Table Entry (ILTTE):

- Set ILTTE[ILID] = corresponding Link ID.
- Set IMA ID accordingly in the ICP Cell Template.

As an initiator, the NE (“end” is relative) must have established a group with X links provisioned.

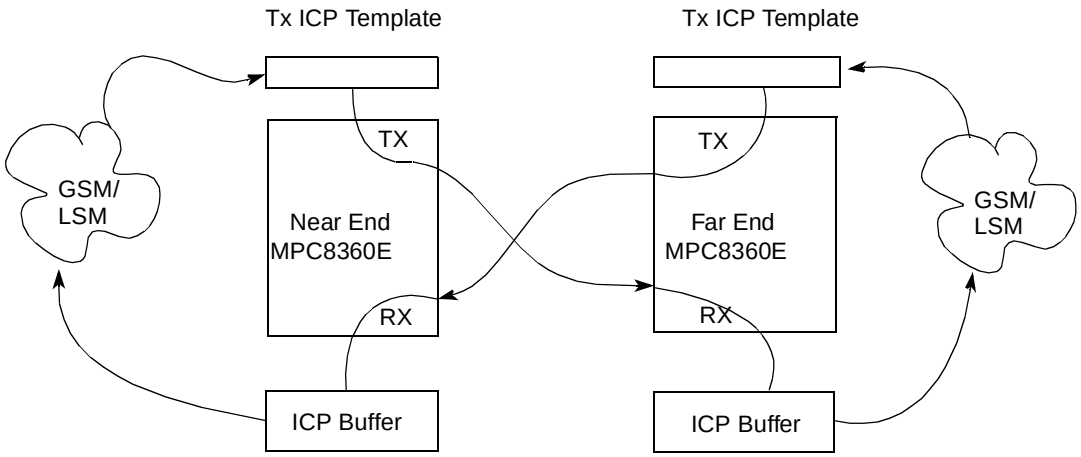

Figure 43-33. Near-End versus Far-End

43.5.3.4.2 Responder (Rx) Actions

The IMA GSM/LSM software receives ICP cells in the ICP buffer conveying the state of the FE group and links. After it determines that the required minimum number of links are available, it can proceed to enable the group delay synchronization (GDS) mechanism in which the all links in the corresponding group are

analyzed to find the one with the shortest propagation delay. The amount of delay tolerated is programmable and is programmed by setting the beginning and ending addresses (size) of the delay compensation buffers (DCB). Note that the size of all DCBs must be the same and must be initialized before the GDS mechanism is activated. Activate GDS:

- Set IGRSTATE[GDSS] to enable GDS. After GDS is enabled, the user must not alter GDSS.

When group delay synchronization is achieved, a GDS event is generated and ATM stream reconstruction can take place. For the processor to perform ATM stream reconstruction, the user must switch all links in the group to active mode so that they can receive data cells, as specified earlier in this section. The initialization of the ATM TX and RX data structures required to generate and receive the ATM stream is out of the scope of this document, but it is documented in Chapter 32, "ATM Controller AAL0, AAL1, and AAL5."

43.5.3.5 Link Addition Procedure

Adding a link to an existing group requires changes to both the group and link table entries. Aside from the normal exchange of ICP cells by the state machines at the FE and NE, the steps described in this section should be followed. In general, a new link entry is appended to the existing list of link table entries and the required parameters initialized. This has no impact until the corresponding link is enabled through the PHYEN fields in the IMA root table.

The following sequence to achieve Rx link working state must be executed for each link independently of whether the link is added to a group either through LDS or GDS.

1. Reset all RX parameters in the new link table entry to zero.
2. Assign the corresponding group number for the new link: ILRCNTL[IGNUM] = x.
3. Assign the channel number for ICP cell reception: RICPCH = x.
4. Enable the desired interrupts: IRINTMSK = x.
5. Allow for the reception of ICP cells during the IFSM stage: ILRCNTL[MON_ICP] = 1.
6. Indicate that this link has not yet been assigned to a group: ILRCNTL[GA] = 0.
7. Configure this link/PHY as an IMA link by adding the link to the UTOPIA address compression table and updating the RXPHYEN_TSIZE.
8. Enable the corresponding link/PHY at the TC layer for example if using SAM as the TC layer set MTC_MODE[RXEN], or clear MTC_MODE[RAD] if the MTC is already in SYNC state but not passing cells up. If an external TC layer is used, set the corresponding enable bit for the external TC layer device.
9. Software receives and accepts ICP cell values (M, LID, and so on).
10. Program expected LID: ILID = x.
11. Program the expected ICP offset: LICPOS = x.
12. Initialize the DCB pointers accordingly: DCBEP, DCBSP, DCBFP. Note, it is recommended that the DCB be initialized to zero.
13. Configure link to loss of IMA frame state: ILRSTATE[FSES] = 2.
14. Start the IMA frame synchronization mechanism (IFSM) by assigning this link to the group: ILRCNTL[GA] = 1.

15. Software must now wait for the IFSW event.

The Rx steps for GDS, setting up a new group are as follows:

1. Formulate the new content of group order table RGRPORDER0 with the new link(s) included (see Section 43.4.4.2.4, “Receive Group Order Tables”), but do not flip GOTP (GOTP must remain 0).
2. Update RNUMLINKS. The stall threshold must be recalculated.This parameter defines the acceptable tolerance to an emptied DCB condition (stalled link, see LS event). The recommended new value is: STALL_THR = 2 x RNUMLINKS x (3 + RX_FIFO). See Section 43.4.4.2, “IMA Group Receive Table Entry”: IGRTE[STALL_THR] = x.
3. Start the delay compensation process for the link(s) by setting the corresponding bit(s) in the group table REF_LINK parameter.
4. Start the GDS procedure as shown in Section 43.5.3.4, “Group Startup Procedure.

   Software must now wait for the group delay synchronization process to complete. A group delay synchronized (GDS) event is generated as soon as this happens.
5. If the GDS completes successfully, it is now safe for the link(s) to receive data. See Section 43.5.3.4, “Group Startup Procedure on how to activate the group and its links.

The Rx steps for LDS, adding a link to an existing group proceed as follows. This procedure can be invoked only if a GDS has successfully completed for the group.

1. Now that we have a “frame” synchronized link, we can proceed to allow the link to be delay synchronized. Assuming ILRCNTL[ADD_NEW] = ILRCNTL[ADD_NEW] indicate that this is a new link by inverting the current “add-new” bit value: ILRCNTL[ADD_NEW] = x. Basically ensure that ILRCNTL[ADD_NEW] is not equal to ILRSTATE[ADD_NEW_M].
2. Formulate a new group order table with the new link included (see Section 43.4.4.2.4, “Receive Group Order Tables”).
3. Use the new group order table by inverting the current GOTP value: IGRCNTL[GOTP] = x.
4. Update RNUMLINKS. The “Stall Threshold” needs to be recalculated. This parameter defines the acceptable tolerance to an emptied DCB condition (stalled link, see LS event). The recommended new value is: STALL_THR = 2 x RNUMLINKS x (3 + RX_FIFO). See Section 43.4.4.2, “IMA Group Receive Table Entry”: IGRTE[STALL_THR] = x.
5. Start the delay compensation process for this link (in IMA Root Table) by setting the corresponding bit in REF_LINK. See Table 43-3.
6. Software must now wait for the link delay synchronization process to complete. A link delay synchronized (LDS) event is generated by the QUICC Engine module as soon as this happens.
7. It is now safe for the link to receive data; set the link to active mode: ILRCNTL[RXSC] = 1.

To configure the Tx parameters, perform the following steps:

1. Reset all TX parameters in the new link table entry to zero.
2. Assign corresponding group number for the new link: ILTCNTL[IGNUM] = x.
3. Enable desired interrupts: ITINTMSK = x.
4. Software formats content of ICP template accordingly (see section “Transmit ICP Cell Signaling”).
5. Program the Link’s ID (LID) in the IMA Link Transmit Table Entry (ILTTE): ILID = x.

6. Program the ICP offset (ILTTE): LICPOS = x.
7. Initialize the Transmit Queue pointers accordingly: ITQSP, ITQEP, ITQFP, and ITQXP.
8. Construct the new TX Group Order Table (includes the added/new link).
9. Point to new TX Group Order Table in the corresponding IMA Group Transmit Table Entry (IGTTE): TGRPORDER = New Table Offset.
10. Configure this link/PHY as an IMA link by adding an entry to the UTOPIA compression and then updating TXPHYEN_TSIZE parameter to reflect the new table size.
11. Enable the corresponding link/PHY by enabling the TC layer. Up to this stage the TC layer should be disabled and should not request any cells from the IMA or ATM layers. For example if the TC layer for this link is polled on the UTOPIA bus it should not respond to the TxClav (requesting a cell) before this stage is complete. If the SAM is the TC for the link being added software should set the MTC_MODE[TXEN] at this stage and not before.
12. Software must now wait for the corresponding FE link to go to active state. (See Section 43.4.4.1.4, “ICP Cell Templates.”) The link can be configured to active mode to send data cells. Prior to this point, only filler and ICP cells were transmitted. ILTCNTL[TXSC] = 1.
13. Increment the number of links currently in the group (IGTTE): TNUMLINKS += 1.
14. If this link is the TRL set its ILTCNTL[TRL]. This bit must not be set until the previous steps have completed.

43.5.3.6 Link Removal Procedure

Removing a link from an existing group requires changes to both the group and link table entries. Aside from the normal exchange of ICP cells by the state machines at the FE and NE, the following steps should be followed. In general, a link entry is removed from the existing list of link table entries and the required parameters initialized.

43.5.3.6.1 Rx Link Removal

1. Formulate new group order table with the “dropped” link excluded (see Section 43.4.4.2.4, “Receive Group Order Tables”).
2. Update RNUMLINKS. The “Stall Threshold” needs to be recalculated. This parameter defines the acceptable tolerance to an emptied DCB condition (stalled link; see LS event). The recommended new value is: STALL_THR = 2 x RNUMLINKS x (3 + RX_FIFO). See section “IMA Group Receive Table Entry”: IGRTE[STALL_THR] = x.
3. Inhibit storing of cells in DCB for “dropped” link (in IMA Root Table): REF_LINK &= ~x (i.e., clear the corresponding link bit in the REF_LINK entry).
4. Indicate that the link should be dropped: ILRCNTL[RXSC] = 2.
5. Software should wait (poll) for removal of the link from the DCB routine. The corresponding bit in the group table LINK_DCB entry is cleared, so no more cells are stored in the DCB. For example, while ((LINK_DCB & REF_LINK_BITMASK) != 0)/* wait */;. If this wait does not succeed within RNUMLINKS*STALL_THR cell times on the physical interface, we must

assume that all links in the group are down. See Section 43.5.3.6.2, “Rx Steps No RxClav For All Member Links In A Group. The value of RNUMLINKS used must be the value before decrementing in step 2.

6. Use the new group order table by inverting the current GOTP value: IGRCNTL[GOTP] = x.
7. Indicate that this link is no longer assigned to a group: ILRCNTL[GA] = 0.
8. Inhibit reception of cells over the dropped link by disabling the TC layer such that it does not pass any more cells to the IMA layer. Disable the TC layer, for example, if using the SAM clear MTC_MODE[RXEN]. If the TC layer is connected on the UTOPIA bus, disable it by ensuring that it passes no more cells onto the UTOPIA bus for this link. If the application requires that the TC layer remains cell delineated (no LOCD) at this step then software should adhere to the following steps:
    a) Leave MTC_MODE[RXEN] = 1
    b) Set MTC_MODE[RAD]
9. Wait a period of time that is equal to 2 cells time on the physical interface (for example, 2 cells duration on an E1 interface).
10. Software should wait (poll) for the processor to use the new group order table. This simply ensures that it is safe to modify/reuse the dropped link parameters because the processor is no longer using the dropped link’s data structures. Ensure that the group order pointer points to the new group order table (at this point, no more cells are extracted out of the dropped link’s DCB). For example, use while (dcblink != new_pointer). DCBLINK is an entry in the IGRTE. If this wait does not succeed within RNUMLINKS*STALL_THR cell times on the physical interface, we must assume that all links in the group are down. See Section 43.5.3.6.2, “Rx Steps No RxClav For All Member Links In A Group in that case. The value of RNUMLINKS used must be the value before decrementing in step 2.

43.5.3.6.2 Rx Steps No RxClav For All Member Links In A Group

Note that if only one link is used in a group the software must monitor the TC layer to detect that this link has stalled. If all links in the group go down simultaneously (for example, due to removal of cables), this scenario should be treated as the last link stall case and the TC layer indications must also be used to determine that the links should be removed. In general, if the TC layer no longer passes cells to the IMA layer (e.g. no RxClav assertions for all links in the group), the removal procedure in Section 43.5.3.6.1, “Rx Link Removal” will not be successful. Therefore, if all links in a group are no longer passing cells, follow the procedure in Section 43.5.3.6.2, “Rx Steps No RxClav For All Member Links In A Group”. This procedure should also be used if the group is to be torn down during GDS.

1. Inhibit reception of cells over the dropped link(s) by disabling the TC layer(s) so that they do not pass any more cells to the IMA layer. Disable the TC layer(s), for example, if the SAM clear MTC_MODE[RXEN] is used for each link. If the TC layer(s) are connected on the UTOPIA bus, disable each one to ensure that they pass no more cells onto the UTOPIA bus.
2. Wait a period of time that is equal to 2 cells time on the physical interface (for example, 2 cells duration on an E1 interface)
3. It is now safe to configure the group and link tables to their default values.

4. If all or some of the links are to be used again, follow the group initialization procedure (see Section 43.5.3.4, “Group Startup Procedure”).

43.5.3.6.3 TX Parameters For Non-TRL Link

1. Inhibit transmission of cells over the dropped link by disabling requests from the link for cells. The TC layer (PHY number for this link) should not request any more cells on the UTOPIA bus. If SAM is used, clear each TC layer MTC_MODE[TXEN].
2. Formulate the new group order table with the dropped link excluded (see Section 43.4.4.1.3, “Transmit Group Order Table”).
3. Point to new TX group order table in the corresponding IMA group transmit table entry (IGTTE): TGRPORDER = New Table Offset.
4. Decrement the number of links in the group (IGTTE): TNUMLINKS -= 1.
5. Wait a period of time that is equal to 2 cells time on the physical interface (for example, 2 cells duration on an E1 interface).

43.5.3.6.4 TX Parameters TRL Link

The TRL link removal requires all other links in the group to be removed. because the TRL controls the filling of the transmit queues of all links in the group. After the TRL is removed, all other links queues are no longer passed cells. This procedure should also be performed when the last link is removed from the group because by definition the last link must be the TRL.

1. Inhibit transmission of cells over all links in the group by disabling requests from these links for more cells. The TC layers (PHY numbers for each link) should not request any more cells on the UTOPIA bus. If SAM is used, clear each TC layers MTC_MODE[TXEN].
2. Remove the TRL by clearing ILTCNTL[TRL].
3. For all member links, execute the TX link removal procedure as described in Section 33.5.4.5.3, “TX Link Removal.

43.5.3.7 Link Receive Deactivation Procedure

The following procedure assumes that the link was part of the IMA group during the group delay synchronization procedure and that an IFSW (IMA Frame Synchronization Working) event has already been received for the link.

1. Update RNUMLINKS. The “Stall Threshold” needs to be recalculated. This parameter defines the acceptable tolerance to an emptied DCB condition (stalled link, see LS event). The recommended new value is: STALL_THR = 2 x RNUMLINKS x (3 + RX_FIFO). See Section 43.4.4.2, “IMA Group Receive Table Entry”: IGRTE[STALL_THR] = x.
2. Inhibit storing of cells in DCB for “dropped” link (in IMA Root Table): REF_LINK &= ~x (i.e., clear the corresponding link bit in the REF_LINK entry).
3. Indicate that the link should be dropped: ILRCNTL[RXSC] = 2.
4. Software should wait (poll) until the link is removed from the DCB routine. The corresponding bit in the group table LINK_DCB entry is cleared so that no more cells are stored in the DCB). For example, use while ((LINK_DCB & REF_LINK_BITMASK) != 0) /* wait */;. If this wait does

not succeed within RNUMLINKS*STALL_THR cell times on the physical interface, we must assume that all links in the group are down. See Section 43.5.3.6.2, “Rx Steps No RxClav For All Member Links In A Group. The value of RNUMLINKS used must be the value before decrementing in step 1.

5. Formulate new group order table with the dropped link excluded (see Section 43.4.4.2.4, “Receive Group Order Tables").
6. Use the new group order table by inverting the current GOTP value: IGRCNTL[GOTP] = x.
7. Set the link to filler mode ILRCNTL[RXSC] = 0.
8. Initialize the DCB pointers accordingly: DCBSP = DCBFP, DCBRP = Null.
9. Initialize link DCB in external memory to zero.
10. If this was the last link in group (i.e. involved in passing cells from the DCB to the ATM microcode) software must also clear IGRSTATE[GDSS].

43.5.3.8 Link Receive Reactivation Procedure

The following procedure assumes that the link is part of the IMA group during the group delay synchronization procedure and that an IMA frame synchronization working (IFSW) event has already been received for the link.

1. Indicate that this is a new link (GDS/reconstruction function) by inverting the current “add_new” bit value: ILRCNTL[ADD_NEW] = x.
2. Formulate the new group order table with the new link included (see Section 43.4.4.2.4, “Receive Group Order Tables”).
3. Use the new group order table by inverting the current GOTP value: IGRCNTL[GOTP] = x.
4. Increment RNUMLINKS in the group receive table.
5. The “Stall Threshold” needs to be recalculated. This parameter defines the acceptable tolerance to an emptied DCB condition (stalled link, see LS event). The recommended new value is: STALL_THR = 2 x RNUMLINKS x (3 + RX_FIFO). See Section 43.4.4.2, “IMA Group Receive Table Entry”: IGRTE[STALL_THR] = x.
6. Start the delay compensation process for this link (in IMA Root Table) by setting the corresponding bit in REF_LINK. See Table 43-3.
7. Software must now wait for the link delay synchronization process to complete. A LDS (Link Delay Synchronized) event will be generated by the processor as soon as this happens.
8. It is now safe for the link to receive data, set link to “active” mode: ILRCNTL[RXSC] = 01.

43.5.3.9 Transmit Event Response Procedures

The following TX events can occur in IMA mode. It is recommended that all events be handled through an exception/interrupt service routine (ISR) because the response time inherent with interrupt-driven events should diminish the negative impact/propagation of such events:

- Transmit queue underrun (TQU)—Indicates that a transmit queue was emptied. This implies that the offending link (PHY) is requesting cells at a faster rate relative to the TRL. If the TRL is out of spec, then multiple links report TQUs because all links in the group are faster relative to the TRL.

The offending link should be removed (see Section 43.5.3.6, “Link Removal Procedure”). Check the following: PHY, TX Queue depth (start and end pointers should not be the same); TNUMLINKS is equal (not less or greater) than the number of active links.

- Transmit queue overflow (TQO)—Indicates that a transmit queue was not ready to receive a cell (full). This implies that the offending link (PHY) is requesting cells at a slower rate relative to the TRL. If the TRL is out of spec, then multiple links report TQOs because all links in the group are slower relative to the TRL. The offending link should be removed (see Section 43.5.3.6, “Link Removal Procedure”). Check the following: PHY, TX Queue depth (depth should be the same as other queues); TNUMLINKS is equal (not less or greater) than the number of active links.

43.5.3.10 Receive Event Response Procedures

The following RX events may take place when operating in IMA mode. It is recommended that all events be handled via an “exception/interrupt service routine” (ISR) as the response time inherent with interrupt driven events should diminish the negative impact/propagation of such events:

- Link stalled (LS)—The link’s DCB has emptied, either because the PHY is no longer functioning or it is relatively slower than the other links. The offending link should be removed (see Section 43.5.3.6, “Link Removal Procedure”). If only one link is used in a group, the software must monitor the TC layer to detect that this link has stalled. No LS event is reported in the IMA interrupt queue for this case. To restart an IMA group properly after last/only link has recovered, the user must follow the group startup procedure.
- DCBO (DCB Overflow)—The delay compensation buffer has no more space. The source of the problem can be varied:
  - — the offending PHY is sending at a faster rate (out of spec.)
  - — the propagation delay of one of the other links in the group is greater than anticipated (need to make DCB larger)
  - — the size of the offending link was programmed incorrectly, that is, smaller (the size of all DCBs in the group should be the same).

  The offending link should be removed or deactivated (see Section 43.5.3.6, “Link Removal Procedure” or Section 43.5.3.7, “Link Receive Deactivation Procedure). This event corresponds to the link out of delay synchronization defect (LODS) and should be reported to the FE (through the ICP cell, RxDefect = LODS). The processor continues to report this event if the condition persists (unless the event is masked).
- Link delay synchronized (LDS)—The new/added link to an existing group has achieved synchronization (link delay). The link can receive data at this point, (see Section 43.5.3.5, “Link Addition Procedure”).
- Group delay synchronized (GDS)—Group delay synchronized achieved or not achieved. In some cases, the GDS cannot complete. This can happen if a link experiences problems during the GDS process, for example, losing SYNC state for the IFSM. If this occurs, it is not possible to determine the link’s true differential delay with respect to other member links of the group. To determine

whether the GDS process completed successfully, the ucode sets IGRSTATE[GDSS] to either of the following values after the GDS interrupt is generated:

— IGRSTATE[GDSS] = 00 – GDS process failed, a link lost IFSM SYNC during GDS process

— IGRSTATE[GDSS] = 11 – GDS process complete

Software can then read IGRSTATE[GDSS] and use this status information before deciding whether to change the links to the active state or to try to resynchronize again at the group level. In addition to the preceding status information, the ILRSTATE[ADD_NEW_M] bit of the link that caused the failure of the GDS process is flipped so that it is logically inverted with respect to the ILRCNTL[ADD_NEW] bit. If the GDS fails software can restart a new GDS with the link that caused the failure excluded. Software must reset the DCB pointers for all of the links to their default values. If the excluded link subsequently reaches the WORKING state it can be added to the group again using the LDS procedure see Section 43.5.3.5, “Link Addition Procedure” for more information. Note that a link losing SYNC during the GDS process can cause DCBO interrupt for other links in the group. If this situation occurs the GDS process should be restarted as described.

- Link (IMA) frame synchronization defect (IFSD)—The link has lost synchronization (for example, unexpected IFSN value for a number (GAMMA + 2) of consecutive frames). The interrupt will be issued every (GAMMA + 2) IMA frames whilst the IMA Error/Maintenance State Machine is in the DEFECT state. If this condition persists, the software can choose to remove the link after a certain threshold of consecutive IFSD interrupts are encountered. The threshold that would trigger the removal of the link is system-specific. Alternatively the software can leave the link in the group assigned state and wait for the link to recover, the recovery will be flagged through an IFSW interrupt. The IFSD event corresponds to the “Loss of IMA Frame” (LIF) state and the software should react to this by informing the FE of the problem (through the ICP cell, RxDefect = LIF). The processor maintains counters (if enabled) to track the overall quality of a particular link: see OIF (Out of IMA Frame) and ICPVIOL (ICP Violation) in Section 43.4.5.3, “IMA Link Receive Statistics Table.” The software can use one of the processor timers as a time stamp when handling IFSD events and check if the persistence time threshold has been crossed when subsequent events occur. The LIF state time stamp should be reset when the IFSW event is reported.

NOTE

If the periodic IFSD interrupts handling is not required by the software, upon the first instance of IFSD for this link the software can mask the interrupt. Then the software can wait for the IFSW interrupt which signals IFSM recovery and the working state for this link. When processing the IFSW interrupt it is recommended that the IFSD is unmasked.

- Link (IMA) frame synchronization working (IFSW)—The link has achieved frame synchronization. This event is reported when a link has been assigned to a group (startup or link addition) or it was previously assigned and working, but had a defect (see IFSD event). If going from defect to working, the software should update the RxDefect field of the ICP. Again, a time stamp (timer) can be used to measure the persistence time.
- DCB synchronization lost (DSL)—A link in a group with IGRSTATE[GDSS] = 11 loses synchronization and enters HUNT state at the IFSM. Because the link has lost synchronization, its differential delay with respect to other member links in the group must recalculated via the LDS.

When this interrupt occurs, software should remove or deactivate the link because the QUICC Engine module does not automatically perform the LASR procedure. Note that when the interrupt is generated the ILRSTATE[DL] bit is set. If the link is to be added to the group again, software can perform the link removal or deactivation procedure described in Section 43.5.3.6, “Link Removal Procedure or Section 43.5.3.7, “Link Receive Deactivation Procedure. The link can then be re-added to the group using the link addition procedure see Section 43.5.3.5, “Link Addition Procedure for a removed link or Section 43.5.3.8, “Link Receive Reactivation Procedure for a deactivated link. For fast recovery from the DSL event the software should perform the following tasks:

— Link deactivation see Section 43.5.3.7, “Link Receive Deactivation Procedure
— Poll ILRSTATE[FSES] checking for WORKING state, ILRSTATE[FSES] = 0b00. The poll of ILRSTATE[FSES] must last at least (GAMMA +1) IMA frames.
— If WORKING state is reached then perform reactivation see Section 43.5.3.8, “Link Receive Reactivation Procedure
— Else if ILRSTATE[FSES] = 0b1x then the DEFECT state has been reached and an IFSD event will be generated for this link.

The relationship of the DSL interrupt versus the IFSD interrupt is depicted in Figure 43-34. The DSL interrupt is issued when the IFSM reaches the HUNT state. The SYNC to HUNT transition also creates the ANOMALY state for the IMA Error and Maintenance State Diagram. The link can recover from the ANOMALY state and return to the WORKING state before an IFSD. The DSL is issued only for links that have achieved GDS or LDS or for links that have started but not completed the LDS process.

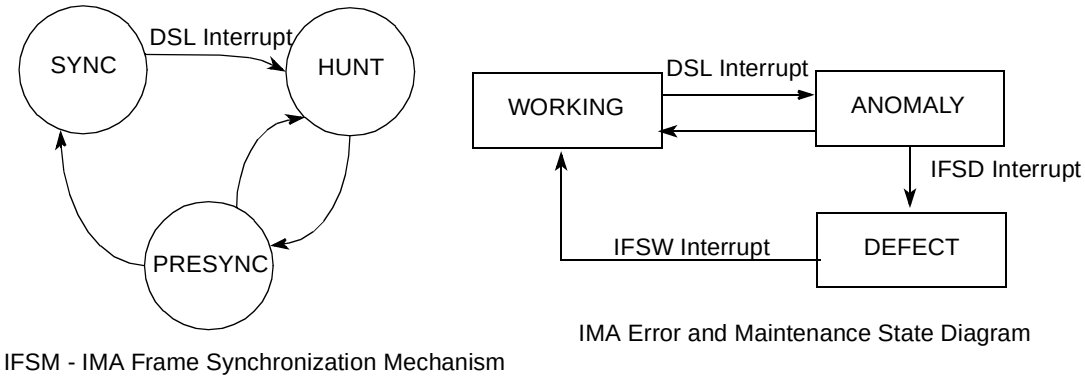

Figure 43-34. Receive Event Generation For ATM Forum IMA State Machines

43.5.3.11 Test Pattern Procedure

Test patterns verify the “connectivity” of a link in a particular group. Through an ICP cell, the NE requests that a test pattern be looped back to the FE over all links currently in the group. For this test, the FE looks only at ICP cells received over the link being tested (LID = x). Upon receiving an ICP cell, the FE echoes the pattern back to the NE over all the links in the group. The major task of initiating and verifying the pattern on all the links in the group falls on the software. The processor simply transmits and receives the

modified/changed ICP cells. If the software detects that the FE has echoed the pattern, connectivity is verified.

43.5.3.11.1 As Initiator (NE)

Alter the (unused) ICP cell template to the “Test Link” command to the FE:

1. Tx Test Control = Set to “Active” and select LID (link) to be tested.
2. Tx Pattern = X (0–255).
3. Increment SCCI.
4. Make this the active ICP template (see Section 43.5.3.1, “Transmit ICP Cell Signaling”).
5. Repeat steps 1–4 until the expected pattern is received in any of the incoming ICP cells (alternate ICP templates must be used).

After the request is sent to perform the test (pattern) to the FE, the NE software must wait for the TX test pattern to be echoed back/received in the RX Pattern field of the ICP cell (any of the active links in the group can be monitored for the RX Pattern). After verifying connectivity, the test can be deactivated (set Tx Test Control = “Inactive” and repeat steps 3 and 4).

43.5.3.11.2 As Responder (FE)

When the FE receives a request to perform the pattern test on any active links, it must monitor the selected link (see Tx LID of Tx Test Control) for reception of an ICP cell. It must also monitor the other links’ ICP cells and ensure that all links in the group have a valid Test Link Command field. After verifying that all links in the group have a valid Test Link Command field in their ICP cells, software should copy the Tx Pattern from the test link to the Rx Pattern field of the ICP Cell and transmit the ICP cell. Alter the ICP cell:

1. Rx Pattern = Tx Pattern (of received ICP Cell).
2. Increment SCCI
3. Make this the active ICP template (see Section 43.5.3.1, “Transmit ICP Cell Signaling”).
4. Repeat steps 1-3 until the test is inactive.

To comply with this requirement all links in the group must have MON_ICP bit set:

1. Monitor link for changes in SCCI: ILRCNTL[MON_ICP] = 1.

The IMA microcode passes to the ICP cell queue all received ICP cells with a Link Test Command field displaying the active state. This is true regardless of the SCCI value received. The SCCI field is ignored in this case in order to comply with the requirement that all links in the group must detect a Link Test Command field in the active state before passing the test link’s Tx Test Pattern field to the transmitter’s Rx Test Pattern field.

43.5.3.12 End-to-End Channel Signaling Procedure

43.5.3.12.1 Transmit

Software can use the end-to-end channel signaling field to signal to the far end. Because the end-to-end channel is not covered by the SCCI field and there are no standard requirements for the minimum number

of frames between changes of the end-to-end channel field, it is not necessary to follow the procedure for ICP cell signaling to do this; instead, the end-to-end channel field of the ICP template currently in use can be directly updated. However, if a minimum number of frames between changes is desired, then the procedure for ICP cell signaling can be used, skipping the step in which the SCCI is updated.

43.5.3.12.2 Receive

No special facility is included for reception of the end-to-end channel. The end-to-end channel field is part of the received ICP cells, so its information can be read by software from those cells. However, ICP cells are only received when the SCCI field changes, so changes in the end-to-end channel will not be received until the SCCI field also changes (when there is a change in the status and/or control of the far end).

Chapter 44
Universal Serial Bus Controller

The universal serial bus (USB) controller provides communication with other devices through a USB connection.This chapter describes the QUICC Engine USB controller, including basic operation, the parameter RAM, and registers.

44.1 Overview

The USB controller is an industry-standard extension to the PC architecture. The QUICC Engine USB controller supports data exchange between a wide range of simultaneously accessible peripherals. Attached peripherals share USB bandwidth through a host-scheduled, token-based protocol.

The USB physical interconnect is a tiered-star topology, and the center of each star is a hub. Each wire segment is a point-to-point connection between the host and a hub or function, or a hub connected to another hub or a function. The USB transfers signal and power over a four-wire cable, and the signaling occurs over two wires and point-to-point segments. The USB full-speed signaling bit rate is 12 Mbps. Also, a limited capability low-speed signaling mode is defined at 1.5 Mbps. Refer to *USB Specification Revision 2.0*. This specification can be downloaded from http://www.usb.org.

The QUICC Engine USB controller consists of a transmitter module, receiver module, and two protocol state machines. The protocol state machines control the receiver and transmitter modules. One state machine implements the function state diagram and the other implements the host state diagram. The USB controller can implement a USB function endpoint, a USB host, or both for testing purposes (loopback diagnostics).

44.1.1 USB Controller Key Features

The USB function mode features are as follows:

- Four independent endpoints support control, bulk, interrupt, and isochronous data transfers
- CRC16 generation and checking
- CRC5 checking
- NRZI encoding/decoding with bit stuffing
- 12- or 1.5-Mbps data rate
- Flexible data buffers with multiple buffers per frame
- Automatic retransmission upon transmit error

The USB host controller features are as follows:

- Supports control, bulk, interrupt, and isochronous data transfers
- CRC16 generation and checking

- NRZI encoding/decoding with bit stuffing
- Supports both 12- and 1.5-Mbps data rates (automatic generation of preamble token and data rate configuration). Note that low-speed operation requires an external hub.
- Flexible data buffers with multiple buffers per frame
- Automatic transmission of SOF (Start-of-Frame) tokens
- Supports local loopback mode for diagnostics (12 Mbps only)

44.2 Host Controller Limitations

The following tasks are not supported by the hardware and must be implemented in software:

- Scheduling the various transfers within and between frames
- Retransmission after an error and error recovery

Additionally, when the packet-level interface described in Section 44.4.1.1, “Packet-Level Interface” is in use, the tokens must be prepared by the software. Because the QUICC Engine USB host controller does not integrate the root hub, an external hub is required when more than one device is connected to the host. Also, note that the host controller programming model does not conform to the open host controller interface (OHCI) or universal host controller interface (UHCI) standards in which software drivers are hardware-independent.

44.2.1 USB Controller Pin Functions and Clocking

The USB controller interfaces to the USB bus through a differential line driver and differential line receiver. The $\overline{\text{OE}}$ (output enable) signal enables the line driver when the USB controller transmits on the bus.

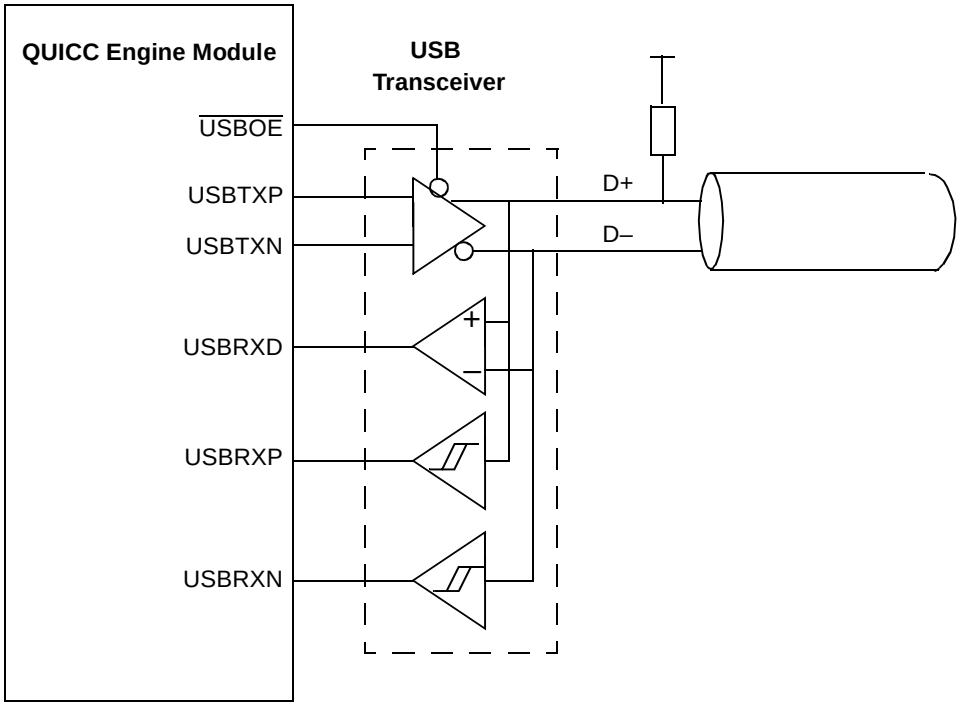

Figure 44-1. USB Interface

The DPLL circuitry uses the reference clock for the USB controller (USBCLK) to recover the bit rate clock. The source for USBCLK is selected by GMXGCR[USBCS]; see Section 21.5.1, "CMX General Clock Route Register (CMXGCR)." The QUICC Engine module can run at different frequencies, but the USB reference clock must be four times the USB bit rate. Thus, USBCLK must be 48 MHz for a 12-Mbps full-speed transfer or 6 MHz for a 1.5-Mbps low-speed transfer.

There are six I/O pins associated with the USB port. Their functionality is described in Table 44-1. Additional control lines that might be needed by some transceivers (for example, speed select, low-power control) may be supported by general purpose output lines.

Table 44-1. USB Pin Functions

<table>
<tr><th>Signal</th><th>I/O</th><th>Function</th></tr>

</td></tr>
</table>

44.3 USB Function Description

As shown in Figure 44-2, the USB function consists of transmitter and receiver sections and a control unit. The USB transmitter contains four independent FIFOs, each containing 16 bytes. There is a dedicated FIFO for each of the four supported endpoints. The USB receiver has a single 16-byte FIFO.

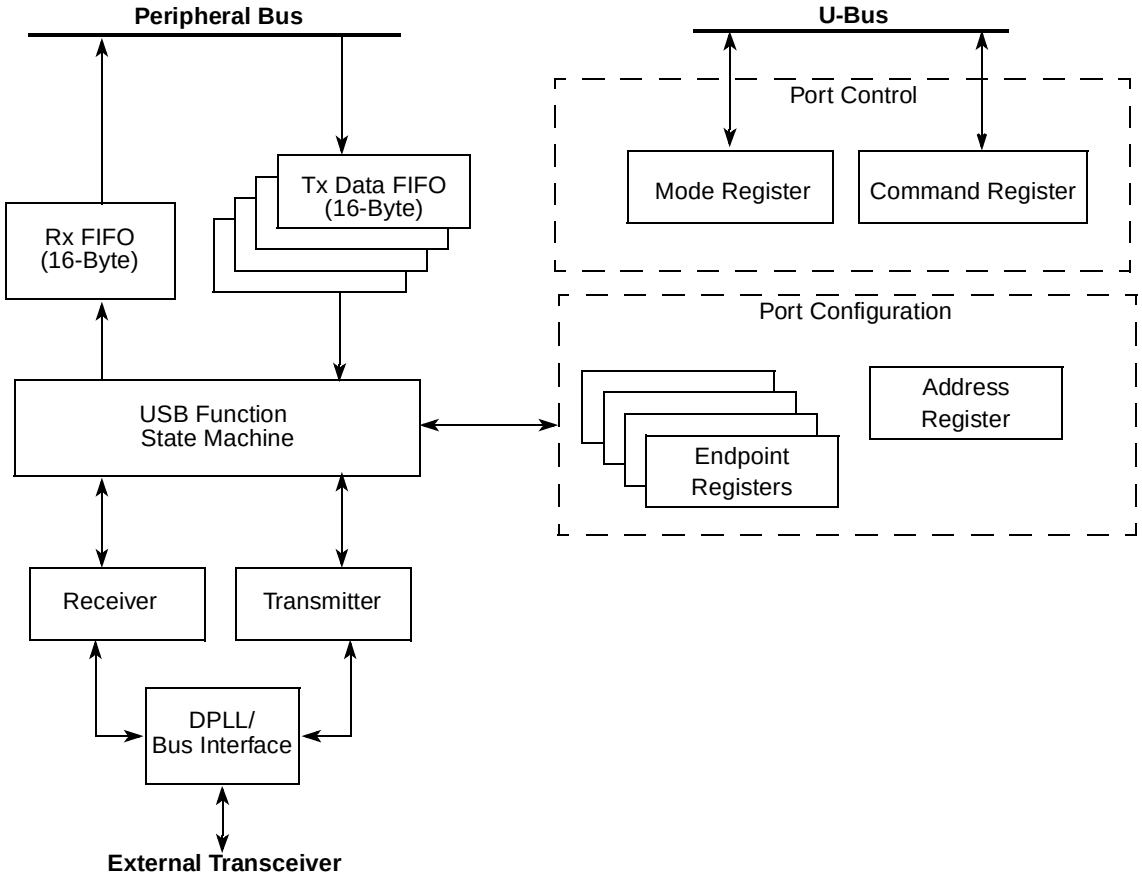

Figure 44-2. USB Function Block Diagram

44.3.1 USB Function Controller Transmit/Receive

After reset condition, the USB function is addressable at the default address (0x00). During the enumeration process the USB function is assigned by the host with a unique address. The USB slave address register (refer to Section 44.4.7.2, “USB Slave Address Register (USADR)”) should be programmed with the assigned address. The USB function controller supports four independent endpoints. Each endpoint can be configured to support either control, interrupt, bulk, or isochronous transfers modes. This is done by programming the endpoint registers (refer to Section 44.4.7.3, “USB Endpoint Registers (USEP0–USEP3)”).

NOTE

It is mandatory that endpoint 0 be configured as a control transfer type. The USB system software uses this endpoint as a control pipe. Additional control pipes can be provided by other endpoints.

After it is enabled, the USB function controller looks for valid token packets. Figure 44-3 and Table 44-2 describe the behavior of the USB controller for each token. The USB function controller ignores tokens that are not valid (that is, PID check fails or CRC check fails or packet length is not 3 bytes).

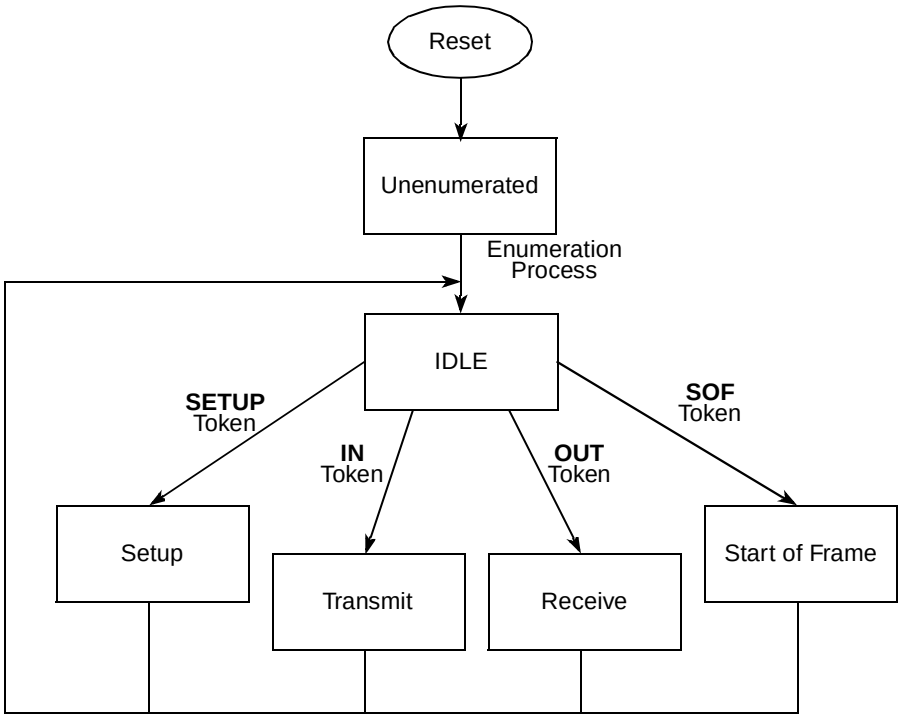

Figure 44-3. USB Controller Operating Modes

Table 44-2. USB Tokens

<table>
<tr><th>Token</th><th>Description</th></tr>
<tr><td>OUT</td><td>Reception begins when an OUT token is received. The USB controller fetches the next BD associated with the endpoint; if the BD is empty, the controller starts sending the incoming packet to the buffer. After the buffer is full, the USB controller clears RxBD[E] and generates an interrupt if RxBD[I] = 1. If the incoming packet is larger than the buffer, the USB controller fetches the next BD, and, if it is empty, sends the rest of the packet to its buffer. The entire packet, including the DATA0/DATA1 PID, are written to the receive buffers. Software must check data packet synchronization by monitoring the DATA0/DATA1 PID sequence toggle.

If the packet reception has no CRC or bit stuff errors, the USB receiver sends the handshake selected in the endpoint configuration register USEPn[RHS] (see table below) to the host. If an error occurs, no handshake packet is returned and error status bits are set in the last RxBD associated with this packet.

USB Out Token Reception
<table><tr><th>USEPn[RHS]</th><th>Data Packet Corrupted</th><th>Handshake Sent to Host</th></tr><tr><td>xx</td><td>Yes</td><td>None (data discarded)</td></tr><tr><td>00 (Normal)</td><td>No</td><td>ACK</td></tr><tr><td>01 (Ignore)</td><td>No</td><td>None</td></tr><tr><td>10 (NAK)</td><td>No</td><td>NAK</td></tr><tr><td>11 (STALL)</td><td>No</td><td>STALL</td></tr></table></td></tr>
<tr><td>IN</td><td>To guarantee a transfer, the control software must preload the endpoint FIFO with a data packet before receiving an IN token. Software should set up the endpoint TxBD table and set USCOM[STR]. The USB controller fills the transmit FIFO and waits for the IN token. When the token is received and the FIFO is loaded with the last data byte or with at least four bytes, transmission begins. The four-byte minimum is a threshold to prevent underruns in the FIFO. If data is not ready in the transmit FIFO or if USEPn[THS] is set to respond with NAK, a NAK handshake is returned. If USEPn[THS] is set to respond with STALL, a STALL handshake is returned, as shown in the following table. When the end of the last buffer is reached (TxBD[L] is set), the CRC is appended. After the frame is sent, the USB controller waits for a handshake packet. If the host fails to acknowledge the packet, the timeout status bit TxBD[TO] is set. Software must set the proper DATA0/DATA1 PID in the transmitted packet.

USB In Token Reception
<table><tr><th>USEPn[THS]</th><th>FIFO Loaded</th><th>Handshake Sent to Host</th></tr><tr><td rowspan="2">00 (Normal)</td><td>No</td><td>NAK (data discarded)</td></tr><tr><td>Yes</td><td>Data packet is sent</td></tr><tr><td>01 (Ignore)</td><td>—</td><td>None</td></tr><tr><td>10 (NAK)</td><td>—</td><td>NAK (data discarded)</td></tr><tr><td>11 (STALL)</td><td>—</td><td>STALL</td></tr></table></td></tr>
</table>

Table 44-2. USB Tokens (continued)

Token	Description
SETUP	The format of setup transactions is similar to OUT but uses a SETUP rather than an OUT PID. A SETUP token is recognized only by a control endpoint. When a SETUP token is received, setup reception begins. The USB controller fetches the next BD associated with the endpoint; if it is empty, the controller starts transferring the incoming packet to the buffer. When the buffer is full, the USB controller clears RxBD[E] and generates an interrupt if RxBD[I] = 1. If the incoming packet is larger than the buffer, the USB controller fetches the next BD and, if it is empty, continues transferring the rest of the packet to this buffer. The entire data packet including the DATA0 PID is written to the receive buffers. If the packet was received without CRC or bit stuff errors, an ACK handshake is sent to the host. If an error occurs, no handshake packet is returned and error status bits are set in the last RxBD associated with this packet.
Start of frame (SOF)	When an SOF packet is received, the USB controller issues a SOF maskable interrupt and the frame number entry in the parameter RAM is updated.
Preamble (PRE)	The PRE token signals the hub that a low-speed transaction is about to occur. The PRE token is read only by the hub. The USB controller ignores the PRE token function in function mode.

44.4 USB Host Description

When programmed as a host, the USB controller supports a limited host functionality. The following sections describe the available host functionality, its limitations, and the programming model (see Figure 44-4). The USB controller consists of transmitter and receiver sections, a host control unit, and a function control unit for testing purposes. The USB transmitter contains four independent FIFOs, each containing 16 bytes. Endpoint 0 is dedicated to host transactions; endpoints 1–3 are for function transactions in test mode. There is a dedicated FIFO for each of the four supported endpoints; the endpoint 0 FIFO is for host transactions. The USB receiver has a single 16-byte FIFO.

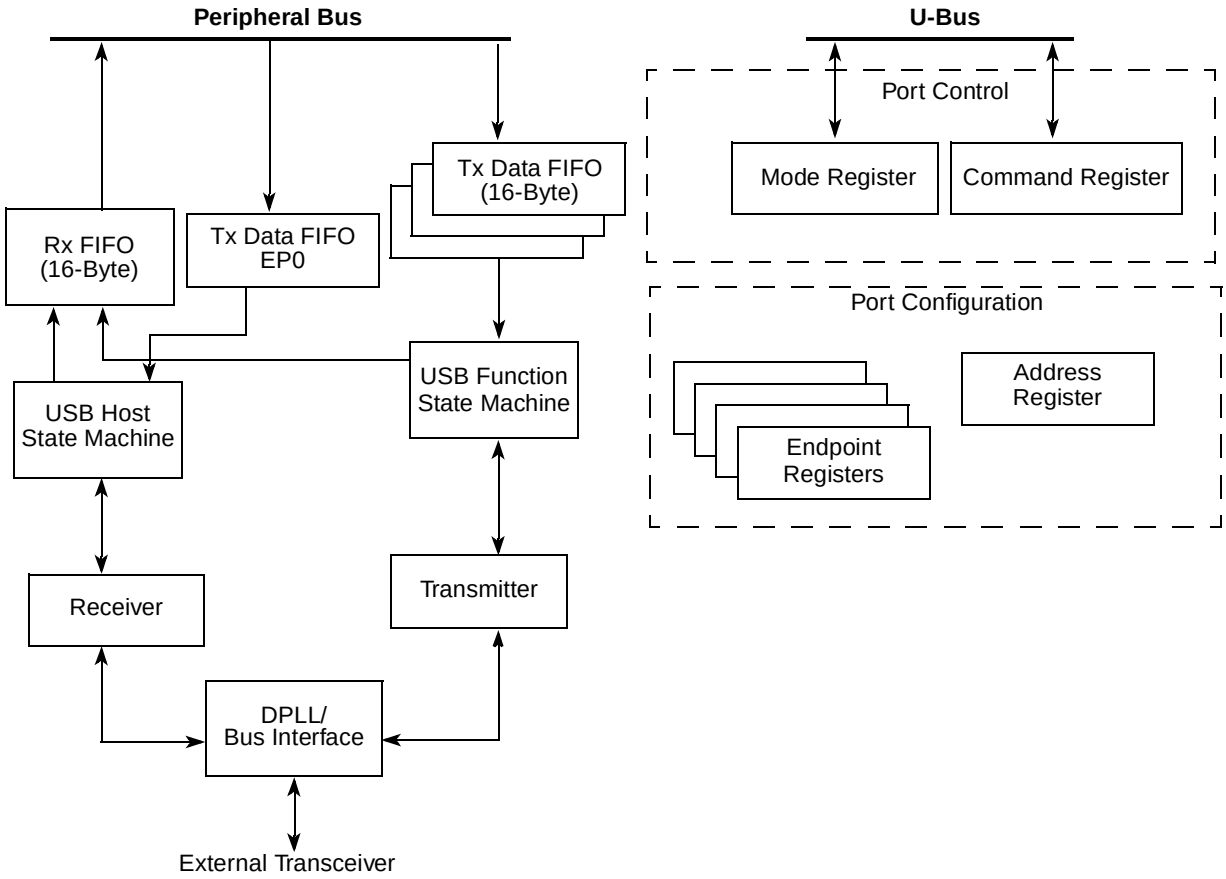

Figure 44-4. USB Controller Block Diagram

44.4.1 USB Host Controller Transmit/Receive

The USB host controller initiates all USB transactions in the system. After reset, the USMOD[HOST] bit should be set to enable host operation (refer to Section 44.4.7.1, “USB Mode Register (USMOD)”). USEP1 should be programmed for host operation as described in Section 44.4.7.3, “USB Endpoint Registers (USEP0–USEP3).”

After it is enabled by setting the USMOD[EN] bit, the USB host controller waits for a packet in its transmit FIFO. When the FIFO contains data for transmission, the host transaction begins. Figure 44-3 and Table 44-2 describe the behavior of the USB host controller for each transaction. Low-speed transactions start with a preamble that is generated by the USB host controller state machine when the TxBD[LSP] bit is set. When USMOD[TEST] is programmed, both the host state machine and function state machine are active. Endpoints 2–4 receive/transmit data according to tokens received from host. For the programming model and a functional description, see Section 44.4.7, “USB Function Programming Model.”

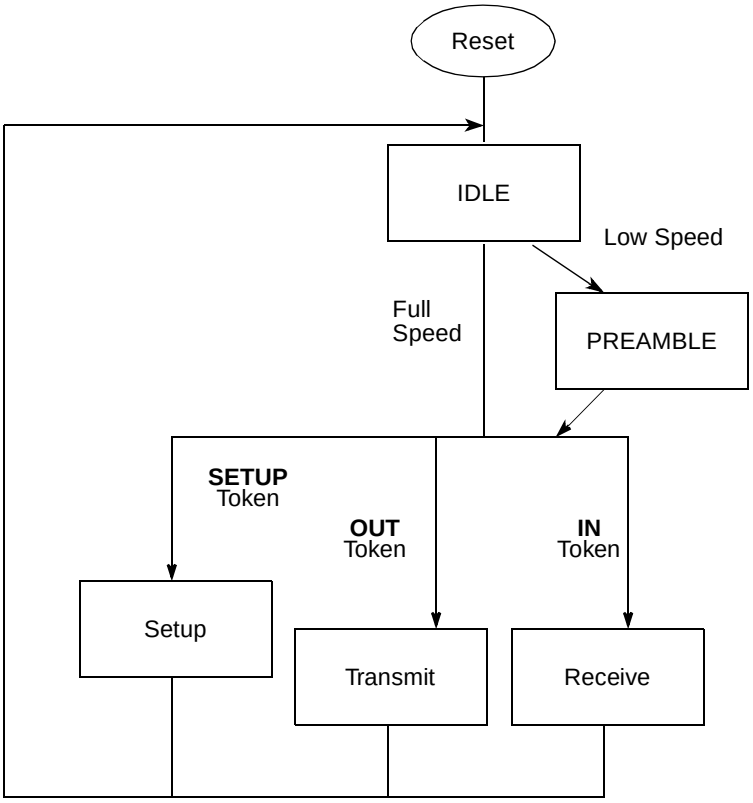

Figure 44-5. USB Controller Operating Modes

44.4.1.1 Packet-Level Interface

If USEP0[RTE] is cleared, the USB host controller uses a packet-level interface to communicate with the user. Each transmit packet is prepared in a buffer and referenced by a TxBD as described in Section 44.5.3, "USB Transmit Buffer Descriptor (TxBD) for Host." Each receive packet is stored in a buffer referenced by a RxBD as described in Section 44.5.1, "USB Receive Buffer Descriptor (RxBD) for Host and Function." A SETUP or OUT transaction requires at least two TxBDs, one for the token and one or more for the data packet. An IN transaction requires one TxBD for the token and one or more RxBDs for the data packet. Tokens are not checked for validity and are transmitted as is. The user is responsible for token validity as well as CRC5 generation.

44.4.1.2 Transaction-Level Interface

If USEP0[RTE] is set, the USB host controller uses a transaction-level interface to communicate with the user. Each transaction uses one TrBD as described in Section 44.5.4, "USB Transaction Buffer Descriptor (TrBD) for Host." The USB host controller generates the token based on TrBD[TOK]. For SETUP and OUT transactions, the TrBD points to a single buffer containing the data packet to be transmitted. For IN transactions, the TrBD points to a single buffer that is used for the receive data packet.

Table 44-3. USB Tokens

<table>
<tr><th>Token</th><th colspan="2">Description</th></tr>
<tr><td>OUT</td><td>Packet-Level Interface

Transmission begins when the USB host controller fetches a TxBD containing an OUT token and a data TxBD and loads them to the host FIFO. The token and data are transmitted and a handshake is expected.
If a handshake is not received within the expected time interval, the USB controller clears TxBD[R] of data BD, sets the TxBD[TO] indication and generates a TXE1 interrupt. When STALL or NAK is received within the expected time interval, the USB controller clears TxBD[R] of data BD, sets the TxBD[STALL] or TXBD[NAK] indication, and generates a TXE1 interrupt. When ACK is received within the expected time interval, the USB controller clears TxBD[R] of data BD, and generates an interrupt if TxBD[I] = 1. No indication is set. The token TxBD[R] is cleared right after the OUT token transmission.</td><td>Transaction-Level Interface

Transmission begins when the USB host controller fetches a TrBD with the TOK field indicating an OUT transaction. The token is generated and then the data packet from the buffer is transmitted and a handshake is expected. If a handshake is not received within the expected time interval, the USB controller clears TrBD[R], sets the TrBD[TO] indication and generates a TXE1 interrupt. When STALL or NAK is received within the expected time interval, the USB controller clears TrBD[R], sets the TrBD[STALL] or TrBD[NAK] indication and generates a TXE1 interrupt. When ACK is received within the expected time interval, the USB controller clears TrBD[R], and generates a TXB interrupt if TrBD[I] = 1.No indication is set.</td></tr>
</table>

USB Out Transaction

Token	Data	Handshake Received by Host	Indication on TxBD/TrBD
OUT	Sent by host	None	TO
		ACK	None
		NAK	NAK
		STALL	STALL

Table 44-3. USB Tokens (continued)

<table>
<tr><th>Token</th><th colspan="2">Description</th></tr>
<tr><td>IN</td><td>Packet-Level Interface

Transmission begins when the USB host controller fetches a TxBD containing an IN token and loads the token to FIFO. After the IN token is transmitted the USB host controller waits for reception of data within expected time interval. On reception of a valid DATA PID an RxBD is fetched. The received data and DATA PID are stored in receive FIFO. If RxBD[E] is set PID and data is moved to the buffer. While receiving the data the USB host controller calculates CRC16, performs bit un-stuffing. On end of reception calculated CRC is compared to received and octet alignment is checked, RxBD[E] is cleared, RxBD[PID] is set according to received DATA PID and error indications are set if required:RxBD[CR] for failed CRC check, RxBD[NO] for non-octet sized data and RxBD[AB] if bit stuffing error occurred.
If no valid DATA PID or no data at all received during the expected time interval a TO indication in the token TxBD is set.</td><td>Transaction-Level Interface

Transmission begins when the USB host controller fetches a TrBD with the TOK field indicating an IN transaction. After the IN token is generated and transmitted, the USB host controller waits for reception of data within the expected time interval. The received data packet is stored in buffer reference by the TrBD. While receiving the data the USB host controller calculates CRC16 and performs bit un-stuffing. At end of the packet, the calculated CRC is compared to the received value and octet alignment is checked, TrBD[R] is cleared, TrBD[PID] is set according to the received DATA PID and error indications are set if required: TrBD[CR] for failed CRC check, TrBD[NO] for non-octet sized data and TrBD[AB] if bit stuffing error occurred. If any of the above errors are reported, TrBD[RXER] is also set, and a TXE1 interrupt is generated. If no valid DATA PID or no data at all received during the expected time interval, a TrBD[TO] is set and a TXE1 interrupt is generated. If no errors occurred and TrBD[I] is set, a TXB interrupt is generated to indicate successful completion of the transaction.</td></tr>
<tr><td colspan="3">USB In Transaction

<table>
<tr><th>Token</th><th>Data Transmitted by Function</th><th>Handshake Generated by Host</th><th>Indication on BD</th></tr>
<tr><td rowspan="3">IN</td><td>Received correctly</td><td>ACK</td><td>RxBD[E]/TrBD[R] is cleared</td></tr>
<tr><td>Received corrupted</td><td>None</td><td>RxBD[CR]/TrBD[CR] or RxBD[AB]/TrBD[AB] or RxBD[NO]/TrBD[NO]</td></tr>
<tr><td>None</td><td>None</td><td>TxBD[TO]/TrBD[TO]</td></tr>
</table>
</td></tr>
<tr><td>SETUP</td><td colspan="2">The format of setup transactions is similar to OUT but uses a SETUP rather than an OUT PID. A SETUP token is recognized only by a control endpoint and cannot be answered with NAK or STALL, therefore, the host expects either an ACK or no handshake at all.</td></tr>
<tr><td>Start of Frame (SOF)</td><td colspan="2">SOF is generated every 1 ms. The timing must be exact and is controlled by an internal timer. From the host state machine point of view it is a packet to transmit, placed in its FIFO, transmitted as is.</td></tr>
<tr><td>Preamble (PRE)</td><td colspan="2">The PRE token signals the hub that a low-speed transaction is about to occur. The PRE token is read only by the hub. The USB host controller generates a full-speed PRE token before sending a packet to a low-speed peripheral.</td></tr>
</table>

44.4.2 SOF Transmission for USB Host Controller

The mechanism used by the USB host controller to support the automatic transmission of SOF tokens is enabled by setting USMOD[SFTE]. SOF packets should be transmitted every 1 ms. Because the time interval between two SOF packets must be more precise than software can accomplish, a hardware timer is used to trigger the generation and transmission of SOF tokens. When the timer expires, the frame number (stored in the USB Frame Number register) is incremented, and an SOF token is generated and loaded to the host endpoint. When the SOF token is loaded to the FIFO, it is transmitted like any other packet.

The application software should guarantee that the USB host completes all pending transactions prior to the 1 ms tick so that the transmit FIFO is empty at this point.The current value of the SOF timer and frame number can be read at any time to synchronize the software with the USB frames. See Section 44.4.7.8, "USB Start of Frame Timer (USSFT)" and Section 44.4.7.9, "USB Frame Number (USFRN)." Failure to ensure that the FIFO is empty at the end of the frame period may result in the SOF packet not being transmitted. This situation is reported by setting the MSF bit of the USB Event Register.

44.4.3 USB Function and Host Parameter RAM Memory Map

The USB controller parameter RAM area, shown in Table 44-4, begins at the USB base address, 0x8B00 (offset from RAM_Base). Note that the user must initialize certain parameter RAM values before the USB controller is enabled.

Table 44-4. USB Parameter RAM Memory Map

Address	Name[1]	Width	Description
USB Base + 00	**EP0PTR**	Half word	Endpoint pointer registers 0–3. The endpoint parameter block pointers are index pointers to each endpoint's parameter block. Parameter blocks can be allocated to any address divisible by 32 in the dual port RAM. See Figure 44-6. The map of the endpoint parameter block is shown in Table 44-5 **Note**: When USB host mode is set **EP0PTR** must be used for the host endpoint.
USB Base + 02	**EP1PTR**	Half word	
USB Base + 04	**EP2PTR**	Half word	
USB Base + 06	**EP3PTR**	Half word	
USB Base + 08	RSTATE	Word	Receive internal state. Reserved for QUICC Engine module use only. Should be cleared before the USB controller is enabled.
USB Base + 0C	RPTR	Word	Receive internal data pointer. Updated by the SDMA channels to show the next address in the buffer to be accessed.
USB Base + 10	**FRAME_N**	Half word	Frame number.
USB Base + 12	RBCNT	Half word	Receive internal byte count. A down-count value that is initialized with the MRBLR value and decremented with every byte written by the SDMA channels.
USB Base + 14	RTEMP	Word	Receive temp. Reserved for QUICC Engine module use only.
USB Base + 18	RXUSB_ Data	Word	Rx Data temp
USB Base + 1C	RXUPTR	Half word	Rx microcode return address temp

[1] The items in **boldface** should be initialized by the user before the USB controller is enabled; other values are initialized by the QUICC Engine module..

After they are initialized, the parameter RAM values do not normally need to be accessed by user software. They should only be modified when no USB activity is in progress.

44.4.4 Endpoint Parameters Block Pointer (EP*n*PTR)

EP*n*PTR are DPRAM indices to an endpoint parameter block, which can be allocated to any address that is divisible by 32. The format of the endpoint pointer registers (EP*n*PTR) is shown in Figure 44-6.

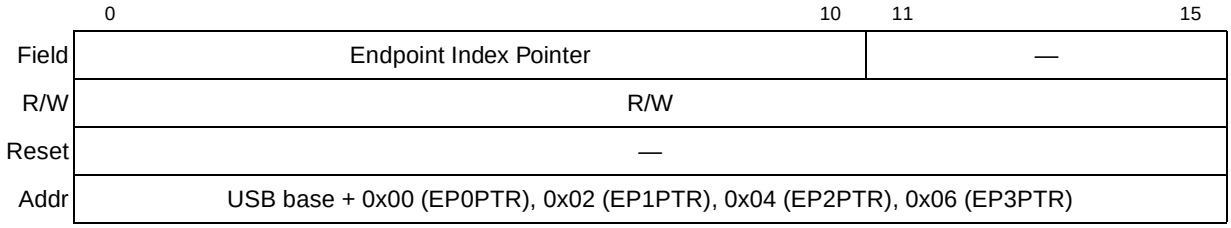

Figure 44-6. Endpoint Pointer Registers (EP*n*PTR)

The map of the endpoint parameter block is shown in Table 44-5.

Table 44-5. Endpoint Parameter Block

Offset[1]	Name[2]	Width	Description
0x00	**RBASE**	16 bits	RxBD/TxBD base addresses. Define the starting location in dual-port RAM for the USB controller's TxBDs and RxBDs. This provides flexibility in how BDs are partitioned. Setting W in the last BD in each list determines how many BDs to allocate for the controller's send and receive sides. These entries must be initialized before the controller is enabled. Overlapping USB BD tables with another serial controller's BDs causes erratic operation. RBASE and TBASE values should be divisible by 8. When the transaction-level interface is used in host mode, TBASE points to the TrBD ring, and RBASE is unused.
0x02	**TBASE**	16 bits	
0x04	**RBMR**	8 bits	Rx/Tx Bus Mode registers. They contain the transaction specification associated with DMA channel accesses to external memory. See Section 44.4.6, "USB Bus Mode Registers (RBMR and TBMR)."
0x05	**TBMR**	8 bits	
0x06	**MRBLR**	16 bits	Maximum receive buffer length. Defines the maximum number of bytes the QUICC Engine module writes to the USB receive buffer before moving to the next buffer. MRBLR must be divisible by 4. The QUICC Engine module can write fewer data bytes to the buffer than the MRBLR value if a condition such as an error or end-of-packet occurs, but it never exceeds MRBLR. Therefore, user-supplied buffers should never be smaller than MRBLR. MRBLR is not designed to be changed dynamically for the currently active RxBD during USB operation; however, MRBLR can be modified safely for the next and subsequent RxBDs using a single bus cycle with one 16-bit move (not two 8-bit bus cycles back-to-back). Transmit buffers for the USB controller are not affected by the MRBLR value. Transmit buffer lengths can vary individually, as needed. The number of bytes to be sent is chosen by programming TxBD[Data Length]. When using the transaction-level interface in host mode, this field is used by the QUICC Engine module and does not have to be initialized by the user.

Table 44-5. Endpoint Parameter Block (continued)

Offset[1]	Name[2]	Width	Description
0x08	**RBPTR**	16 bits	RxBD pointer. Points to the next BD the receiver transfers data to when it is in an idle state or to the current BD while processing a frame. Software should initialize RBPTR after reset. When the end of the BD table is reached, the QUICC Engine module initializes this pointer to the value programmed in RBASE. Although the user does not need to write RBPTR in most applications (except initialization), it can be changed when the receiver is disabled or when no receive buffer is being used. When the transaction-level interface operates in host mode, this field is unused.
0X0A	**TBPTR**	16 bits	TxBD pointer. Points to the next BD that the transmitter transfers data from when it is in an idle state or to the current BD during frame transmission. Software should initialize TBPTR after reset. When the end of BD table is reached, the QUICC Engine module. initializes this pointer to the value programmed in the TBASEn entry. Although the user never needs to write TBPTR, in most applications (except initialization), it can be changed when the transmitter is disabled or when no transmit buffer is being used.
0X0C	TSTATE[3]	32 bits	Transmit internal state. Reserved for QUICC Engine module use only. Should be cleared before enabling the USB controller.
0x10	TPTR[3]	32 bits	Transmit internal data pointer. Updated by the SDMA channels to show the next address in the buffer to be accessed.
0x14	TCRC[3]	16 bits	Transmit temp CRC. Reserved for QUICC Engine module use only.
0x16	TBCNT[3]	16 bits	Transmit internal byte count. A down-count value that is initialized with the TxBD data length and decremented with every byte read by the SDMA channels.
0x18	TTEMP	32 bits	Tx temp
0x1C	TXUSBU_PTR	16 bits	Tx microcode return address temp
0x1E	Reserved	16 bits	

1 Offset from endpoint parameter block base.
2 Note that the items in **boldface** should be initialized by the user.
3 These parameters need not be accessed in normal operation but may be helpful for debugging.

44.4.5 Frame Number (FRAME_N)

FRAME_IN is used for frame number updates in both function mode and host mode. In function mode, it is written by the USB controller; in host mode it is written by the application software and the USB controller. This entry is updated by the USB controller in function mode when an SOF (start of frame) token is received, including the SOF token it transmitted in host mode. The entry contains 11 bits that represent the frame number. An SOF interrupt is issued upon an update of this entry.

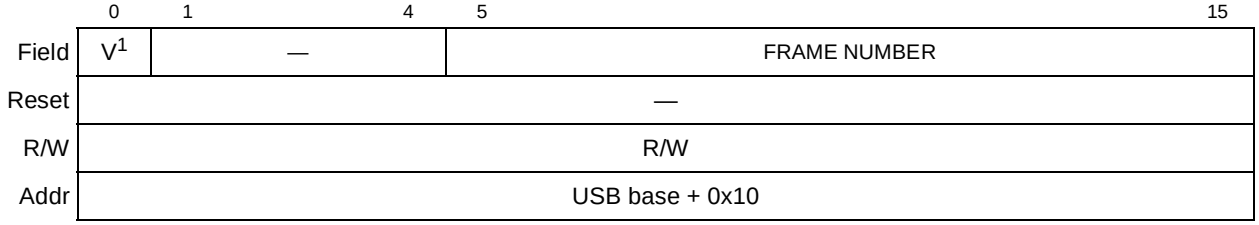

Figure 44-7. Frame Number (FRAME_N) in Function Mode—Updated by USB Controller

[1] This bit is set if the SOF token is received error free.

Table 44-6 describes FRAME_N fields in function mode.

Table 44-6. FRAME_N Field Descriptions

Bits	Name	Description
0	V	The valid bit is set if the SOF token is received without error.
1–4	—	Reserved, should be cleared.
5–15	FRAME NUMBER	The frame number is loaded with the value received in the SOF packet. Be sure the frame number is cleared before beginning USB operation.

In host mode, this entry must be updated by the application software between the transmission of one SOF (start of frame) token and the next. See Section 44.4.1.2, “Transaction-Level Interface,” for details. The software should prepare the frame number and the CRC and place it in FRAME_N field.

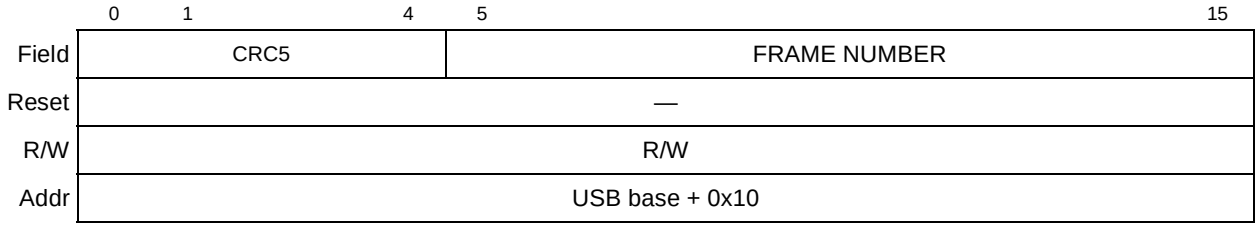

Figure 44-8. Frame Number (FRAME_N) in Host Mode—Updated by Application Software

Table 44-7 describes FRAME_N fields in host mode.

Table 44-7. FRAME_N Field Descriptions

Bits	Name	Description
0–4	CRC5	CRC5 calculated on frame number
5–11	FRAME NUMBER	The frame number is inserted by the application software.

44.4.6 USB Bus Mode Registers (RBMR and TBMR)

Figure 44-9 shows the fields in the receive/transmit bus mode registers.

	0	1	2	3	4	5	6	7
Field	—		GBL	BO		CETM	DTB	—

Figure 44-9. USB Bus Mode Registers (RBMR and TBMR)

Table 44-8 describes RBMR and TBMR fields.

Table 44-8. RBMR and TBMR Fields

Bits	Name	Description
0–1	—	Reserved, should be cleared.
2	GBL	Global 0 Snooping disabled 1 Snooping enabled To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”
3–4	BO	Byte ordering The user configures 00, 01, 11 Reserved 10 Big-endian byte ordering. As data is transmitted onto the serial line from the data buffer, the most-significant byte of the buffer word contains data to be transmitted earlier than the least-significant byte of the same buffer word.
5	CETM	QUICC Engine Transaction Mark The level of this bit is reflected on the main system bus on signal M1SCRD4 or M2SCRD4 or LSRCRD4 depending on the actual external bus where the transaction occurs. This is useful to mark on the bus the transactions initiated by the QUICC Engine module, for debug purposes.
6	DTB	Indicates on what bus the data is located 0 On the coherent system bus (CSB) 1 On the QUICC Engine secondary bus
7	—	Reserved, should be cleared.

44.4.7 USB Function Programming Model

The following sections describe USB controller registers.

44.4.7.1 USB Mode Register (USMOD)

USMOD, shown in Figure 44-10, controls the USB controller operation mode.

	0	1	2	3	4	5	6	7
Field	LSS	RESUME	—		SFTE	TEST	HOST	EN
Reset	0000_0000							
R/W	R/W							
Addr	0x006C0							

Figure 44-10. USB Mode Register (USMOD)

Table 44-9 describes USMOD fields.

Table 44-9. USMOD Fields

Bits	Name	Description
0	LSS	Low-speed signaling. Selects the signaling speed. The actual bit rate depends on the USB clock source. 0 Full-speed (12-Mbps) signaling. Normal operation. 1 Low-speed (1.5-Mbps) signaling. For a point-to-point connection with a low-speed device.
1	RESUME	Generate resume condition. When set, this bit generates a resume condition on the USB. This bit should be used if the function wants to exit the suspend state.
2–3	—	Reserved, should be cleared.
4	SFTE	Start-of-Frame Timer Enable. Setting this bit enables the Start-of-Frame timer and automatic SOF transmission. See Section 44.4.7.8, “USB Start of Frame Timer (USSFT)” and Section 44.4.2, “SOF Transmission for USB Host Controller,” for more information. 0 SOF timer is disabled 1 SOF timer is enabled
5	TEST	USB controller test (loopback) mode 0 Test mode is disabled 1 Test mode is enabled **Note:** This bit may be set only when HOST is set (USB host mode).
6	HOST	USB host mode 0 USB host is disabled 1 USB host is enabled
7	EN	Enable USB. When the EN bit is cleared, the USB is in a reset state. 0 USB is disabled 1 USB is enabled **Note:** Other bits of the USMOD should not be modified by the user while EN is set.

44.4.7.2 USB Slave Address Register (USADR)

USADR holds the address for this USB port when operating as function.

	0	1 … 7
Field	—	SADx
Reset	0000_0000	
R/W	R/W	
Addr	0x006C1	

Figure 44-11. USB Slave Address Register (USADD)

Table 44-10 describes the USADR fields.

Table 44-10. USADR Fields

Bits	Name	Description
0	—	Reserved, should be cleared.
1–7	SADx	Slave address 0–6. Holds the slave address for the USB port when configured as function.

44.4.7.3 USB Endpoint Registers (USEP0–USEP3)

There are four memory-mapped endpoint configuration registers.

	0–3	4–5	6–7	8–9	10	11	12–13	14–15
Field	EPN	—	TM	—	MF	RTE	THS	RHS
Reset	0000_0000_0000_0000							
R/W	R/W							
Addr	0x006C4 (USEP0); 0x006C6 (USEP1); 0x006C8 (USEP2); 0x006CA (USEP3)							

Figure 44-12. USB Endpoint Registers (USEP0–USEP3)

Table 44-11 describes the fields of USEP0–USEP3. The setting for USB host controller should be set only in USEP0, when USMOD[HOST] is set.

Table 44-11. USEP*n* Field Descriptions

Bits	Name	USB Function Mode	USB Host Mode
0–3	EPN	Endpoint number. For USB **function** controller defines the supported endpoint number.	For USB **host** controller, should be cleared
4–5	—	Reserved, should be cleared	Reserved, should be cleared
6–7	TM	Transfer mode for USB **function** controller 00 Control 01 Interrupt 10 Bulk 11 Isochronous	Transfer mode for USB **host** controller 00 Control /interrupt/bulk 11 Isochronous
8–9	—	Reserved, should be cleared.	Reserved, should be cleared
10	MF	Enable multi-frame. For USB **function** controller allows loading of the next transmit packet into the FIFO before transmission completion of the previous packet. 0 Transmit FIFO can hold only one packet 1 Transmit FIFO can hold more than one packet **Note:** For USB function configuration: Should be cleared unless the endpoint is configured for ISO transfer mode.	Enable multi-frame for USB **host** controller. Should be always set.
11	RTE	Retransmit enable for USB **function** controller 0 No retransmission 1 Automatic frame retransmission is enabled. The frame is retransmitted if a transmit error occurs (timeout). RTE can be set only if the transmit packet is contained in a single buffer. If it is not, retransmission should be handled by software. RTE should be cleared for an endpoint configured for ISO transfer mode	Transaction-level interface for USB **host** controller 0 Packet-level interface as described in Section 44.4.1.1, “Packet-Level Interface.” 1 Transaction-level interface as described in Section 44.4.1.2, “Transaction-Level Interface.”

Table 44-11. USEP*n* Field Descriptions (continued)

Bits	Name	USB Function Mode	USB Host Mode
12–13	THS	Transmit handshake for USB **function** controller. This field determines the response to an IN transaction. 00 Normal handshake 01 Ignore IN token 10 Force NACK handshake. Not allowed for control endpoint. 11 Force STALL handshake. On a control endpoint this value is used to generate a protocol stall; the USB function controller clears THS when a SETUP token is received.	Transmit handshake for USB **host** controller 00 Normal handshake
14–15	RHS	Receive handshake for USB **function** controller. This field determines the response to an OUT transaction. 00 Normal handshake 01 Ignore OUT token 10 Force NACK handshake and discard the data. This value can be used for flow control. It is not allowed for a control endpoint. 11 Force STALL handshake. On a control endpoint, this value is used to generate a protocol stall; the USB function controller clears RHS when a SETUP token is received.	Receive handshake for USB **host** controller 00Normal handshake

44.4.7.4 USB Command Register (USCOM)

USCOM is used to start the USB transmit operation.

	0	1	2	3	4	5	6	7
Field	STR	FLUSH	ISFT	DSFT	—		EP	
Reset	0000_0000							
R/W	R/W							
Addr	0x006C2							

Figure 44-13. USB Command Register (USCOM)

Table 44-12 describes the USCOM fields.

Table 44-12. USCOM Fields

Bits	Name	Description
0	STR	Start FIFO fill. Causes the USB controller to start filling the corresponding endpoint transmit FIFO with data. Transmission begins after the IN token for this endpoint is received. The STR bit is always read as cleared.
1	FLUSH	Flush FIFO. Causes the USB controller to flush the corresponding endpoint transmit FIFO. Before flushing the FIFO, the user should issue the Stop_Tx command. After the FIFO is flushed, the user should issue the Restart_Tx command (Refer to Section 44.6, “USB QUICC Engine Commands.”). FLUSH is always read as cleared.
2	ISFT	Increment Start-of-Frame Time. Increments the start-of-frame time by one. ISFT can be used to synchronize the USB frames to an external timing source.

Table 44-12. USCOM Fields (continued)

Bits	Name	Description
3	DSFT	Decrement Start-of-Frame Time. Setting the DSFT bit decrements the start-of-frame time by one. This bit can be used to synchronize the USB frames to an external timing source.
4–5	—	Reserved, should be cleared.
6–7	EP	Endpoint. Selects one of the four supported endpoints.

44.4.7.5 USB Event Register (USBER)

USBER reports events recognized by the USB channel and generates interrupts. Upon recognition of an event, the USB sets its corresponding bit in the USBER. Interrupts generated by this register can be masked in the USB mask register. The USBER may be read at any time. A bit is cleared by writing a one (writing a zero does not affect a bit's value). More than one bit may be cleared at a time. All unmasked bits must be cleared before the QUICC Engine module clears the internal interrupt request. This register is cleared at reset.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Field	—				MSF	SFT	RESET	IDLE	TXE4	TXE3	TXE2	TXE1	SOF	BSY	TXB	RXB
Reset	0000_0000_0000_0000															
R/W	R/W															
Addr	0x006D0															

Figure 44-14. USB Event Register (USBER)

Table 44-13 describes USBER fields.

Table 44-13. USBER Fields

Bits	Name	Description
0–3	—	Reserved, should be cleared.
4	MSF	Missed start-of-frame. Set when the start-of-frame timer wraps from 11,999 to 0 but no SOF packet has been transmitted because the FIFO was not empty.
5	SFT	The start-of-frame timer (USSFT[SFT]) wrapped from 11,999 to 0.
6	RESET	Reset condition detected. USB reset condition was detected asserted.
7	IDLE	IDLE status changed. A change in the status of the serial line was detected. The real time suspend status is reflected in the USB status register.
8–11	TXEx	Tx error. An error occurred during transmission for Endpoint x (packet not acknowledged or underrun).
12	SOF	Start of frame. A start of frame packet was received. The packet is stored in the FRAME_N parameter ram entry.
13	BSY	Busy condition. Received data has been discarded due to a lack of buffers. This bit is set after the first character is received for which there is no receive buffer available.
14	TXB	Tx buffer. A buffer has been transmitted. This bit is set when the transmit data of the last character in the buffer is written to the transmit FIFO (if L = 0 (last bit)) or after the last character was transmitted on the line (if L = 1).
15	RXB	Rx buffer. A buffer has been received. This bit is set after the last character has been written to the receive buffer and the RxBD is closed.

44.4.7.6 USB Mask Register (USBMR)

USBMR is a 16-bit read/write register (0x006D4) in the same bit format as the USBER. If a bit in the USBMR is set, the corresponding interrupt in the USBER is enabled. If the bit is cleared, the corresponding interrupt in the USBER is masked. This register is cleared at reset.

44.4.7.7 USB Status Register (USBS)

USBS, described in Figure 44-15 and Table 44-14, allows the user to monitor real-time status condition on the USB lines.

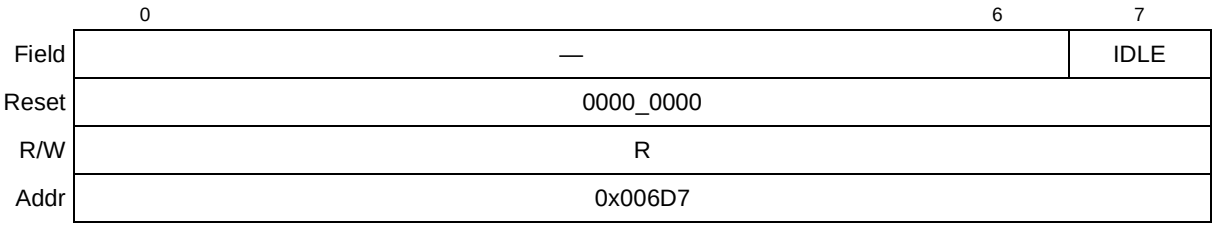

Figure 44-15. USB Status Register (USBS)

Table 44-14 describes USBS fields.

Table 44-14. USBS Fields

Bits	Name	Description
0–6	—	Reserved
7	IDLE	Idle status. IDLE is set when an idle condition is detected on the USB lines, it is cleared when the bus is not idle.

44.4.7.8 USB Start of Frame Timer (USSFT)

When enabled by USMOD[SFTE], the USSFT contains the current time within the frame with a resolution of one bit time. When the value of USSFT wraps from 11,999 to 0, an SOF packet is transmitted, and USBER[SFT] is set. The USSFT can be read at any time.

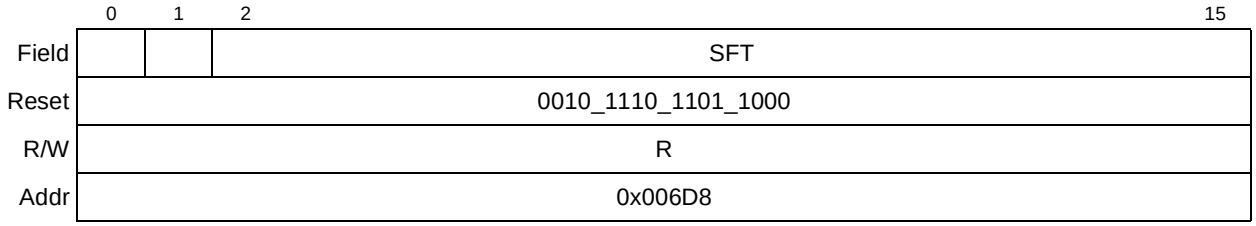

Figure 44-16. USB Start of Frame Timer (USSFT)

Table 44-15 describes the USSFT fields.

Table 44-15. USSFT Fields

Bits	Name	Description
0–1	—	Reserved, should be cleared.
2–15	SFT	Start of Frame Time. This field contains the number of bit times since the last SOF trigger. Note that the actual SOF transmission occurs slightly later.

44.4.7.9 USB Frame Number (USFRN)

The USFRN value is used as the frame number field in the automatically-transmitted SOF packet in host mode. The USFRN can be read at any time. Normally, it is not necessary to write to this register, but it is permitted if the user wishes to set the frame number.

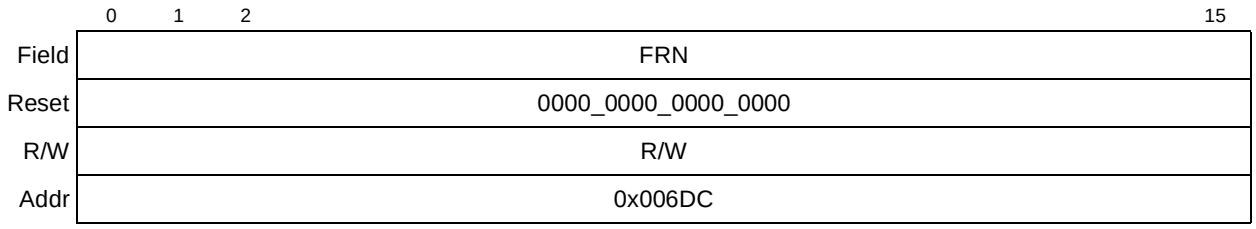

Figure 44-17. USB Frame Number (USFRN)

Table 44-16 describes the USFRN fields.

Table 44-16. USFRN Fields

Bits	Name	Description
0–15	FRN	Frame Number. This field contains the frame number of the current frame. It is automatically incremented every 1 ms.

44.5 USB Buffer Descriptor Ring

The data associated with the USB channel is stored in buffers that are referenced by BDs organized in BD rings located in the dual-port RAM (refer to Figure 44-18). These rings have the same basic configuration as those used by the UCCs. There are up to four separate transmit BD rings and four separate receive BD rings, one for each endpoint. The BD ring allows the user to define buffers for transmission and buffers for reception. Each BD ring forms a circular queue. The QUICC Engine module confirms reception and transmission or indicates error conditions using the BDs to inform the processor that the buffers have been serviced. The buffers can reside in either external or internal memory.

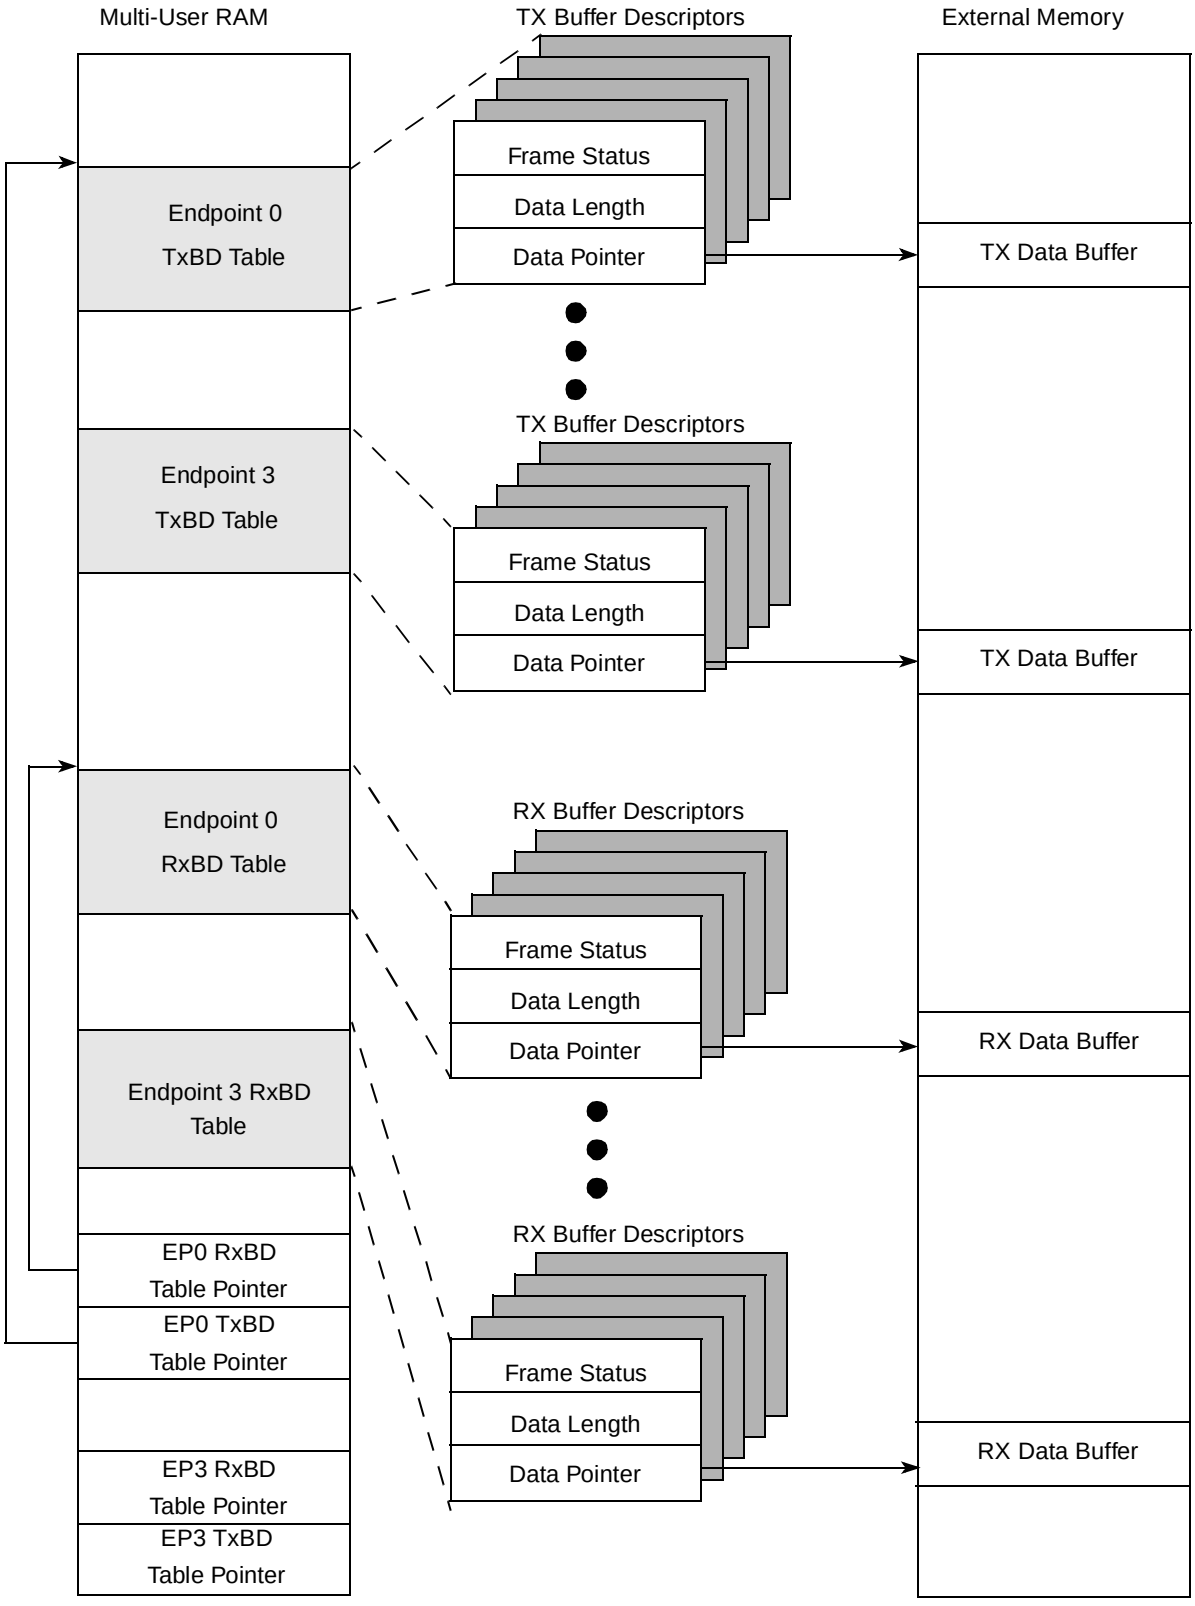

Figure 44-18. USB Memory Structure

44.5.1 USB Receive Buffer Descriptor (RxBD) for Host and Function

The QUICC Engine module reports information about each buffer of received data using RxBDs. The QUICC Engine module closes the current buffer, generates a maskable interrupt, and starts receiving data in the next buffer when the current buffer is full. Additionally, it closes the buffer on the following conditions:

- End of packet detected
- Overrun error occurred
- Bit stuff violation detected

As shown in Figure 44-19, the first word of the RxBD contains status and control bits. The user configures these bits before reception, and the QUICC Engine module sets them after the buffer is closed. The second word contains the data length—in bytes—that was received. The third and fourth words contain a pointer that always points to the beginning of the received data buffer. The RxBD is identical for both the host mode (when the packet-level interface is used) and the function mode. There are no RxBDs in host mode when the transaction-level interface is used.

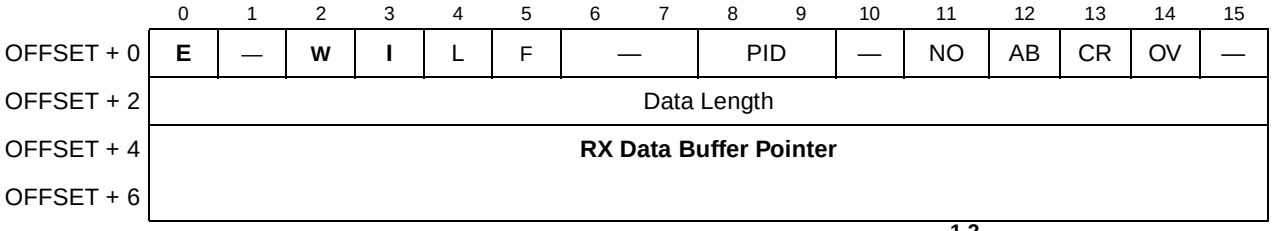

Figure 44-19. USB Receive Buffer Descriptor (RxBD)[1,2]

1 Entries in **boldface** must be initialized by the user.

2 All fields should be written by the CPU core before the USB is enabled.

Table 44-17 describes USB receive buffer descriptor fields.

Table 44-17. USB RxBD Fields

Offset	Bits	Name	Description
0x00	0	**E**	Empty 0 The data buffer associated with this RxBD has been filled with received data, or data reception has been aborted due to an error condition. The CPU core is free to examine or write to any fields of this RxBD. The QUICC Engine module does not use this BD again while the E-bit remains zero. 1 The data buffer associated with this BD is empty, or reception is currently in progress. This RxBD and its associated receive buffer are owned by the QUICC Engine module. When the E-bit is set, the CPU core should not write any fields of this RxBD.
	1	—	Reserved, should be cleared
	2	**W**	Wrap (Final BD in table) 0 This is not the last BD in the RxBD table. 1 This is the last BD in the RxBD table. After this buffer has been used, the QUICC Engine module receives incoming data into the first BD in the table (the BD to which RBASE points). The number of RxBDs in this table is programmable and is determined only by the W-bit and the overall space constraints of the dual-port RAM.

Table 44-17. USB RxBD Fields (continued)

Offset	Bits	Name	Description
	3	**I**	Interrupt 0 No interrupt is generated after this buffer is filled. 1 The USBER[RXB] bit is set when the QUICC Engine module completely fills this buffer, indicating the need for the CPU core to process the buffer. The RXB bit can cause an interrupt if it is enabled.
	4	L	Last. The USB controller sets this bit when the buffer is closed due to detection of end-of-packet condition on the bus, or as a result of error. Written by the USB controller after the received data is placed into the associated data buffer. 0 Buffer does not contain the last byte of the message. 1 Buffer contains the last byte of the message.
	5	F	First. The USB controller sets this bit when the buffer contains the first byte of a packet. Written by the USB controller after the received data is placed into the associated data buffer. 0 Buffer does not contain the first byte of the message 1 Buffer contains the first byte of the message
	6–7	—	Reserved, should be cleared
	8–9	PID	Packet ID. The USB controller sets this bit to indicate the type of the packet. This bit is valid only if the USB RXBD[F] is set. Written by the USB controller after the received data is placed into the associated data buffer. 00 Buffer contains DATA0 packet 01 Buffer contains DATA1 packet 10 Buffer contains SETUP packet. This option can never be set on host RxBD.
	10	—	Reserved, should be cleared
	11	NO	Rx non-octet aligned packet. A packet that contained a number of bits not exactly divisible by eight was received. Written by the USB controller after the received data is placed into the associated data buffer.
	12	AB	Frame aborted. Bit stuff error occurred during reception. Written by the USB controller after the received data is placed into the associated data buffer.
	13	CR	CRC error. This frame contains a CRC error. The received CRC bytes are always written to the receive buffer. Written by the USB controller after the received data is placed into the associated data buffer.
	14	OV	Overrun. A receiver overrun occurred during reception. Written by the USB controller after the received data is placed into the associated data buffer.
	15	—	Reserved, should be cleared
0x02	0–15	Data Length	Data length is the number of octets that the QUICC Engine module has written into this BD's data buffer. It is written once by the QUICC Engine module as the BD is closed. **Note:** The actual amount of memory allocated for this buffer should be greater than or equal to the contents of the MRBLR.
0x04	0–31	**Rx Data Buffer Pointer**	The receive buffer pointer, which always points to the first location of the associated data buffer, must be divisible by 4. The buffer may reside in either internal or external memory

Data length represents the number of octets that the QUICC Engine module has written into this BD's buffer. It is written once by the QUICC Engine module as the BD is closed.

The receive buffer pointer always points to the first location of the associated buffer. The pointer must be divisible by 4. The buffer may reside in either internal or external memory.

44.5.2 USB Transmit Buffer Descriptor (TxBD) for Function

Data that the USB function wishes to transmit to the host is arranged in buffers referenced by the TxBD ring. The first word of the TxBD contains the status and control bits.

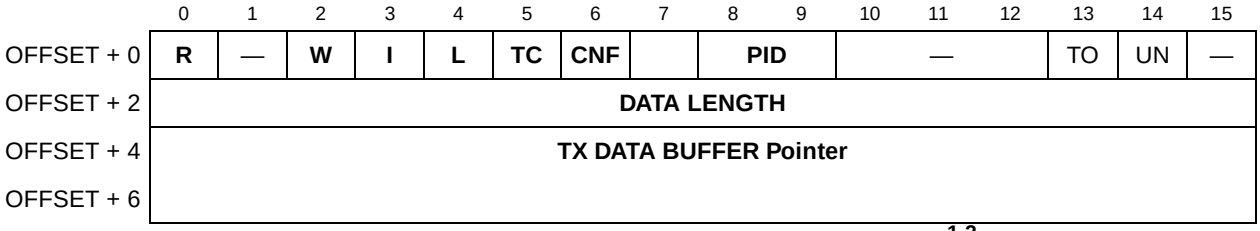

Figure 44-20. USB Transmit Buffer Descriptor (TxBD)[1,2]

1 Entries in **boldface** must be initialized by the user.

2 All fields should be prepared by the user before transmission.

Table 44-18 describes USB TxBD fields.

Table 44-18. USB Function TxBD Fields

Offset	Bits	Name	Description
0x00	0	**R**	Ready 0 The data buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated data buffer. The QUICC Engine module clears this bit after the buffer has been transmitted or after an error condition is encountered. 1 The data buffer, which has been prepared for transmission by the user, has not been transmitted or is currently being transmitted. No fields of this BD may be written by the user once this bit is set.
	1	—	Reserved, should be cleared
	2	**W**	Wrap (Final BD in table) 0 This is not the last BD in the TxBD table. 1 This is the last BD in the TxBD table. After this buffer has been used, the QUICC Engine module sends data using the first BD in the table (the BD pointed to by TBASEx). The number of TxBDs in this table is programmable and is determined only by the TxBD[W] and the overall space constraints of the dual-port RAM.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer has been serviced. 1 The TXB or TXE bit in the event register is set when this buffer is serviced. TXB and TXE can cause interrupts if they are enabled.
	4	**L**	Last 0 Buffer does not contain the last byte of the message 1 Buffer contains the last byte of the message
	5	**TC**	Transmit CRC. Valid only when the L bit is set; otherwise it is ignored. Prepare TC before sending data. 0 Transmit end-of-packet after the last data byte. This setting can be used for testing purposes to send a bad CRC after the data. 1 Transmit the CRC sequence after the last data byte.

Table 44-18. USB Function TxBD Fields (continued)

Offset	Bits	Name	Description
	6	CNF	Transmit confirmation. Valid only when the L bit is set; otherwise it is ignored. Applies to multi-frame enabled endpoints (USEP*n*[MF] = 1); refer to Section 44.4.7.3, "USB Endpoint Registers (USEP0–USEP3)." 0 Continue to load the transmit FIFO with the next packet. Several packets may be loaded to the FIFO. 1 Last packet that is loaded to the FIFO. No more packets are loaded to the FIFO after a packet marked CNF until it is transmitted.
	7		Reserved, should be cleared
	8–9	**PID**	Packet ID. This bit field is valid for the first BD of a packet; otherwise it is ignored. 0X Do not append PID to the data. 10 Transmit DATA0 PID before sending the data. 11 Transmit DATA1 PID before sending the data.
	10–12	—	Reserved, should be cleared
	13	TO	Time out. Indicates that the host failed to acknowledge the packet.
	14	UN	Underrun. Indicates that the USB encountered a transmitter underrun condition while sending the buffer.
	15	—	Reserved, should be cleared
0x02	0–15	**Data length**	The data length is the number of octets that the QUICC Engine module should transmit from this BD's data buffer. It is never modified by the QUICC Engine module. This value should normally be greater than zero.
0x04	0–31	**Tx data buffer pointer**	The transmit buffer pointer, which always points to the first location of the associated data buffer, may be even or odd.The buffer may reside in either internal or external memory.

Data length (the second half word of a TxBD) is the number of octets the QUICC Engine module should send from this BD's data buffer. It is never modified by the QUICC Engine module. Tx buffer pointer (the third and fourth half words of a TxBD) always points to the first location of the buffer in internal or external memory. The pointer may be even or odd.

44.5.3 USB Transmit Buffer Descriptor (TxBD) for Host

The TxBD described in this section is used when the packet-level interface is active. See Section 44.4.1.1, "Packet-Level Interface."

Data to be transmitted with the USB to the QUICC Engine module by is arranged in buffers referenced by the TxBD ring. The first word of the TxBD contains status and control bits.

Figure 44-21. USB Transmit Buffer Descriptor (TxBD)[1,2]

1 Entries in **boldface** must be initialized by the user.

2 All fields should be prepared by the user before transmission.

Table 44-18 describes USB TxBD fields.

Table 44-19. USB Host TxBD Fields

Offset	Bits	Name	Description
0x00	0	**R**	Ready 0 The data buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated data buffer. The QUICC Engine module clears this bit after the buffer has been transmitted or after an error condition is encountered. 1 The data buffer, which the user has prepared for transmission, has not been transmitted or is being transmitted. No fields of this BD may be written by the user once this bit is set.
	1	—	Reserved, should be cleared
	2	**W**	Wrap (Final BD in Table) 0 This is not the last BD in the TxBD table. 1 This is the last BD in the TxBD table. After this buffer has been used, the QUICC Engine module sends data using the first BD in the table (the BD to which TBASEx points). The number of TxBDs in this table is programmable and is determined only by the TxBD[W] and the overall space constraints of the dual-port RAM.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer is serviced. The TXB bit in the event register is set when this buffer is serviced. TXB can cause an interrupt if it is enabled.
	4	**L**	Last 0 Buffer does not contain the last byte of the message. 1 Buffer contains the last byte of the message.
	5	TC	Transmit CRC. Valid only when the L bit is set; otherwise it is ignored. Prepare TC before sending data. 0 Transmit end-of-packet after the last data byte. This setting can be used for testing purposes to send a bad CRC after the data. 1 Transmit the CRC sequence after the last data byte.

Table 44-19. USB Host TxBD Fields (continued)

Offset	Bits	Name	Description
	6	CNF	Transmit confirmation. Valid only when the L bit is set; otherwise it is ignored. Applies to multi-frame enabled endpoints (USEP*n*[MF] = 1); see Section 44.4.7.3, "USB Endpoint Registers (USEP0–USEP3)." 0 Continue to load the transmit FIFO with the next packet. No handshake or response is expected from the function for this packet. 1 Wait for handshake or response from the function before starting the next packet, or this is the last packet. Do not clear CNF for a token preceding a data packet unless the data packet's BD is ready.
	7	LSP	Low-speed transaction. Use for tokens only. 0 The following transaction is with the host or a full-speed device. 1 The following transaction is with a low-speed device. Required only for tokens. Note that LSP should always be cleared in slave mode.
	8–9	**PID**	Packet ID. This bit field is valid for the first BD of a packet; otherwise it is ignored. 0X Do not append PID to the data. 10 Transmit DATA0 PID before sending the data. 11 Transmit DATA1 PID before sending the data.
	10	—	Reserved, should be cleared
	11	NAK[1]	NAK received. Indicates that the endpoint has responded with a NAK handshake. The packet was received error-free; however, the endpoint could not accept it.
	12	STAL[1]	STALL received. Indicates that the endpoint has responded with a STALL handshake. The endpoint needs attention through the control pipe.
	13	TO[1]	Time out. Indicates that the endpoint failed to acknowledge the packet.
	14	UN[1]	Underrun. Indicates that the USB encountered a transmitter underrun condition while sending the buffer.
	15	—	Reserved, should be cleared
0x02	0–15	**Data length**	The data length is the number of octets that the QUICC Engine module should transmit from this BD's data buffer. It is never modified by the QUICC Engine module. This value should normally be greater than zero.
0x04	0–31	**Tx data buffer pointer**	The transmit buffer pointer, which always points to the first location of the associated data buffer, may be even or odd.The buffer may reside in either internal or external memory.

[1] Written by the USB controller after it finishes sending the associated data buffer.

Data length (the second half word of a TxBD) is the number of octets the QUICC Engine module should send from this BD's data buffer. It is never modified by the QUICC Engine module. Tx buffer pointer (the third and fourth half words of a TxBD) always points to the first location of the buffer in internal or external memory. The pointer may be even or odd.

44.5.4 USB Transaction Buffer Descriptor (TrBD) for Host

The TrBD described in this section is used when the transaction-level interface is active. See Section 44.4.1.2, "Transaction-Level Interface."

Data to be transmitted with the USB to the QUICC Engine module by is arranged in buffers referenced by the TrBD ring. The first word of the TrBD contains status and control bits.

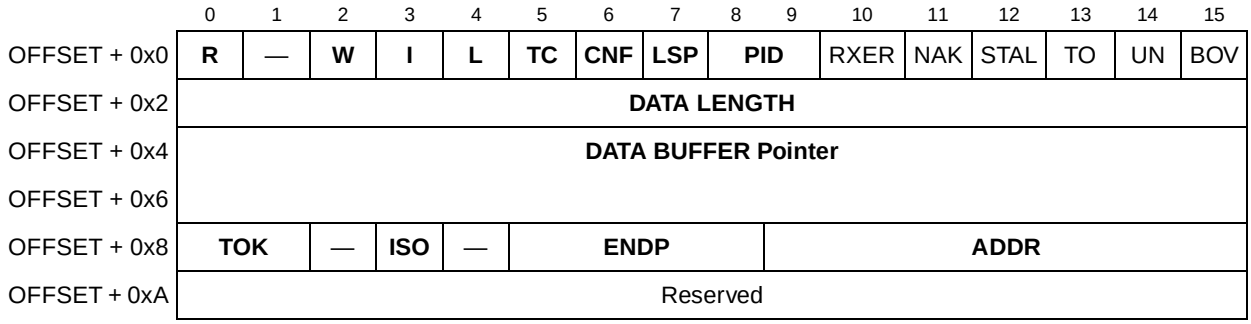

Figure 44-22. USB Transaction Buffer Descriptor (TrBD)[1,2]

1 Entries in **boldface** must be initialized by the user.

2 All fields should be prepared by the user before transmission.

Table 44-18 describes USB TrBD fields.

Table 44-20. USB Host TrBD Fields

Offset	Bits	Name	Description
0x00	0	**R**	Ready 0 The data buffer associated with this BD is not ready for transmission. The user is free to manipulate this BD or its associated data buffer. The QUICC Engine module clears this bit after the buffer has been transmitted or after an error condition is encountered. 1 The data buffer, which the user has prepared for transmission, has not been transmitted or is being transmitted. The user can write to no fields of this BD after this bit is set.
	1	—	Reserved, should be cleared.
	2	**W**	Wrap (Final BD in Table) 0 This is not the last BD in the TrBD table. 1 This is the last BD in the TrBD table. After this buffer has been used, the QUICC Engine module sends data using the first BD in the table (the BD to which TBASE points). The number of TrBDs in this table is programmable, and is determined only by the TrBD[W] and the overall space constraints of the dual-port RAM.
	3	**I**	Interrupt 0 No interrupt is generated after this buffer is serviced. 1 The TXB bit in the event register is set when this buffer is serviced. TXB can cause an interrupt if it is enabled.
	4	**L**	Last Should always have a value of 1 because each TrBD represents an entire transaction.
	5	**TC**	Transmit CRC. Append CRC to transmitted data packet. 0 Transmit end-of-packet after the last data byte. This setting can be used for testing purposes to send a bad CRC after the data. 1 Transmit the CRC sequence after the last data byte.
	6	**CNF**	Transmit confirmation. Should always have a value of 1 to obtain a confirmation for each transaction.
	7	**LSP**	Low-speed transaction. 0 This transaction is with the host or a full-speed device. 1 This transaction is with a low-speed device. Transmit a PRE packet before the token.

Table 44-20. USB Host TrBD Fields (continued)

Offset	Bits	Name	Description
	8–9	**PID**	Packet ID. For OUT/SETUP transactions, the user prepares this field with the following values: 0X Do not append PID to the data packet. 10 Transmit DATA0 PID before sending the data packet. 11 Transmit DATA1 PID before sending the data packet. For IN transactions, this field is provided by the USB host controller with the following values: 00 Buffer contains DATA0 packet. 01 Buffer contains DATA1 packet.
	10	RXER[1]	Receive Error. This bit indicates that an error was detected while receiving the data packet of an IN transaction. If RXER is 1, bits 11–15 have a different meaning as explained below.
	11	NAK/NO[1]	RXER = 0: NAK received. Indicates that the endpoint has responded with a NAK handshake (OUT transaction). The packet was received error-free; however, the endpoint could not accept it. RXER = 1: Rx non-octet aligned packet. A packet that contained a number of bits not exactly divisible by eight was received. Written by the USB controller after the received data has been placed into the associated data buffer.
	12	STAL/AB[1]	RXER = 0: STALL received. Indicates that the endpoint has responded with a STALL handshake (OUT transaction). The endpoint needs attention through the control pipe. RXER = 1: Frame aborted. Bit stuff error occurred during reception. Written by the USB controller after the received data has been placed into the associated data buffer.
	13	TO/CR[1]	RXER = 0: Timeout. Indicates that the endpoint failed to acknowledge the token (IN transaction) or the data packet (OUT/SETUP transaction). RXER = 1: CRC error. This frame contains a CRC error. The received CRC bytes are always written to the receive buffer. Written by the USB controller after the received data has been placed into the associated data buffer.
	14	UN/OV[1]	RXER = 0: Underrun. Indicates that the USB encountered a transmit FIFO underrun condition while sending the data packet (OUT/SETUP transaction). RXER = 1: Overrun. An internal receive FIFO overrun occurred during reception. Written by the USB controller after the received data has been placed into the associated data buffer.
	15	BOV[1]	Buffer Overflow. IN transactions only. Indicates that the number of received bytes is larger than the buffer size as provided in the Data Length field.
0x02	0–15	**Data Length**	For OUT/SETUP transactions, the user prepares this field with the number of bytes to be sent from the data buffer. It is not modified by the QUICC Engine module. For IN transactions, the user prepares this field with the size of the data buffer, which must be divisible by 4. The QUICC Engine module returns the actual number of bytes written to the data buffer. If the number of received bytes, including the 2-byte CRC, is larger than the data buffer, the QUICC Engine module sets the BOV bit .
0x04	0–31	**Data Buffer Pointer**	The data buffer pointer. The buffer can reside in either internal or external memory. For OUT/SETUP transactions, this points to the buffer containing the data packet to transmit. It may have any alignment. For IN transactions, this points to the buffer into which the data packet should be received, The pointer must be divisible by 4.
0x08	0–1	**TOK**	Token Type This field determines the type of token to be transmitted and the type of transaction. 00 SETUP 01 OUT 10 IN 11 Reserved

Table 44-20. USB Host TrBD Fields (continued)

Offset	Bits	Name	Description
	2	—	Reserved, should be cleared.
	3	**ISO**	Isochronous. Indicates that the transaction is isochronous, so no handshake is required. 0 Bulk/Control/Interrupt. The handshake packet is automatically expected or generated by the USB host controller. 1 Isochronous. No handshake packets are expected or generated. This bit actually controls the value that is written to USEP0[TM] before this transaction is processed.
	5	—	Reserved, should be cleared.
	5–8	**ENDP**	Endpoint. The endpoint number to be included in the token.
	9–15	**ADDR**	Address Device address to be included in the token.
0x0A	0–15	—	Reserved, should be cleared.

[1] Written by the USB controller after it finishes sending or receiving the associated data buffer.

44.6 USB QUICC Engine Commands

The following transmit commands are issued to the QUICC Engine command register (CECR). Refer to Section 20.4.1, “QUICC Engine Command Register (CECR).”

44.6.1 STOP Tx Command

The STOP Tx command disables the transmission of data on the selected endpoint. After the command is issued, the corresponding endpoint FIFO should be flushed. No further data is transmitted until the Restart Tx command is issued.

44.6.2 RESTART Tx Command

The RESTART Tx command enables the transmission of data from the corresponding endpoint on the USB. This command is expected by the USB controller after a STOP Tx command or after a transmission error (underrun or timeout).

44.7 USB Controller Errors

The USB controller reports frame reception and transmission error conditions using the BDs and the USB event register (USBER). Transmission errors are shown in Table 44-21. Errors that exist exclusively in host mode or function mode are marked as such.

Table 44-21. USB Controller Transmission Errors

Error	Description
Transmit underrun	If an underrun occurs, the transmitter forces a bit stuffing violation, terminates buffer transmission, closes the buffer, sets TxBD[UN] and the corresponding USBER[TXE*n*]. The endpoint resumes transmission after the RESTART TX ENDPOINT command is received.
Transmit timeout	Transmit packet not acknowledged. If a timeout occurs, the controller tries to retransmit if USEP*n*[RTE] = 1. If RTE = 0 or the second attempt fails, the controller closes the buffer and sets TxBD[TO] and USBER[TXE*n*]. The endpoint resumes transmission after receiving a RESTART TX ENDPOINT command.
Tx data not ready	For **USB function mode** only. This error occurs if an IN token is received, but the corresponding endpoint's transmit FIFO is empty, or if the target endpoint is configured to NAK or STALL. The controller sets USBER[TXE*n*].
Reception of NAK or STALL handshake	For **USB host mode** only. If this error occurs, the channel closes the buffer, sets the corresponding status bit in the TxBD (NAK or STAL) and sets the USBER[TXE] bit. When the packet-level interface is used, the host resumes transmission after reception of the RESTART TRANSMIT command.

Table 44-22 describes the USB controller reception errors.

Table 44-22. USB Controller Reception Errors

Error	Description
Overrun Error	If the 16-byte receive FIFO overruns, the previously received byte is overwritten. The controller closes the buffer and sets both RxBD[OV] and USBER[RXB]. For **USB function mode** the NAK handshake is sent after the end of the received packet if the packet was received error-free.
Busy Error	A frame was received and discarded due to lack of buffers. The controller sets USBER[BSY].
Non Octet-Aligned Packet	If this error occurs, the controller writes the received data to the buffer, closes the buffer and sets both RxBD[NO] and USBER[RXB].
CRC Error	When a CRC error occurs, the controller closes the buffer, and sets both RxBD[CR] and USBER[RXB]. In isochronous mode (USEP*n*[TM] = 0b11), the USB controller reports a CRC error; however, there are no handshake packets (ACK) and the transfer continues normally when an error occurs.
Buffer Overflow	For **USB host mode** transaction-level interface only. If the received data packet is larger than the allocated buffer, the remaining data is discarded, and TrBD[BOV] is set. The TXE1 interrupt bit is set.

Appendix A
MPC8358E

This appendix illustrates the MPC8358E and in particular the differences between it and the MPC8360E as described in this manual.

A.1 Features

Major features of the MPC8358E are as follows:

- e300c1 PowerPC processor core
  - Enhanced version of the MPC603e processor core
  - High-performance, superscalar processor core
  - Floating-point, integer, load/store, system register, and branch processing units
  - 32-Kbyte instruction cache, 32-Kbyte data cache
  - Dynamic power management
  - Enhanced hardware program debug features
  - Software-compatible with the Freescale processor families implementing the PowerPC architecture
- QUICC Engine unit
  - Two 32-bit RISC controllers for flexible support of the communications peripherals
  - Serial DMA channel for receive and transmit on all serial channels
  - QE peripheral request interface (for SEC, PCI, IEEE Std 1588™)
  - Six UCCs supporting the following protocols and interfaces (not all of them simultaneously):
    - 10/100 Mbps Ethernet/IEEE Std 802.3™ through MII and RMII interfaces.[1]
    - 1000 Mbps Ethernet/IEEE Std 802.3 through a media-independent interface (GMII, RGMII, RTBI, TBI) on UCC1 and UCC2
    - 10/100 Mbps Ethernet/IEEE Std 802.3 L2 switch port through MII and RMII interfaces.
    - IEEE Std 1588 protocol supported
    - 9.6K jumbo frames
    - ATM full-duplex SAR, up to 622 Mbps (OC-12/STM-4), AAL0, AAL1 and AAL5 in accordance ITU-T I.363.5
    - ATM AAL2 CPS, SSSAR, and SSTED up to 155 Mbps (OC-3/STM-1) Mbps full duplex (with 4 CPS packets per cell) in accordance ITU-T I.366.1 and I.363.2
    - ATM traffic shaping for CBR, VBR, UBR, and GFR traffic types compatible with ATM forum TM4.1 for up to 64K simultaneous ATM channels
    - ATM AAL1 structured and unstructured circuit emulation service (CES 2.0) in accordance with ITU-T I.163.1 and ATM Forum af-vtoa-00-0078.000

1.SMII or SGMII media-independent interface is not currently supported

- IMA (Inverse Multiplexing over ATM) for up to 31 IMA links over 8 IMA groups in accordance with the ATM forum AF-PHY-0086.000 (Version 1.0) and AF-PHY-0086.001 (Version 1.1)
- ATM Transmission Convergence layer support in accordance with ITU-T I.432
- ATM OAM handling features compatible with ITU-T I.610
- PPP, Multi-Link (ML-PPP), Multi-Class (MC-PPP) and PPP mux in accordance with the following RFCs: 1661, 1662, 1990, 2686 and 3153
- IP support for IPv4 and IPv6 packets including TOS, TTL and header checksum processing
- Ethernet over first mile IEEE Std 802.3ah™
- Shim header
- Ethernet-to-Ethernet/AAL5/AAL2 inter-working
- L2 Ethernet switching using MAC address or IEEE Std 802.1P/Q™ VLAN tags
- ATM (AAL2/AAL5) to Ethernet (IP) interworking in accordance with RFC2684 including bridging of ATM ports to Ethernet ports
- Extensive support for ATM statistics and Ethernet RMON/MIB statistics
- AAL2 protocol rate up to 4 CPS at OC-3/STM-1 rate
- Packet over Sonet (POS) up to 622-Mbps full-duplex 124 MultiPHY[1]
- POS hardware; microcode must be loaded as an IRAM package
- Transparent up to 70-Mbps full-duplex
- HDLC up to 70-Mbps full-duplex
- HDLC BUS up to 10 Mbps
- Asynchronous HDLC
- UART
- BISYNC up to 2 Mbps
- User-programmable FIFO size
- QUICC Multichannel Controller (QMC) for 64 TDM channels

— One UTOPIA/POS interface supporting 31/124 MultiPHY

— Universal serial bus (USB) controller

— Two serial peripheral interfaces (SPI); SPI2 is dedicated to Ethernet PHY management

— Four TDM interfaces with 1-bit mode for E3/T3 rates in clear channel

— Sixteen independent baud rate generators and 30 input clock pins for supplying clocks to UCC serial channels

— Four independent 16-bit timers that can be interconnected as four 32-bit timers

— Interworking functionality:

- Layer 2 10/100-Base T Ethernet switch
- ATM-to-ATM switching (AAL0, 2, 5)
- Ethernet-to-ATM switching with L3/L4 support
- PPP interworking

- Security engine is optimized to handle all the algorithms associated with IPSec, SSL/TLS, SRTP, 802.11i, iSCSI, and IKE processing. The security engine contains four crypto-channels, a controller, and a set of crypto execution units (EUs).
  - Public key execution unit (PKEU) supporting the following:
    - RSA and Diffie-Hellman
    - Programmable field size up to 2048 bits
    - Elliptic curve cryptography
    - F2m and F(p) modes
    - Programmable field size up to 511 bits
  - Data encryption standard execution unit (DEU)
    - DES, 3DES
    - Two key (K1, K2) or three key (K1, K2, K3)
    - ECB and CBC modes for both DES and 3DES
  - Advanced encryption standard unit (AESU)
  - Implements the Rinjdael symmetric key cipher
  - Key lengths of 128, 192, and 256 bits, two key
    - ECB, CBC, CCM, and counter modes
  - ARC four execution unit (AFEU)
    - Implements a stream cipher compatible with the RC4 algorithm
    - 40- to 128-bit programmable key
  - Message digest execution unit (MDEU)
    - SHA with 160-, 224-, or 256-bit message digest
    - MD5 with 128-bit message digest
    - HMAC with either SHA or MD5 algorithm
  - Random number generator (RNG)
  - Four crypto-channels, each supporting multi-command descriptor chains
    - Static and/or dynamic assignment of crypto-execution units via an integrated controller
    - Buffer size of 256 bytes for each execution unit, with flow control for large data sizes
  - Storage/NAS XOR parity generation accelerator for RAID applications
- DDR SDRAM memory controller
  - Programmable timing supporting DDR SDRAM
  - DDR bus can be configured as a 32-bit or 64-bit bus
  - 32- or 64-bit data interface
  - Four banks of memory, each up to 1 Gbyte
  - DRAM chip configurations from 64 Mbits to 1 Gigabit with x8/x16 data ports
  - Full ECC support
  - Page mode support (up to 16 simultaneous open pages for DDR1, up to 32 simultaneous open pages for DDR2)

- Contiguous or discontiguous memory mapping
- Read-modify-write support
- Sleep mode support for self refresh SDRAM
- Supports auto refreshing
- Supports source clock mode
- On-the-fly power management using CKE
- Registered DIMM support
- 2.5-V SSTL2 compatible I/O for DDR1, 1.8-V SSTL2 compatible I/O for DDR2
- External driver impedance calibration
- On-die termination (ODT)

- PCI interface
  - PCI Specification Revision 2.3 compatible
  - Data bus widths:
    - Single 32-bit data PCI interface that operates at up to 66 MHz
  - PCI 3.3-V compatible (not 5-V compatible)
  - PCI host bridge capabilities on both interfaces
  - PCI agent mode supported on PCI interface
  - Support for PCI-to-memory and memory-to-PCI streaming
  - Memory prefetching of PCI read accesses and support for delayed read transactions
  - Support for posting of processor-to-PCI and PCI-to-memory writes
  - On-chip arbitration, supporting five masters on PCI
  - Support for accesses to all PCI address spaces
  - Parity support
  - Selectable hardware-enforced coherency
  - Address translation units for address mapping between host and peripheral
  - Dual address cycle supported when the device is the target
  - Internal configuration registers accessible from PCI
- Local bus controller (LBC)
  - Multiplexed 32-bit address and data
  - Eight chip selects support eight external slaves
  - Up to eight-beat burst transfers
  - 32-, 16-, and 8-bit port sizes are controlled by an on-chip memory controller
  - Three protocol engines available on a per chip select basis:
    - General-purpose chip select machine (GPCM)
    - Three user programmable machines (UPMs)
    - Dedicated single data rate SDRAM controller

  - Parity support
  - Default boot ROM chip select with configurable bus width (8-, 16-, or 32-bit)
- Programmable interrupt controller (PIC)
  - Functional and programming compatibility with the MPC8260 interrupt controller
  - Support for 8 external and 35 internal discrete interrupt sources
  - Support for one external (optional) and seven internal machine checkstop interrupt sources
  - Programmable highest priority request
  - Four groups of interrupts with programmable priority
  - External and internal interrupts directed to communication processor
  - Redirects interrupts to external $\overline{\text{INTA}}$ pin when in core disable mode
  - Unique vector number for each interrupt source
- Dual industry-standard I^2C interfaces
  - Two-wire interface
  - Multiple master support
  - Master or slave I^2C mode support
  - On-chip digital filtering rejects spikes on the bus
  - System initialization data is optionally loaded from I^2C-1 EPROM by boot sequencer embedded hardware
- DMA controller
  - Four independent virtual channels
  - Concurrent execution across multiple channels with programmable bandwidth control
  - All channels accessible by local core and remote PCI masters
  - Misaligned transfer capability
  - Data chaining and direct mode
  - Interrupt on completed segment and chain
  - DMA external handshake signals: $\overline{\text{DMA\_DREQ}}$[0:3]/$\overline{\text{DMA\_DACK}}$[0:3]/$\overline{\text{DMA\_DONE}}$[0:3]. There is one set for each DMA channel. The pins are multiplexed to the parallel IO pins with other QE functions.
- DUART
  - Two 4-wire interfaces (RxD, TxD, RTS, CTS)
  - Programming model compatible with the original 16450 UART and the PC16550D
- System timers
  - Periodic interrupt timer
  - Real-time clock
  - Software watchdog timer
  - Eight general-purpose timers
- IEEE Std 1149.1™ compliant, JTAG boundary scan
- Integrated PCI bus and SDRAM clock generation

A.2 MPC8360E Features Not Present in the MPC8358E

- UCC interfaces 6 and 7
- MCC
- Two UPCs
- TDM interfaces E, F, G, and H
- DDRC2

Table A-1 shows a comparison between the MPC8358E and the MPC8360E.

Table A-1. MPC8358E and MPC8360E Comparison

	MPC8358E	MPC8360E
Core	e300	e300
CPU Speed	Up to 400MHz	Up to 667MHz
QUICC Engine Speed	Up to 400MHz	Up to 500MHz
L1 Instruction/Data Cache	32K Instruction 32K Data	32K Instruction 32K Data
Memory Controller	1x32-bit or 1x64-bit DDR1	1x64-bit or 2x32-bit DDR1
Local bus	Yes	Yes
PCI	1- 32-bit up to 66MHz	1- 32-bit up to 66MHz
Ethernet	Up to 6- 10/100 Up to 2- 10/100/1000	Up to 8- 10/100 Up to 2- 10/100/1000
HDLC/TDMs	Up to 128 / 4 (QMC ucode)	Up to 256 / 8
UTOPIA	1x31 or 1x128 MPHY	2x128 MPHY
USB	Low/Full Speed	Low/Full Speed
Security Engine	E version only	E version only
UART	Dual	Dual
I^2C	Dual	Dual
SPI	Dual	Dual
MCC	No	One
Interrupt Controller	Yes	Yes
Package	740 TBGA (37.5x37.5) 1mm pitch	740 TBGA (37.5x37.5) 1mm pitch

A.3 MPC8358E Block Diagram

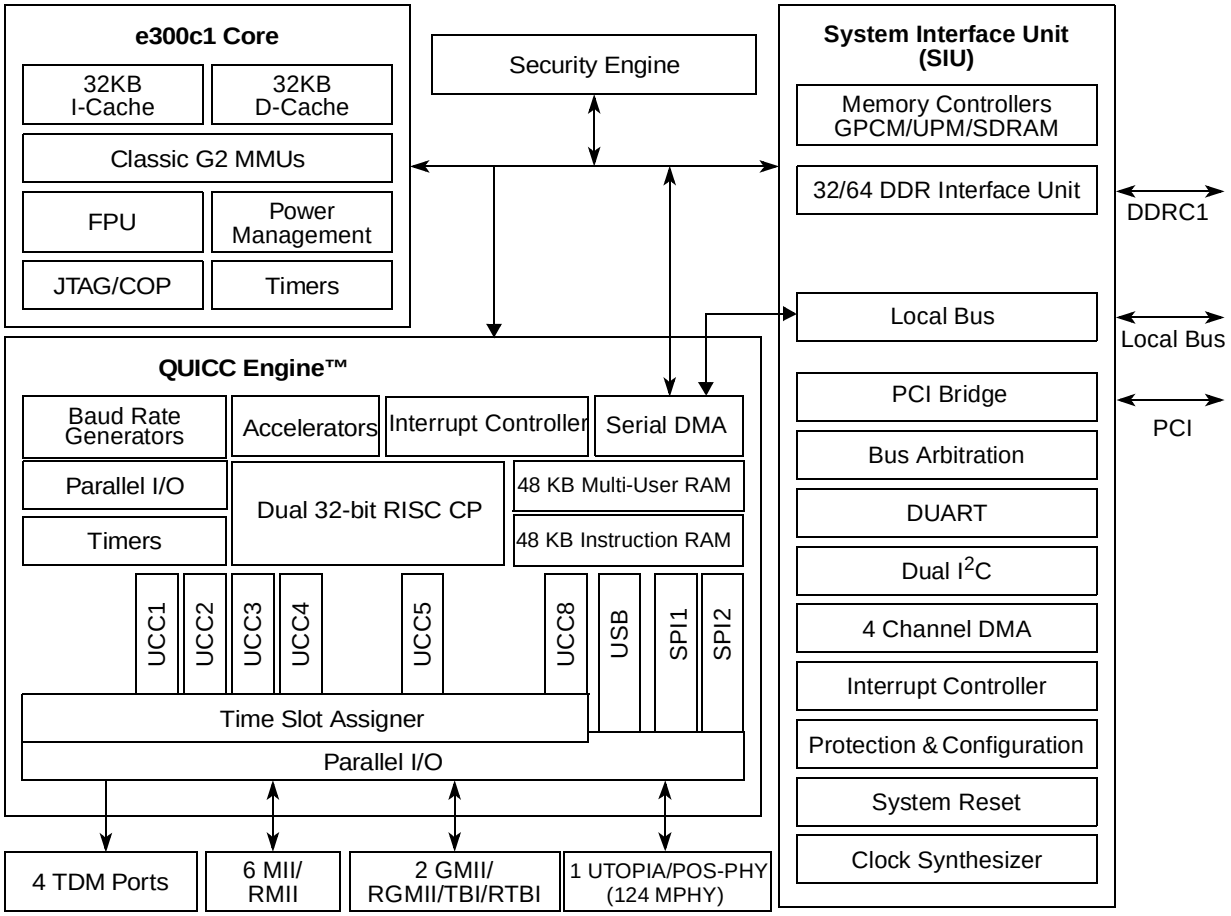

Figure A-1. MPC8358 Block Diagram

A.4 Implementation and Impact of Six UCCs

References to UCC6 and UCC7 are not applicable because the MPC8358 contains six UCCs (UCC1-5 and UCC8) instead of eight UCCs.

A.4.1 Unimplemented Signals

The following signals that support UCC6 and UCC7 are not implemented on MPC8358E:

- CMXUCR4[GR6]
- CMXUCR4[UC6]
- CMXUCR4[RU6CS]
- CMXUCR4[TU6CS]
- CMXUCR2[GR7]
- CMXUCR2[UC7]
- CMXUCR2[RU7CS]
- CMXUCR2[TU7CS]

NOTE

The alternative functionality of the associated port pins remains available, as described in Chapter 3, "Signal Descriptions," and Section 3.4, "Parallel I/O Ports."

A.4.2 Reserved Memory Map Areas

The following memory mapped areas are reserved because UCC6 and UCC7 are not available:

- 0x0_2600 - 0x0_27FF
- 0x0_3400 - 0x0_35FF

A.4.3 UCC General Setup

Although most UCC registers contain configurations bits for eight UCCs, ensure that these are only configuring UCC1-5 and UCC8. Refer to Chapter 23, "Unified Communications Controllers (UCCs)." Registers affected include CIPYCC, CMXGCR, CECR, MTC_TX_ATM_PRAM, MTC_RX_ATM_PRAM. If interrupts are used, ensure that only valid UCCEx, UCCMx, bits in CIMR and bits in CIPNR that correspond to UCC1-5 and UCC8 are manipulated and observed.

A.5 MCC

All references to MCC registers are not applicable since MPC8358 does not contain MCC. Thus, all SIRAM entries must be set for UCC (SIRAM[0] must always equal zero).

A.6 UPC Availability

Due to internal constraints, the MPC8358E supports only one UPC, either UPC1 or UPC2. Some features may become unavailable when one UPC is chosen over the other due to shared functionality on the port pins. Therefore, the user should choose either UPC1 or UPC2 depending on other features being utilized on the device. For example, some MII options are unavailable when UPC1 is chosen and PCI is unavailable when using UPC2, refer to Section 3.4, "Parallel I/O Ports" for pin muxing limitations.

The CMXUPCR register contains configurations bits for both UPCs, ensure that these are only configuring one UPC. Refer to Section 21.5.9, "CMX UPC Clock Route Register (CMXUPCR)."

NOTE

The alternative functionality of the associated port pins remains available, as described in Chapter 3, "Signal Descriptions," and Section 3.4, "Parallel I/O Ports."

A.7 Unimplemented TDM Registers

The following registers that support TDME-TDMH are not implemented on MPC8358E:

- CMXSI1CRH
- SIAMR
- SIBMR
- SICMR
- SIDMR
- SITERC
- SITFRC
- SITGRC
- SITHRC
- SIRERC
- SIRFRC
- SIRGRC
- SIRHRC
- SIGLMRL

NOTE

The alternative functionality of the associated port pins remains available, as described in Chapter 3, "Signal Descriptions," and Section 3.4, "Parallel I/O Ports."

A.8 DDR

The MPC8358 has only one DDR SDRAM memory controller (DDRC1). Thus, it can only support one 32-bit or one 64-bit bus. Therefore all references to the secondary DDR controller do not apply to the MPC8358E. In the memory map, these items do not apply:

0x00_D000 – 0x00_DFFF Secondary DDR Memory Controller

0x0_1804 SDMCSAR—Secondary DDR memory controller start address register

0x0_1844 SDMCEA

0x0_1884 SDMCAR

Appendix B
Revision History

This appendix provides a list of the major differences between revisions of the *MPC8360E PowerQUICC II Pro Integrated Communications Processor Family Reference Manual*. Note that this list only covers the major changes.

B.1 Changes From Revision 1 to Revision 2

Section, Page No.	Changes
Global	The EFM chapter will be removed in future reference manuals. This functionality will be supported in the future via a RAM-based microcode package.
2.3/2-1	Added the following after the third paragraph: “Unless stated otherwise in a particular block, all accesses to and from the memory mapped registers must be made with 32-bit accesses. There is no support for accesses of sizes other than 32 bits.”
2-3, 2-2	Added global timer blocks to Table 2-1, “IMMR Memory Map,” and Table 2-2, “Memory Map,” as shown below. Note that the cross-references refer to this document only and are subject to change in the next revision of the document.

Table 2-1. IMMR Memory Map

Address	Use	Actual Size	Window	Cross Reference
0x00_0500–0x00_05FF	Global timers module 1	64 bytes	256 bytes	Table 2-2
0x00_0600–0x00_06FF	Global timers module 2	64 bytes	256 bytes	Table 2-2

Table 2-2. Memory Map

Offset	Register	Access	Reset	Section/Page
Global Timers Module 1				
0x0_0500	GTCFR1—Timer 1 and 2 global timers configuration register	R/W	0x00	5.8.5.1/5-10
0x0_0501–0x0_0503	Reserved, should be cleared	—	—	—
0x0_0504	GTCFR2—Timer 3 and 4 global timers configuration register	R/W	0x00	5.8.5.1/5-10

0x0_063C	GTPSR3—Timer 3 global timers prescale register			
0x0_063E	GTPSR4—Timer 4 global timers prescale register			

In same section, same table (page 2-17), removed register CAPTURE_EXT_ADDRESS from secondary DDR controller (offset 0x0_DE54).

3.1, 3-2 — In Figure 3-1, made IRQ0/MCP_IN input only.

3.4.7, 3-28 — Replaced this section, formerly entitled “RGMII pins,” with the following:

3.4.7 Gigabit Ethernet Pins

3.4.7.1 RGMII pins

The MPC8360 supports two RGMII ports. For RGMII of UCC1 there is one set of pins. For RGMII of UCC2 there are two sets of pins which can be used. For RGMII of UCC2 the user should select which option to use and then program all the pins to conform to this selection.

Table 3-10. RGMII Pins

SIGNAL	UCC1 RGMII	UCC2 RGMII option 1	UCC2 RGMII option 2
CLK_IN	PC8	PC3	PC7
TxD[0]	PA3	PA17	PF5
TxD[1]	PA4	PA18	PF6

Table 3-10. RGMII Pins (continued)

SIGNAL	UCC1 RGMII	UCC2 RGMII option 1	UCC2 RGMII option 2
TxD[2]	PA5	PA19	PF21
TxD[3]	PA6	PA20	PG24
Tx_EN	PA7	PA21	PF22
GTX_CLK	PC9	PC2	PF26
RxD[0]	PA9	PA23	PF23
RxD[1]	PA10	PA24	PF24
RxD[2]	PA11	PA25	PG30
RxD[3]	PA12	PA26	PF25
Rx_DV	PA15	PA29	PG31
Rx_CLK	PA0	PA31	PF20

3.4.7.2 GMII and TBI Pins

The MPC8360 supports two GMII or TBI ports. For GMII/TBI of UCC1 there is one set of pins. For TxD[4:7] of UCC1 there are two options for each signal. For GMII/TBI of UCC2 there is one set of pins which can be used. The user should select which option to use and then program all the pins to conform to this selection.

Table 3-11. GMII and TBI Pins

SIGNAL	UCC1 GMII/TBI	UCC2 GMII/TBI
CLK_IN	PC[8,9,10,11,14,15]	PC[2,3,6,7,15,16,17]
TxD[0]	PA3	PA17
TxD[1]	PA4	PA18
TxD[2]	PA5	PA19
TxD[3]	PA6	PA20
TxD[4]	PB6 or PC25	PB2
TxD[5]	PB7 or PC24	PB3
TxD[6	PB9 or PC23	PB5
TxD[7]	PB10 or PC22	PB8
Tx_ERR	PA8	PA22
Tx_EN	PA7	PA21
GTX_CLK	PC9	PC2
RxD[0]	PA9	PA23
RxD[1]	PA10	PA24
RxD[2]	PA11	PA25

Table 3-11. GMII and TBI Pins (continued)

SIGNAL	UCC1 GMII/TBI	UCC2 GMII/TBI
RxD[3]	PA12	PA26
RxD[4]	PA13	PA27
RxD[5]	PB1	PB12
RxD[6]	PB0	PB13
RxD[7]	PB4	PB11
Rx_ERR	PA16	PA30
Rx_DV	PA15	PA29
Rx_CLK	PA0	PA31
Rx_CLK1 (for TBI 2 clocks mode)	PC29	PC28

4.3.2.1/4-12 In Table 4-8, “Reset Configuration Word Low Bit Settings,” changed DDRCM bit description from
“The 2:1 mode is useful mostly when for a 32-bit data bus memory device.”
to
“The 2:1 mode is useful mostly for a 32-bit data bus width.”

4.3.2.2/4-16 In Figure 4-4, “Reset Configuration Word High Register (RCWHR),” and Table 4-12, “Reset Configuration Word High Bit Settings,” changed bit 29 (LALE) to be “Reserved”.

4.3.3.2.1, 4-24 Replaced the note with the following:

NOTE

When reset configuration words are loaded from an I^2C EEPROM, an I^2C serial EEPROM of extended addressing type must be used.

4.3.3.3.2, 4-28 In Table 4-24, changed the Name from ‘Reserved, should be cleared’ to Reserved’ for bits 1, 12-15, 16-19, and 20-27.

4.3.3.3.2/4-28 Reformatted Table 4-24, “Hard-Coded Reset Configuration Word High Field Values.”

4.4.3/4-31 Removed overbar from the two instances of CFG_CLKIN_DIV.

4.4.3, 4-32 Removed the first row (I^2C1) from Table 4-26, “Configurable Clock Units.”

4.5.3/4-40 In Table 4-37, “Clock Control DDR,” added a footnote for offset 0x10 as follows:

Offset 0x10 is a offset from the clock control DDR offset 0x001000.

5.4.3.4/5-27 In Table 5-39, “SPCR Bit Settings,” added note to PCIPR (bits 6-7):
“DMA has the same priority as PCI.”

5.4.3.8/5-33 In Table 5-43, “DDRCDR Field Descriptions,” revised field description bit settings for DDRCDR[DSO_NZ] and DDRCDR[DSO_PZ] as follows:

Table 5-43. DDRCDR Field Descriptions

Bits	Name	Description
2–5	DSO_PZ	DDR driver software p-impedance override 0000 Half strength—Highest Z 1000 Much higher Z than nominal 1100 Higher Z than nominal 1110 Nominal impedance setting 1111 Lower Z than nominal
6–9	DSO_NZ	DDR driver software n-impedance override 0000 Half strength—Highest Z 1000 Much higher Z than nominal 1100 Higher Z than nominal 1110 Nominal impedance setting 1111 Lower Z than nominal

5.5.3, 5-37 Replace text of section (up to 5.5.4) with the following:

The WDT unit can operate in the following modes:

- WDT enable/disable mode:

  If the software watchdog timer is not needed, the user can disable it. The SWCRR[SWEN] bit enables the watchdog timer. It should be cleared by software after a system reset to disable the software watchdog timer. When the watchdog timer is disabled, the watchdog counter and prescaler counter are held in a stopped state.

  — WDT enable mode (SWCRR[SWEN] = 1)

    This is the default value after soft reset.

  — WDT disable mode (SWCRR[SWEN] = 0)

- WDT reset/interrupt output mode

  Without software periodic servicing, the software watchdog timer times out and issues a reset or a nonmaskable interrupt (*mcp*), programmed in SWCRR[SWRI].

  According to the value of SWCRR[SWRI], the WDT timer causes a hard reset or machine check interrupt to the core.

  — Reset mode (SWCRR[SWRI] = 1).

    Software watchdog timer causes a hard reset (this is the default value after hard reset).

  — Interrupt mode (SWCRR[SWRI] = 0).

    Software watchdog timer causes a machine check interrupt to the core.

- WDT prescaled/non-prescaled clock mode

  The WDT counter clock can be prescaled by programming the SWCRR[SWPR] bit that controls the divide-by-65,536 of the WDT counter.

  — Prescale mode (SWCRR[SWPR] = 1)

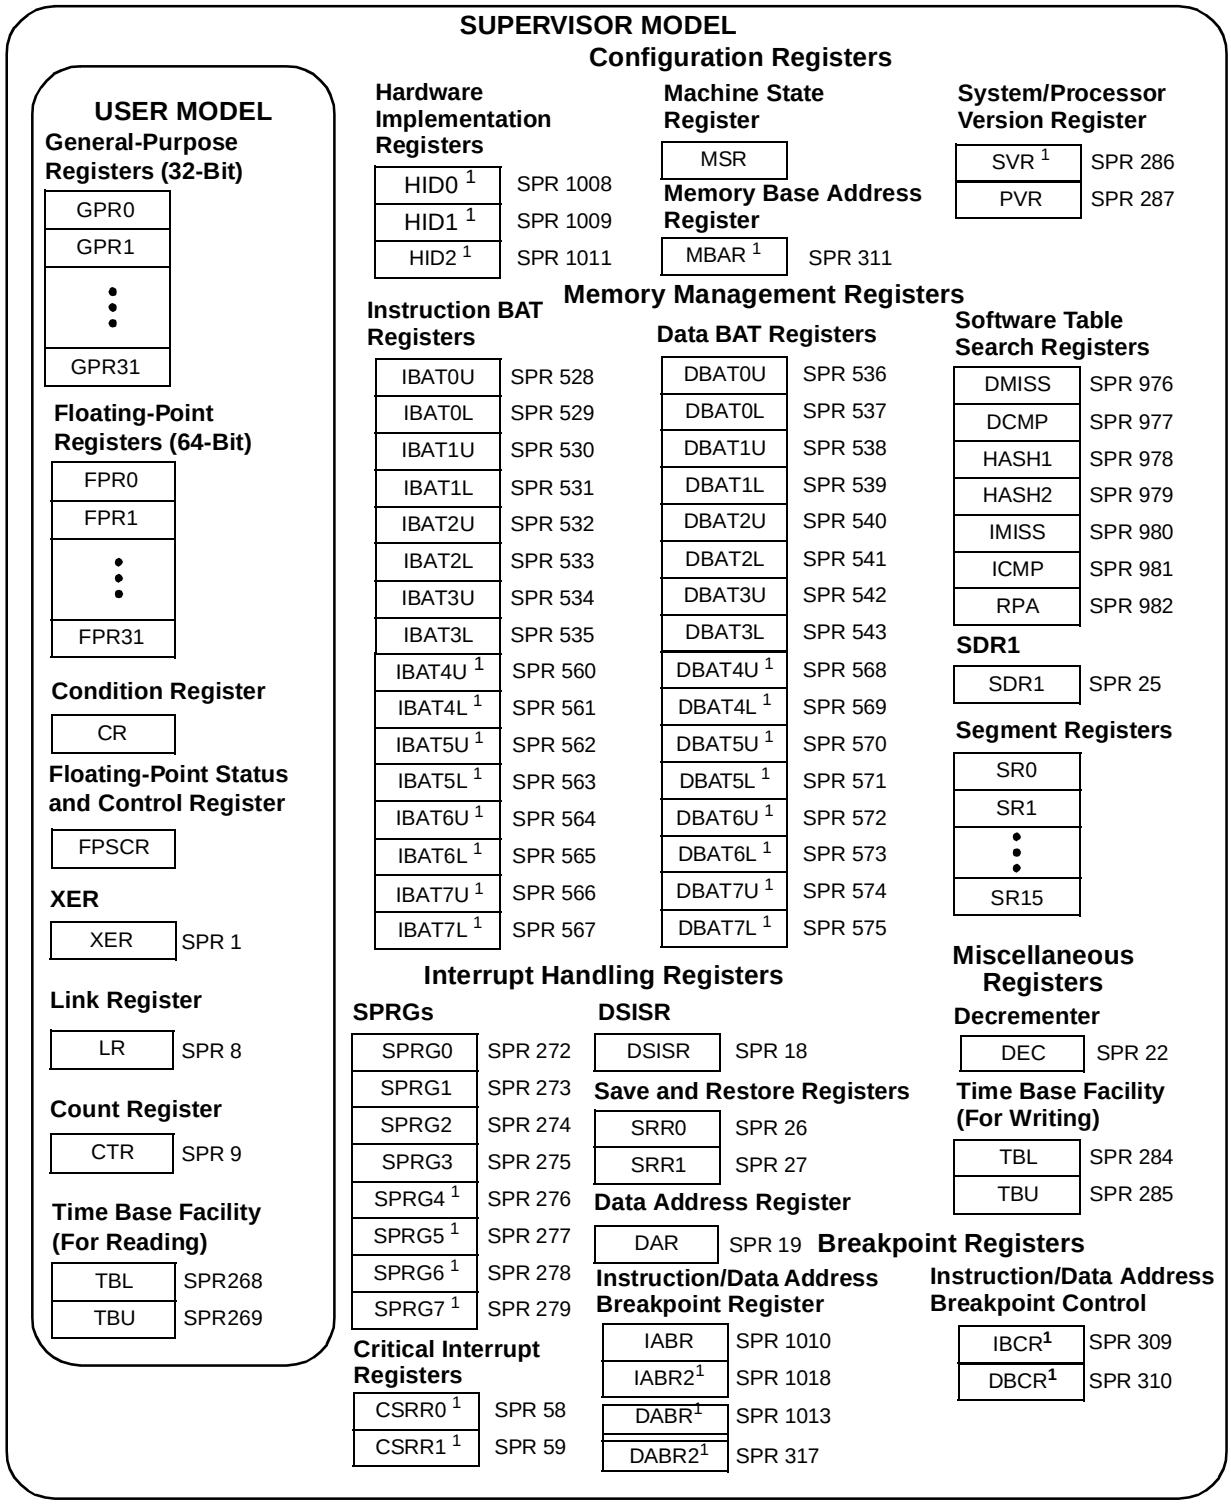
    The WDT clock is prescaled.

  — Non-prescale mode (SWCRR[SWPR] = 0)

    The WDT clock is not prescaled.

5.8, 5-57	Added new Section 5.8, “Global Timers.” Any cross-references refer to this document only and are subject to change in the next revision of the reference manual. **Note that this erratum appeared in a previous revision of this addendum; however, this revision contains the following change:** **Any references to register GTGCR have been changed to GTCFR.**

7.3.1, 7-14 Added Figure 7-2 as follows:



1 These registers are e300 core implementation-specific (not defined by the PowerPC architecture).

Figure 5-1. e300 Programming Model—Registers

7.3.1.3.3, 7-20 — Added new table to show how HID0[ECLK] and HID0[SBCLK] are used to set the frequency of the *clk_out* signal.

Table 7-3. Using HID0[ECLK] and HID0[SBCLK] to Configure *clk_out*

hreset	**ECLK**	**SBCLK**	***clk_out***
Asserted	x	x	Bus clock (small pulse for every rising edge of sysclk)
Negated	0	0	Clock output off
	0	1	Core clock/2
	1	0	Core clock
	1	1	Bus clock

7.4, 7-38 — Removed Table 7-8, “Difference Between e300 Cores”

8.5.16/8-25 — In Table 8-26, “SIFCR_H Field Descriptions” and Table 8-27, “SIFCR_L Field Descriptions”, changed INT*n* bit description of “corresponds to an external interrupt source” to “corresponds to an internal interrupt source”.

9.1/9-1, 9.2.1/9-3 — Modified text to clarify that statements about setting 8_BE when in 32-bit bus mode applies to DDR1 only.

9.3.2.1, 9-6 — Updated description of MDQS[0:8] in Table 9-3 to read as follows:

Data strobes. Inputs with read data, outputs with write data.

9.4/9-9 — In Table 9-5, “DDR Memory Controller Memory Map,” changed reset value for DDR_IP_REV2 to 0x00*nn*_00*nn* to defer implementation-specific values to register description in Section 9.4.1.17, “DDR IP Block Revision 2 (DDR_IP_REV2).”

9.4.1.6, 9-19 — Modified descriptions of TIMING_CFG_2 fields CPO and FOUR_ACT as follows:

Table 9-11. TIMING_CFG_2 Register Field Descriptions

Bits	**Name**	**Description**
4–8	CPO[1]	$\overline{\text{MCAS}}$-to-preamble override. Defines the number of DRAM cycles between when a read is issued and when the corresponding DQS preamble is valid for the memory controller. For these decodings, “READ_LAT” is equal to the CAS latency plus the additive latency. 00000 READ_LAT + 1 00001 Reserved 00010 READ_LAT 00011 READ_LAT + 1/4 00100 READ_LAT + 1/2 00101 READ_LAT + 3/4 00110 READ_LAT + 1 00111 READ_LAT + 5/4 01000 READ_LAT + 3/2 01001 READ_LAT + 7/4 01010 READ_LAT + 2 01011 READ_LAT + 9/4 01100 READ_LAT + 5/2 01101 READ_LAT + 11/4 01110 READ_LAT + 3 01111 READ_LAT + 13/4 10000 READ_LAT + 7/2 10001 READ_LAT + 15/4 10010 READ_LAT + 4 10011 READ_LAT + 17/4 10100 READ_LAT + 9/2 10101 READ_LAT + 19/4 10110–11111 Reserved

Table 9-11. TIMING_CFG_2 Register Field Descriptions (continued)

Bits	Name	Description
. . .		
26–31	FOUR_ACT	Window for four activates (t_{FAW}). This is applied to DDR2 with eight logical banks only. Must be set to 0001 for DDR1. 000000 Reserved 000001 1 cycle 000010 2 cycles 000011 3 cycles 000100 4 cycles . . . 010011 19 cycles 010100 20 cycles 010101–111111 Reserved

[1] For CPO decodings other than 00000 and 11111, ‘READ_LAT’ is rounded up to the next integer value

9.4.1.7/9-20 In Table 9-12, “DDR_SDRAM_CFG Field Descriptions,” added notes to DDR_SDRAM_CFG[RD_EN] and DDR_SDRAM_CFG[RD_EN] field descriptions stating that these fields must not both be set at the same time.

9.4.1.8, 9-23 Changed setting 01 of DDR_SDRAM_CONFIG_2[DQS_CFG] to reserved.

9.4.1.14/9-29 Replaced this section with the following:

The DDR SDRAM clock control configuration register, shown in Figure 9-15, provides a 1/4-cycle clock adjustment.

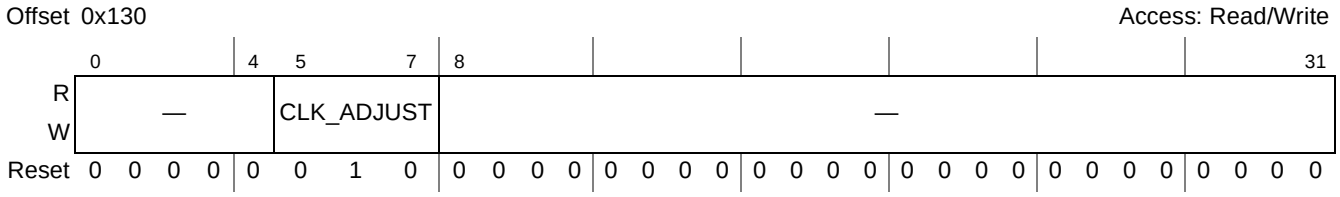


Figure 9-15. DDR SDRAM Clock Control Configuration Register (DDR_SDRAM_CLK_CNTL)

Table 9-20 describes the DDR_SDRAM_CLK_CNTL fields.

Table 9-20. DDR_SDRAM_CLK_CNTL Field Descriptions

Bits	Name	Description
0–4	—	Reserved
5–7	CLK_ADJUST	Clock adjust 000 Clock will be launched aligned with address/command 001 Clock will be launched 1/4 applied cycle after address/command 010 Clock will be launched 1/2 applied cycle after address/command 011 Clock will be launched 3/4 applied cycle after address/command 100 Clock will be launched 1 applied cycle after address/command 101–111 Reserved
8	—	Reserved, should be set to 0
9–31	—	Reserved

9.5.3/9-49	Added sentence to 6th bullet (mode register set): “For DDR2 in 32-bit bus mode, all 32-byte burst accesses from the platform are split into two 16-byte (that is, 4 beat) accesses to the SDRAMs in the memory controller.”
9.6.1, 9-69	Changed DDR2 setting for DQS_CFG (in Table 9-53) to ‘Should be set to 00.’
10.3.1.3, 10-18	Updated MAR (memory address register) to show that field A is 32 bits wide (bits 0–31).
12.4.6/12-9	Changed IMISR access to mixed—two of the bits are w1c. Updated bits to reflect w1c access. Also updated memory map.
12.4.6/12-9, 12.4.7/12-11	Removed the following text from introductory paragraph of IMISR and IMIMR: “IMISR should be accessed only from the CSB and only in agent mode. Accesses while in host mode or from the PCI bus have undefined results.”
12.4.8.1/12-12	In Table 12-11, “DMAMRn Field Descriptions,” added the following to bit fields DAHE and SAHE: “The DMA does not support address hold when the external trigger mode is selected (EMSEN = 1).”
12.4.8.1, 12-13	Added the following note to DMAMR*n*[DAHE] and DMAMR*n*[SAHE]: Note that the address hold feature is not supported when external hardware control is used.
13.1, 13-2	Added the following paragraph: The PCI interface does not flush pending outbound writes as a result of an inbound read command. Systems must not rely on inbound reads to ensure all pending outbound writes have completed. For example, consider the case where a core writes data to a PCI device and then updates a flag in the local DDR memory indicating the write to PCI has completed. An external PCI master may misread the flag ahead of the actual write transaction's completion on the PCI bus.
13.3.3.13, 13-33	Modified PIMMR[BA] as follows:

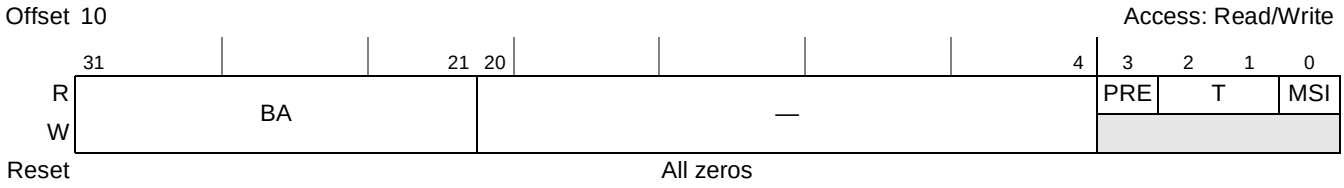

Figure 13-32. PIMMR Base Address Configuration Register

Table 13-34. PIMMR Base Address Configuration Register Field Descriptions

Bits	Name	Description
31–21	BA	Base address. Defines the base address for the internal (on-chip) memory-mapped register space. The size of this space is 2 MB.
20–4	—	Reserved

Table 13-34. PIMMR Base Address Configuration Register Field Descriptions (continued)

Bits	Name	Description
3	PRE	Prefetchable. Hard-wired to 0.
2–1	T	Type. Hard-wired to 00.
0	MSI	Memory space indicator. Hard-wired to 0

14.1, 14-2 Removed second sub-bullet of bullet “Master/slave logic, with DMA capability” (item read “Up to 200-MHz operation)

17.2.1, 17-2 Removed reset values (replaced with ‘—’) from all input signals (TCK, TDI, TMS) in Table 17-1, “JTAG Test Signals Summary.” Modified function column of TCK and $\overline{\text{TRST}}$. Table should appear as follows:

Table 20-1. JTAG Test Signals Summary

Name	Description	Functional Block	Function	Reset Value	I/O
TCK	Test clock	Debug	Clock for JTAG testing.	—	I
TDI	Test data input		Serial input for instructions and data to the JTAG test subsystem. Internally pulled up.	—	I
TDO	Test data output		Serial data output for the JTAG test subsystem. High impedance except when scanning out data.	High impedance	O
TMS	Test mode select		Carries commands to the TAP controller for boundary scan operations. Internally pulled up.	—	I
$\overline{\text{TRST}}$	Test reset		Resets the TAP controller asynchronously. Internally pulled up.	—	I

In same section, in Table 17-2, “JTAG Test—Detailed Signal Descriptions,” removed sentence “An unterminated input appears as a high signal level to the test logic due to an internal pull up resister” from description of $\overline{\text{TRST}}$.

19.2.6/19-22 In Table 19-12, interrupt number 17 should be PTP1 at vector 0b01_0001, interrupt number 19 should be PTP2 at vector 0b01_0011, and interrupt number 21 should be RTC at vector 0b01_0101.

19.3.2/19-35 In Figure 19-27, bit 0 should be PTP1, bit 2 should be PTP2, and bit 4 should be RTC.

19.3.2/19-35 Beneath Figure 19-27, add:

IEEE 1588 Interrupt (PTPx, RTC) are interrupts to the CPU that are asserted by the QUICC Engine module while it is processing an interrupt request from PTPn_TMR_PEVENT or TMR_TEVENT. This mechanism allows for the QUICC Engine RISC to interrupt the host CPU due to certain events which occur while the QUICC Engine UCC's Time Stamp Unit processes a PTP packet or upon detection of an IEEE 1588 Timer event.

20.4.1.1/20-6 In Table 20-4, add opcode 001111 PUSHSCHED, for all peripherals.

20.4.1.1/20-7 In Table 20-5, add description of opcode PUSHSCHED, “Modify the start address for the task running on a given peripheral.”

20.4.1.1.2/20-10 Directly beneath this section, add the following as **Section 20.5.1.2.3 PushSched Command**:

This command is used to modify the start address for the task running on a given peripheral, identified by its SNUM. The next time the scheduler selects this peripheral the RISC will start running from the address programmed in this register. Note that if the Peripheral is enabled while giving this command, the old start address may still be used once before the new start address takes effect. Therefore it is not advisable to change this address while a peripheral is enabled.

The new start address is programmed in the CECDR register, the relevant SNUM is programmed in CECR[7:14], and the scheduler request is enabled by setting CECR[17].

	0	1–6	7–14	15
Field	0	—	SNUM	1
Reset	0000_0000_0000_0000			
R/W	R/W			
Addr	CE_base + 0x00100			

	16	17	18–25	26–31
Field	—	—	—	001111
Reset	0000_0000_0000_0000			
R/W	R/W			
Addr	CE_base + 00102			

Figuren 20-3. CECR for PushSched Command

20.4.4, 20-13 In Table 20-7, the description of CERCR[CIR] was modified in a previous revision of this errata document, revision 1.3. The description should remain unchanged and appear as follows:

Table 20-7. CERCR Field Descriptions

Bit	Name	Description
4	CIR	Common Instruction RAM 0 Each of the two RISC processors has its own 24-Kbyte instruction RAM. Performance may be better since RISCs are not competing on a common resource when fetching instructions. When CIR=0, the instruction ram is seen through IADD as follows: RISC0 0x8_0000–0x8_5FFF RISC1 0x8_8000–0x8_DFFF In case the two RISCs should run the same code, the code should be duplicated in the regions for RISC0 and RISC1. 1 Both RISC processors are sharing a common 48-Kbyte instruction RAM (must be used when instruction RAM code is more than 24 Kbyte). When CIR=1, the instruction RAM is seen as a consecutive 48-Kbyte region at addresses 0x80000–0x8BFFF.

21.5.7, 21-29 — Updated description of CMXUCR3[RU2CS] in Table 21-11 by adding bit setting 1100 as follows:

1100 UCC2 receive clock is GRX_CLK

21.10.5.1/21-51 — Replaced last paragraph with the following:

Upon reaching the reference value, the corresponding GTEVRx[REF] bit is set and an interrupt is issued if GTMDRx[ORI] = 1.

21.10.5.3/21-51 — Changed Pair-cascade mode section, second paragraph; replaced last two sentences with the following:

The captures are controlled from TIN2/TIN4, and the interrupts are generated from GTEVR2/GTEVR4. The cascaded GTRFR, GTCPR, and GTCNR should be referenced with 32-bit bus cycles.

23.3.3/23-7 — Changed “Transmit Polling Timer” to” UCC Transmit Polling Timer” and “UFPT” to “UTPT”.

24.2.4/24-7 — Changed “UFTP” to “UTPT”.

24.4.6.3/24-14 — After step 1, add, “If a protocol switch is performed from fast protocol, follow step 2 in section 24.4.6.5.

24.4.6.5/24-14 — Add the following as step 2. “If a protocol switch is performed from fast protocol: Issue the PushSched host command for UCC Transmitter (CECDR value 0x80), Issue the PushSched host command for UCC Receiver (CECDR value 0x82).

27.4.1/27-4 — In Table 27-1, “UCC Memory Map (Fast Mode),” changed “UFPT” to “UTPT”.

27.4.3/27-10 — Changed “UFTP” to “UTPT”.

29.3.1/29-3 — In Table 29-1, “UCC HDLC Register Summary,” removed UCC data synchronization register.

29.3.3/29-17 — Modified third bullet under “The collision-detection mechanism supports only:” to the following:
“Open-drain connection via port pin configuration or via external transceivers.”

30.5.1.1/30-29 In Table 30-5, “UPSMR Ethernet Field Descriptions,” replaced AUFC field description as follows:

Table 30-5. UPSMR Ethernet Field Descriptions

Bits	Name	Description
16–17	AUFC	Automatic Flow Control Enable 00 No Automatic Flow Control frames are sent by the UEC. CPU may initiate a transmit flow control frame issuing START FLOW CONTROL command. 01 In full duplex mode, the UEC sends a pause frame when RxFIFO reaches its special emergency threshold (that is, URFSET is crossed upwards). When the RxFIFO empties out below the emergency threshold (that is, URFET is crossed downwards), the UEC automatically sends pause frame with MAC parameter duration of “zero pause quantas”. It is assumed the URFET < URFSET. In half-duplex mode, when URFSET is crossed, the MAC applies back pressure algorithm on the line by sending preambles on the line when no data is available for transmit; when URFET is crossed downwards, the UEC disables the back pressure algorithm. See Section 27.5.4, “Receive Virtual FIFO Special Emergency Threshold (URFSET). 10 Reserved (not allowed) 11 In addition to the behavior described when AUFC = 01, the UEC sends a pause frame when the receive buffers are busy. The UEC fills its RxFIFO until it reaches its threshold, and then a flow control frame is sent automatically. This mode serves as an automatic flow control mechanism for external buffers. In half-duplex mode the MAC applies back pressure algorithm on the line by sending preambles on the line when no data is available for transmit.

30.5.1.17/30-47 Added description of UEMPR[Extension Header]:
“Can contain any user-defined data. Note that this does not extend the MAC parameter value, which would cause more delay when a flow control frame is detected.”

30.5.2.2/30-56 In Table 30-27, Offset +0, bit 15, change, “if UPSMR[IPCHK]=1,” should be “if REMODER[IPCHK]=1.”

30.6.2.6.5/30-91 In Table 30-56, “TAD Field Descriptions,” added note to Rej field description:
“For proper operation, if TAD[Rej]=1 the user must program bits TAD[VPriority,CFI,VID]=0.”

30.7.5/30-97 In Table 30-59, “UCC Statistics,” added the following sentence to the field descriptions for RBCA, RMCA, TMCA, and TBCA counters:
“Frames longer than 1518 bytes (if untagged) or 1522 bytes (if tagged) are not counted.”

30.8/30-110 In Table 30-79, removed “or transmitter error (underrun, retransmission limit reached, or late collision)” from RESTART TRANSMIT description.

31.11.3/31-32 In Table 31-25, “1588 RTC External Signals,” added parallel port signal pins columns as shown below:

Table 31-25 describes the IEEE 1588 Real Time Clock external signals:

Table 31-25. 1588 RTC External Signals

Signal name	I/O	Description	Parallel Port Signal Pins	
			Primary Option	Secondary Option
PTP_PPS1	Output	Pulse per second output signal generated by configuring the FIPER1 register. Each time the FIPER1 value is expired one RTC clock period pulse is generated	CE_PC21	CE_PE20
PTP_PPS2	Output	Pulse per second output signal generated by configuring the FIPER2 register. Each time the FIPER2 value is expired one RTC clock period pulse is generated	CE_PC17	CE_PD19
PTP_PPS3	Output	Pulse per second output signal generated by configuring the FIPER3 register. Each time the FIPER3 value is expired one RTC clock period pulse is generated	CE_PC5	CE_PF29
PTP_ALARM1	Output	Alarm output triggers, set if the timer value reaches the alarm1 register	CE_PC0	CE_PE14
PTP_ALARM2	Output	Alarm output triggers, set if the timer value reaches the alarm2 register	CE_PC23	CE_PE6
PTP_REF_CLK	Output	Divided output clock, by configuring the TMR_PRSC register	CE_PC12	CE_PE26
PTP_CLK	Input	External oscillator Real Time Clock	CE_PC30	
PTP_EXT_TRIG1	Input	Input trigger to capture timestamps. The captured timestamp is stored in TMR_ETSS1L/TMR_ETSS1H	CE_PB4	CE_PC14
PTP_EXT_TRIG2	Input	Input trigger to capture timestamps. The captured timestamp is stored in TMR_ETSS2L/TMR_ETSS2H	CE_PC11	CE_PC27

36.6.4/36-18 Add the following table as Table 36-9:

Tablen 36-9. SI Mode Register Description

Bits	Name	Description
0–3	SADx	Starting address for the RAM of TDMx. These four bits define the starting address of the SI RAM section that belongs to TDMx channel. The last entry of a certain TDM is determined by the LST bit in the SI RAM entry. The user must set LST within the entries of SI RAM blocks for every TDM used i.e. before the starting address of the next TDM. 0000 Entries 0-31, bank0 0001 Entries 32-63, bank0 0010 Entries 64-95, bank1 0011 Entries 96-127, bank1 0100 Entries 128-159, bank2 0101 Entries 160-191, bank2 0110 Entries 192-223, bank3 0111 Entries 224-255, bank3 1000 Entries 256-287, bank4 1001 Entries 288-319, bank4 1010 Entries 320-351, bank5 1011 Entries 352-383, bank5 1100 Entries 384-415, bank6 1101 Entries 416-447, bank6 1110 Entries 448-479, bank7 1111 Entries 480-511, bank7 **Note:** Each bank should be addressed by a single TDM only
4–5	SDMx	SI Diagnostic Mode for all eight TDMs 00 normal operation. 01 Automatic echo. In this mode, the channel_x transmitter automatically retransmits the TDM received data on a bit-by-bit basis. The receive section operates normally, but the transmit section can only retransmit received data. In this mode, the L1GRx line is ignored. 10 Internal loopback. In this mode, the TDM transmitter output is internally connected to the TDM receiver input (L1TXDx is connected to L1RXDx). The receiver and transmitter operate normally. The data appears on the L1TXDx pin and in this mode, the L1RQx line is asserted normally. The L1GRx line is ignored. 11 Loopback control. In this mode, the TDM transmitter output is internally connected to the TDM receiver input (L1TXDx is connected to L1RXDx). The transmitter output (L1TXDx) and the L1RQx pin is inactive. This mode is used to accomplish loopback testing of the entire TDM without affecting the external serial lines.
6–7	RFSDx.	Receive frame sync delay for all eight TDM. Determines the number of clock delays between the receive sync and the first bit of the receive frame. Even if CRTx is set, these bits do not control the delay for the transmit frame. 00 No bit delay. The first bit of the frame is transmitted/received on the same clock as the sync. 01 1-bit delay. Use for IDL. 10 2-bit delay 01 3-bit delay
8	Reserved	Reserved. Should be cleared.

Tablen 36-9. SI Mode Register Description (continued)

Bits	Name	Description
9	CRTx	Common receive and transmit pins for all TDM. Useful when the transmit and receive sections of a given TDM use the same clock and sync signals. In this mode, L1TCLKx and L1TSYNCx pins can be used as general-purpose I/O pins. 0 Separate pins. The receive section of this TDM uses L1RCLKx and L1RSYNCx pins for framing and the transmit section uses L1TCLKx and L1TSYNCx for framing. 1 Common pins. The receive and transmit sections of this TDM use L1RCLKx as clock pin of channel x and L1RSYNCx as the receive and transmit sync pin. Use for IDL. RFSD and TFSD are independent of one another in this mode.
10	SLx	Sync level for all TDM's. 0 The L1RSYNCx and L1TSYNCx signals are active on logic "1". 1 The L1RSYNCx and L1TSYNCx signals are active on logic "0".
11	CEx	Clock edge for all TDM's. 0 The data is transmitted on the rising edge of the clock and received on the falling edge (use for IDL). 1 The data is transmitted on the falling edge of the clock and received on the rising edge
12	FEx	Frame sync edge for all TDM's. Determines whether L1RSYNCx and L1TSYNCx pulses are sampled with the falling/rising edge of the channel clock. 0 Falling edge. Use for IDL. 1 Rising edge.
13	GMx	Grant mode for all TDM's. 0 No grant mode is supported. 1 IDL mode. A GRANT mechanism is supported if the corresponding CMXSCR[GRx] is set. The grant is a sample of L1GRx while L1TSYNCx is asserted. This grant mechanism implies the IDL access controls for transmission on the D channel.
14–15	TFSDx	Transmit frame sync delay for all TDM's. Determines the number of clock delays between the transmit sync and the first bit of the transmit frame. 00 No bit delay. The first bit of the frame is transmitted/received on the same clock as the sync. 01 1-bit delay 10 2-bit delay 11 3-bit delay

32.3.8, 32-112 Updated Table 32-53 as follows:

Table 32-53. V-TCT Field Descriptions

Offset	Bits	Name	Description
. . .			
0x00	13	VCON (status)	Virtual channel is on. Should be set by the host before it issues an ATM TRANSMIT command. When the host sets TCT[STPT] (stop transmit), the QUICC Engine block deactivates this channel and clears VCON when the channel is next encountered in the APC scheduling table. The host can issue another ATM TRANSMIT command only after the QUICC Engine block clears VCON.
		VCON (mode)	Cleared by the host to enable the automatic activation in switch mode - AVCON/AVCF mechanism. When this mode is enabled, the TCT[AVCF] bit should be set. See ATM_AVCON_BASE parameter in Table 32-19 for more description.
. . .			

32.3.8.1/36-117 Replaced the last two bulleted list items with the following:

- For WFQ channels which **are not** members in a multicast group perform the following steps:
  - — Issue a host command for inserting the WFQ channel into the WFQ structure. Repeat this command for each channel participating in the WFQ selection. This is an ATM transmit command with special parameters described in Section 32.4.1, “ATM Commands.” The ACT field is set to 0b11 and the Virtual CC is given in the BT field in the command info area.
  - — Issue an host command for scheduling the V-TCT. This is an ATM transmit command with parameters for inserting the CC into the scheduling table (APC or GCRA scheduler). If the V-TCT is scheduled in GBR mode another host command should be issued for inserting the channel to the UBR level and the Command info[ACT]=0b10.

33.6.5.1/36-29 In Table 33-13, “UPDCx in ATM Protocol Field Descriptions,” added reserved row for bits 22-23.

34.1.1, 34-2 Added the following item to features list:

- Up to 32 Mbps sustainable aggregated throughput (for HDLC/Transparent) for normal channels and 16-bits super channels. Up to 16 Mbps for other super channels settings.

34.2.8, 34-46 Replaced beginning of description of MERL[TEO] in Table 34-23, “MCC Emergency Request Level (MERL),” with the following:

Transmit emergency offset is an offset from the beginning of the transmitter request FIFO. The offset is actually the amount of data in the request FIFO. Emergency request will be asserted when the amount of data in the request FIFO equals the amount or more.

36.1/36-1 In Figure 36-1, “SI Block Diagram,” modified note at bottom of figure to read as follows:

See Section 21.1, “Working with Peripherals in NMSI Mode,” for the connections between UCCs and pins in NMSI mode.

36.6.1, 36-12 Relocated note from after Table 36-5 to be after Table 36-4. Changed note to read as follows:

NOTE: On Backward-Compatibility

As in PowerQUICC II Pro, there is a minimal restriction of two entries per frame. There is also a minimal restriction of two bits per UCC entry if CDP or CTSP modes are set.

36.7.1, 36-32 Replaced first sentence of second paragraph with the following:

Each line of RAM consists of two 16-bit entries that define the routing control.

37.17.3, 27-58 In Table 37-27, “Tx Free Buffer Pool Parameter Table,” changed entry in bits column for first row (FBP_BASE) to read ‘0–31.’

37.18.1, 27-60 In Table 37-28, “Receive Buffer Descriptor Fields,” changed entry in bits column for last row (Time Stamp) to read ‘0–31.’

37.19.5, 37-69 Added field GBL to MPT. Updated Figure 37-45 and Table 37-33 as follows:

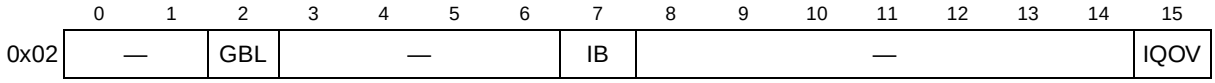

Figure 37-45. Mux Encapsulation Management Table

Table 37-33. Mux Encapsulation Management Table Field Descriptions

Offset	Bit	Size	Name	Description
0x02	2	Hword	GBL	Global. Setting GBL enables snooping of Interrupt queues. This should match BMR[GBL]. To use Global mode, SDMR[GLB_1_MSK] must also be set, see Section 19.1.8.2, “Serial DMA Mode Register (SDMR).”

37.19.2, 37-65 Replaced last sentence of CETM description in Table 37-30, “DeMux Management Table Field Description,” with the following:

See Figure 19-1 and Section 5.4.3.7, “Debug Configuration.”

37.19.7/37-74 In Figure 37-47 and Table 37-36, updated MMR by adding field Not_Act (bit 10) to indicate to the MUX process that this queue is not active. Updated Table 37-36 as follows:

Table 37-36. MMR Field Descriptions

Bits	Name	Description
8–9	—	Reserved. Should be cleared.
10	Not_Act	Not Active- This bit signals to the QE that this MUX queue is currently not active and there is no need to process a superframe for this queue. The host should clear this bit when the queue is operational.
11	—	Reserved. Should be cleared

38.3.1.1/38-15 Changed Figure 38-9, bit 14 from Reserved to RAD.

38.3.1.1/38-15 Changed Table 38-2, bit 14 from Reserved to RAD with this bit description:

Receive ATM Disable
0 Pass cells, except filtered cells, to the ATM or IMA microcode.
1 No cells are passed to the ATM or IMA microcode. The MTC will maintain the cell delineation algorithm and counters will be updated.

39.9.1, 39-31 Replaced sentence before last equation on page 39-31 with the following:

The real starting address of a RCT entry which is associated with channel code 256 is:

42.3.2.8/42-6 Bolded user initialized parameters in Table 42-1, “Global Multichannel Parameters”: MCBASE, QMCSTATE, MRBLR, Tx_S_PTR, RxPTR, GRFTHR, CRFCNT, INTBASE, INTPTR, Rx_S_PTR, TxPTR, C_MASK32, TSATRx, TSATTx, C_MASK16, and QMC_Global_Channel_specific_base.

42.3.4.1/42-16 Bolded user initialized parameters in Table 42-4, “Channel-Specific HDLC Parameters,”: TBASE, CHAMR, TSTATE, TBPTR, ZISTATE, INTMSK, RBASE, MFLR, RSTATE, RBPTR, and ZDSTATE.

42.3.4.2/42-20	Bolded user initialized parameters in Table 42-8, “Channel-Specific Transparent Parameters,”: TBASE, CHAMR, TSTATE, TBPTR, ZISTATE, INTMSK, RBASE, TMBLR, RSTATE, RBPTR, ZDSTATE, and TRNSYNC.
43.5.3.5/43-52	Change Step 8. to read as follows: Enable the corresponding link/PHY at the TC layer for example if using SAM as the TC layer set MTC_MODE[RXEN], or clear MTC_MODE[RAD] if the MTC is already in SYNC state but not passing cells up. If an external TC layer is used, set the corresponding enable bit for the external TC layer device.
43.5.3.5/43-52	Revised step 1 of the Rx steps for LDS section to clarify that after GDS failure ADD_NEW and ADD_NEW_M are correctly configured if the link that caused the failure is to be added after it reaches the working state.
43.5.3.10/43-58	Updated section to clarify that IFSD and GDS events do not require link removals.
43.5.3.10/43-58	Replaced DCB Synchronization Lost (DSL) bulleted section with the following:

- DCB Synchronization Lost (DSL)—A link in a group with IGRSTATE[GDSS] = 11 loses synchronization and enters HUNT state at the IFSM. Because the link has lost synchronization, its differential delay with respect to other member links in the group must recalculated via the LDS. When this interrupt occurs, software should remove or deactivate the link because the QUICC Engine module does not automatically perform the LASR procedure. Note that when the interrupt is generated the ILRSTATE[DL] bit is set. If the link is to be added to the group again, software can perform the link removal or deactivation procedure described in Section 43.5.3.6, “Link Removal Procedure or Section 43.5.3.7, “Link Receive Deactivation Procedure. The link can then be re-added to the group using the link addition procedure see Section 43.5.3.5, “Link Addition Procedure for a removed link or Section 43.5.3.8, “Link Receive Reactivation Procedure for a deactivated link. For fast recovery from the DSL event the software should perform the following tasks:
  - Link deactivation see Section 43.5.3.7, “Link Receive Deactivation Procedure
  - Poll ILRSTATE[FSES] checking for WORKING state, ILRSTATE[FSES] = 0b00. The poll of ILRSTATE[FSES] must last at least (GAMMA +1) IMA frames.
  - If WORKING state is reached then perform reactivation see Section 43.5.3.8, “Link Receive Reactivation Procedure
  - Else if ILRSTATE[FSES] = 0b1x then the DEFECT state has been reached and an IFSD event will be generated for this link.

  The relationship of the DSL interrupt versus the IFSD interrupt is depicted in Figure 43-34. The DSL interrupt is issued when the IFSM reaches the HUNT state. The SYNC to HUNT transition also creates the ANOMALY state for the IMA Error and Maintenance State Diagram. The link can recover from the ANOMALY state and return to the WORKING state before an IFSD. The DSL is issued only for links that have achieved GDS or LDS or for links that have started but not completed the LDS process.

43.5.3.6.1/43-55	Change Step 8. to read as follows: Inhibit reception of cells over the dropped link by disabling the TC layer such that it does not pass any more cells to the IMA layer. Disable the TC layer, for example, if using the SAM clear MTC_MODE[RXEN]. If the TC layer is

connected on the UTOPIA bus, disable it by ensuring that it passes no more cells onto the UTOPIA bus for this link. If the application requires that the TC layer remains cell delineated (no LOCD) at this step then software should adhere to the following steps:

a) Leave MTC_MODE[RXEN] = 1

b) Set MTC_MODE[RAD]

B.2 Changes From Revision 0 to Revision 1

Section, Page No.	Changes
1.2.1, 1-8	Replace the first sentence of the second paragraph on page 1-8 with the following: The core is a superscalar processor that can issue three instructions (two plus a branch) and completes and retires as many as two instructions per clock cycle. Replace the fourth sentence of the fourth paragraph on page 1-8 with the following: The caches use a pseudo least recently used (PLRU) replacement algorithm; the TLBs use a least recently used (LRU) replacement algorithm.
2-3, 2-2	Add the following text to the beginning of this section: Reading from address locations which appear as reserved in the memory map table is not guaranteed to return predictable data. Writing to address locations which appear as reserved in the memory map table is not allowed and could lead to unpredictable behavior of the device. Reserved bits in non-reserved registers will be read as zero unless the reset value of those bits is different due to internal logic considerations. When writing to registers with reserved bits, those reserved bits should be cleared. By doing so, existing software would be able to run on a future modified device in which some reserved bits were allocated for enhanced modes. This would allow for maintaining the legacy functionality when set to zero. In certain specific cases, reserved bits should not be cleared but should keep their reset value. Thus, the software should perform a ‘read-modify-write’ and make sure that it does not change the reset value of those bits. The description of the specific bits will indicate when this is needed.
2.3, 2-5	In Table 2-2, the reset value of SWCRR (system watchdog control register) should appear as 0xFFFF_0007/0xFFFF_0003 (either value possible). A footnote was added to explain as follows: SWCRR[SWEN] reset value directly depends on RCWHR[SWEN] (reset configuration word high).
2.4, 2-35	In Table 2-4, the size of IPGIFG (interframe gap register) should be 4 bytes.
2.4, 2-36	In Table 2-4, the section “Ethernet Statistics Counters” was modified.
3.4.8, 3-28	Added POS I/O signals to Table 3-11 through Table 3-17.
3.4.8, 3-34	In Table 3-12, the input row for PB4 (CPPARBx[SELn]=11) should contain:

	UPC2:RxAddr[0] UTOPIA slave UPC2:RADR[0] POS slave (Secondary Option)
3.4.8, 3-55	In Table 3-17, the input row for PG3 (CPPARGx[SELn]=01) should contain: UPC2:RxAddr[0] UTOPIA slave UPC2:RADR[0] POS slave (Primary Option)
4.1.2, 4-3	Add the following note to the descriptions of both CLKIN and PCI_CLK/PCI_SYNC_IN: NOTE: If PCI is not used, the device clock source must be connected to PCI_CLK/PCI_SYNC_IN, not CLKIN.
4.3.1.1, 4-10	In the meaning of CFG_RESET_SOURCE[0:2] (Table 4-5) for option 010, replace the last sentence with the following: Reset configuration word is loaded from an I^2C EEPROM. PCI_CLK/PCI_SYNC_IN is valid for any PCI frequency up to 66.666 MHz (range of 24–66.666 MHz).
4.3.3.1.1, 4-23	Add the following paragraph after the first paragraph: In these figures, CLOCK/32 is an internal clock. The LCLK*n* signals are not active during the power-on reset sequence.
5.2.4.1.1, 5-6	Add the following bullet below the existing one: • When the e300 core is writing to IMMRBAR, it should use the following sequence: – Read the current value of IMMRBAR using a load word instruction followed by an **isync**. This forces all accesses to configuration space to complete. – Write the new value to IMMRBAR. – Perform a load of an address that does not access configuration space or the on-chip SRAM, but has an address mapping already in effect (for example, boot ROM). Follow this load with an **isync**. – Read the contents of IMMRBAR from its new location, followed by another **isync**.
5.4.1.1, 5-28	Add the following note to the description of $\overline{\text{PCI\_MODE}}$: NOTE: If PCI is not used, the device clock source must be connected to PCI_CLK/PCI_SYNC_IN, not CLKIN.
5.5.4, 5-41	In Table 5-46, the reset value of SWCRR should appear as 0xFFFF_0007/0xFFFF_0003 (either value possible). A footnote was added to explain as follows: SWCRR[SWEN] reset value directly depends on RCWHR[SWEN] (reset configuration word high).

5.5.4.1, 5-42	Added text to description of SWCRR[SWEN]: The reset value directly depends on the value of RCWHR[SWEN] bit.
8.5.19, 8-27	The offset of SCVCR should be 0x60.
8.5.20, 8-28	The offset of SMVCR should be 0x64.
9.4.1.16, 9-30	Remove this section.
9.4.1.30, 9-38	Remove this section.
14.6.1.4, 14-91	Replace paragraph three with the following: The fetch FIFO can hold up to 24 descriptor pointers at a time. When the end of the current descriptor is reached, the descriptor pointed to by the next location in the Fetch FIFO will be read to launch the next descriptor. Writing a descriptor pointer to the fetch FIFO while the FIFO is full will result in a single overflow interrupt to advise the user that the descriptor pointer was not successfully written to the fetch FIFO. The channel will continue processing and software can check the fetch FIFO counter in the crypto-channel pointer status register before attempting to re-enqueue the descriptor pointer. If a second descriptor pointer is written to the fetch FIFO before the single the single overflow error is cleared, the channel will generate a double overflow error interrupt and stop processing descriptors. The channel can be restarted by setting the Continue bit in the crypto-channel configuration register, or completely reset by writing the Reset bit in the same register.
19.1.8.9, 19-14	In Table 19-9, the description of BA should read as follows: Temporary buffer base address in multi-user RAM. The address must be 4KB aligned.
21.4, 21-7	Add the following sentence to footnote 2 of Table 21-1: The UCC1 Tx clock is also the 125MHz reference clock for Gigabit Ethernet when the UCC is configured for GMII/RGMII/TBI/RTBI. Add the following sentence to footnote 4 of Table 21-1: The UCC2 Tx clock is also the 125MHz reference clock for Gigabit Ethernet when the UCC is configured for GMII/RGMII/TBI/RTBI.
27.4.2.1, 27-7	In Table 27-2, in the description of DIAG, remove the note “In Ethernet mode program MACCFG1[8] bit for loopback mode. DIAG bits have no effect..”
27.4.2.1, 27-10	In Table 27-2, in the description of ENR, change the words (in the note) “set the MACCFG1 bit 2” to “set the MACCFG1 bit 29.” In the description of ENT, change the words (in the note) “set the MACCFG1 bit 0” to “set the MACCFG1 bit 31.”
27.5.3, 27-14	The second sentence in the description of field RFET should begin “The recommended value for RFET (for most applications) is ....”
27.5.4, 27-15	The third sentence in the description of field RSFET should begin “The recommended value for RSFET ....”
29.3.3, 29-17	Replace the last two sentences of the third paragraph with the following:

If the echo bit is ever 0 when the transmit bit is 1, a collision occurs between terminals; the station(s) that sent a one stops transmitting. The station that sent a zero continues as normal.

30.5.1.1, 30-29 — Replace the description of PTPE with the following:

PTP Enable
0 - Disable IEEE1588 assist connection to MAC I/F
1 - Enable IEEE1588 assist connection to MAC I/F

30.5.1.6, 30-38 — Add the following sentence to the description of Minimum IFG Enforcement (Table 30-12):

Zero is not a legal value.

30.5.1.8, 30-41 — Replace the description of Mgmt Clock Select in Table 30-14 with the following (note that the bit settings remain unchanged):

This field determines the clock frequency of the Mgmt Clock (CE_MDC). Its default value is 111. The source clock frequency is equal to the QUICC Engine clock divided by 16.

30.5.1.10, 30-42 — In Table 30-16, “MIIMADD Field Descriptions,” replace the text in PHY Address description with the following:

This field represents the 5-bit PHY address field of Mgmt cycles. Up to 31 PHYs can be addressed, with one address reserved for internal TBI registers (corresponding to the value of TBIPA[TBIPA] whose default value is 0x00). Re-programming of TBIPA[TBIPA] to a non-zero value allows PHY address to then be set to 0.

30.5.3.3.2, 30-63 — Replace the second row of Table 30-33 (reserved area) with the following:

Offset	Bits	Name	Description (Data structure must be 32 bytes aligned).	Initialized by
0x04-0x07		Reserved	Set to zero	QE
0x08-0x09	0:31	BDRConsumerAddress	Points to the next entry in the BD ring to be executed. This field must be initialized after reset to the first entry in the BD ring.	QE
0x0A - 0x0B		Reserved		QE

30.5.3.3.3, 30-64 — In Table 30-34, add the following reference to the descriptions of NorTSRByteTime (offset 0x50) and FracSiz (offset 0x52):

Also see example calculations in Section 30.15, “Traffic Shaper Programming Considerations.”

30.5.3.5, 30-68 — In Table 30-36, add the following to the description of LossLessFCPtr:

This base address must be programmed if Lossless Flow Control is enabled in REMODER[LossLessFCEn] OR if Advanced Queue Management is enabled by programming TAD[IWCT Index]>0.

If Lossless Flow Control feature is enabled, the user must allocate 8..64 bytes for this data structure depending on the number of queues.

30.6.2.6.5, 30-90 Replace the existing Table 30-56 with the following:

Table 30-56. TAD Field Descriptions

Offset	Bits	Name	Description
0x0	0-15		See description in REMODER register. Section 30.5.3.7, “Rx Ethernet Mode Register (REMODER)
0x2	0-15	QTag	QTag (VPriority,CFI,VID) to be inserted.
0x4		Reserved	Set to zero

30.7.5, 30-97 Table 30-59 was updated extensively.

30.7.7, 30-99 Register names were modified throughout this section.

30.7.7.16, 30-107 The bits of RxDiscOv should be numbered from 16–31.

30.7.7.18, 30-109 Bits 0–15 of CMR are reserved; the non-reserved fields are in bits 16–31. (MT64 is bit 16, MT65 is bit 17, MT128 is bit 18, ...)

30.15.1.8, 30-163 In Table 30-124, the traffic rate of queue number 5 should be 1/10

31.9.1, 31-17 In Table 31-12, the names of the fields ALM2P and ALM1P should be swapped to match the register figure. In the description of setting 11 for CKSEL, change “reserved by QUICC Engine” to “NA for QUICC Engine.”

32.3.8, 32-118 Remove the fourth sentence of the second paragraph on this page (stating that the table is 64-byte aligned).

33.4.1.1, 33-19 Table 33-3 was revised to include pull up and tri-state requirements.

33.4.1.2, 33-20 Table 33-4 was revised to include tri-state requirements.

33.4.1.3, 33-21 Table 33-5 was revised to include pull up and tri-state requirements.

33.4.1.4, 33-22 Table 33-6 was revised to include tri-state requirements.

33.6.1, 33-26 Change footnote 1 of Table 33-8 to read as follows:

Note on backwards compatibility: the programing model regarding the LPB mode have changed, instead of programing the GUMR[DIAG] as in the 8260, it is done in through UPGCR[DIAG].

43.5.3.6.1, 43-55 In the TX Link Removal, updated step 8 to accomodate those cases where the TC layer must remain in SYNC state in order to send the correct state of link back to the FE.

Glossary

The glossary contains an alphabetical list of terms, phrases, and abbreviations used in this reference manual.

A

Architecture. A detailed specification of requirements for a processor or computer system. It does not specify details of how the processor or computer system must be implemented; instead it provides a template for a family of compatible *implementations*.

Atomic access. A bus access that attempts to be part of a read-write operation to the same address uninterrupted by any other access to that address (the term refers to the fact that the transactions are indivisible). The PowerPC architecture implements atomic accesses through the **lwarx**/**stwcx.** instruction pair.

Autobaud. The process of determining a serial data rate by timing the width of a single bit.

B

Beat. A single state on the e300 bus interface that may extend across multiple bus cycles. A e300 transaction can be composed of multiple address or data *beats*.

Big-endian. A byte-ordering method in memory where the address *n* of a word corresponds to the *most-significant byte*. In an addressed memory word, the bytes are ordered (left to right) 0, 1, 2, 3, with 0 being the *most-significant byte*. See *Little-endian*.

Boundedly undefined. A characteristic of certain operation results that are not rigidly prescribed by the PowerPC architecture. Boundedly- undefined results for a given operation may vary among implementations and between execution attempts in the same implementation.

Although the architecture does not prescribe the exact behavior for when results are allowed to be boundedly undefined, the results of executing instructions in contexts where results are allowed to be boundedly undefined are constrained to ones that could have been achieved by executing an arbitrary sequence of defined instructions, in valid form, starting in the state the machine was in before attempting to execute the given instruction.

Breakpoint. A programmable event that forces the core to take a breakpoint exception.

Burst. A multiple-beat data transfer whose total size is typically equal to a cache block.

Bus clock. Clock that causes the bus state transitions.

Bus master. The owner of the address or data bus; the device that initiates or requests the transaction.

C

Cache. High-speed memory containing recently accessed data or instructions (subset of main memory).

Cache block. A small region of contiguous memory that is copied from memory into a *cache*. The size of a cache block may vary among processors; the maximum block size is one *page*. In PowerPC processors, *cache coherency* is maintained on a cache-block basis. Note that the term ‘cache block’ is often used interchangeably with ‘cache line.’

Cache coherency. An attribute wherein an accurate and common view of memory is provided to all devices that share the same memory system. Caches are coherent if a processor performing a read from its cache is supplied with data corresponding to the most recent value written to memory or to another processor’s cache.

Cache flush. An operation that removes from a cache any data from a specified address range. This operation ensures that any modified data within the specified address range is written back to main memory. This operation is generated typically by a Data Cache Block Flush (**dcbf**) instruction.

Caching-inhibited. A memory update policy in which the *cache* is bypassed and the load or store is performed to or from main memory.

Cast out. A *cache block* that must be written to memory when a cache miss causes a cache block to be replaced.

Changed bit. One of two *page history bits* found in each *page table entry* (PTE). The processor sets the changed bit if any store is performed into the *page*. See also *Page access history bits* and *Referenced bit*.

Clean. An operation that causes a cache block to be written to memory, if modified, and then left in a valid, unmodified state in the cache.

Clear. To cause a bit or bit field to register a value of zero. See also *Set*.

Context synchronization. An operation that ensures that all instructions in execution complete past the point where they can produce an *exception*, that all instructions in execution complete in the context in which they began execution, and that all subsequent instructions are *fetched* and executed in the new context. Context synchronization may result from executing specific instructions (such as **isync** or **rfi**) or when certain events occur (such as an exception).

Copy-back operation. A cache operation in which a cache line is copied back to memory to enforce cache coherency. Copy-back operations consist of snoop push-out operations and cache cast-out operations.

D

Direct-mapped cache. A cache in which each main memory address can appear in only one location within the cache, operates more quickly when the memory request is a cache hit.

Double data rate. Memory that allows data transfers at the start and end of a clock cycle. thereby doubling the data rate.

E

Effective address (EA). The 32-bit address specified for a load, store, or an instruction fetch. This address is then submitted to the MMU for translation to either a *physical memory* address or an I/O address.

Exclusive state. MEI state (E) in which only one caching device contains data that is also in system memory.

F

Frame-check sequence (FCS). Specifies the standard 32-bit cyclic redundancy check (CRC) obtained using the standard CCITT-CRC polynomial on all fields except the preamble, SFD, and CRC.

Fetch. Retrieving instructions from either the cache or main memory and placing them into the instruction queue.

Flush. An operation that causes a cache block to be invalidated and the data, if modified, to be written to memory.

G

General-purpose register (GPR). Any of the 32 registers in the general-purpose register file. These registers provide the source operands and destination results for all integer data manipulation instructions. Integer load instructions move data from memory to GPRs and store instructions move data from GPRs to memory.

Gigabit media-independent interface (GMII) sublayer. Sublayer that provides a standard interface between the MAC layer and the physical layer for 1000-Mbps operation. It isolates the MAC layer and the physical layer, enabling the MAC layer to be used with various implementations of the physical layer.

Guarded. The guarded attribute pertains to out-of-order execution. When a page is designated as guarded, instructions and data cannot be accessed out-of-order.

H

Harvard architecture. An architectural model featuring separate caches and other memory management resources for instructions and data.

I

IEEE 754. A standard written by the Institute of Electrical and Electronics Engineers that defines operations and representations of binary floating-point numbers.

Illegal instructions. A class of instructions that are not implemented for a particular PowerPC processor. These include instructions not defined by the PowerPC architecture. In addition, for 32-bit implementations, instructions that are defined only for 64-bit implementations are considered to be illegal instructions. For 64-bit implementations instructions that are defined only for 32-bit implementations are considered to be illegal instructions.

Implementation. A particular processor that conforms to the PowerPC architecture, but may differ from other architecture-compliant implementations for example in design, feature set, and implementation of *optional* features. The PowerPC architecture has many different implementations.

Inbound windows. Mappings that perform address translation from the external address space to the local address space, attach attributes and transaction types to the transaction, and map the transaction to its target interface.

Inter-packet gap. The gap between the end of one Ethernet packet and the beginning of the next transmitted packet.

Integer unit. An execution unit in the core responsible for executing integer instructions.

In-order. An aspect of an operation that adheres to a sequential model. An operation is said to be performed in-order if, at the time that it is performed, it is known to be required by the sequential execution model. See *Out-of-order.*

Instruction latency. The total number of clock cycles necessary to execute an instruction and make ready the results of that instruction.

K

Kill. An operation that causes a *cache block* to be invalidated without writing any modified data to memory.

L

Latency. The number of clock cycles necessary to execute an instruction and make ready the results of that execution for a subsequent instruction.

L2 cache. Level-2 cache. See *Secondary cache*.

Least-significant bit (lsb). The bit of least value in an address, register, field, data element, or instruction encoding.

Least-significant byte (LSB). The byte of least value in an address, register, data element, or instruction encoding.

Little-endian. A byte-ordering method in memory where the address *n* of a word corresponds to the *least-significant byte*. In an addressed memory word, the bytes are ordered (left to right) 3, 2, 1, 0, with 3 being the *most-significant byte*. See *Big-endian*.

Local access window. Mapping used to translate a region of memory to a particular target interface, such as the DDR SDRAM controller or the PCI controller. The local memory map is defined by a set of eight local access windows. The size of each window can be configured from 4 Kbytes to 2 Gbytes.

M

Media access control (MAC) sublayer. Sublayer that provides a logical connection between the MAC and its peer station. Its primary responsibility is to initialize, control, and manage the connection with the peer station.

Medium-dependent interface (MDI) sublayer—Sublayer that defines different connector types for different physical media and PMD devices.

Media-independent interface (MII) sublayer. Sublayer that provides a standard interface between the MAC layer and the physical layer for 10/100-Mbps operations. It isolates the MAC layer and the physical layer, enabling the MAC layer to be used with various implementations of the physical layer.

MEI (modified/exclusive/invalid). *Cache coherency* protocol used to manage caches on different devices that share a memory system. Note that the PowerPC architecture does not specify the implementation of a MEI protocol to ensure cache coherency.

Memory access ordering. The specific order in which the processor performs load and store memory accesses and the order in which those accesses complete.

Memory-mapped accesses. Accesses whose addresses use the page or block address translation mechanisms provided by the MMU and that occur externally with the bus protocol defined for memory.

Memory coherency. An aspect of caching in which it is ensured that an accurate view of memory is provided to all devices that share system memory.

Memory consistency. Refers to agreement of levels of memory with respect to a single processor and system memory (for example, on-chip cache, secondary cache, and system memory).

Memory management unit (MMU). The functional unit that is capable of translating an *effective* (logical) *address* to a physical address, providing protection mechanisms, and defining caching methods.

Modified state. MEI state (M) in which one, and only one, caching device has the valid data for that address. The data at this address in external memory is not valid.

Most-significant bit (msb). The highest-order bit in an address, registers, data element, or instruction encoding.

Most-significant byte (MSB). The highest-order byte in an address, registers, data element, or instruction encoding.

N

NaN. An abbreviation for not a number; a symbolic entity encoded in floating-point format. There are two types of NaNs—signaling NaNs and quiet NaNs.

No-op. No-operation. A single-cycle operation that does not affect registers or generate bus activity.

O

Outbound Windows. Mappings that perform address translations from local 32-bit address space to the address spaces of PCI1 or PCI2, which may be much larger than the local space. Outbound windows also map attributes such as transaction type or priority level.

P

Packet. A unit of binary data that can be routed through a network. Sometimes packet is used to refer to the frame plus the preamble and start frame delimiter (SFD).

Page. A region in memory. The OEA defines a page as a 4-Kbyte area of memory, aligned on a 4-Kbyte boundary.

Page access history bits. The *changed* and *referenced* bits in the PTE keep track of the access history within the page. The referenced bit is set by the MMU whenever the page is accessed for a read or write operation. The changed bit is set when the page is stored into. See *Changed bit* and *Referenced bit.*

Page fault. A page fault is a condition that occurs when the processor attempts to access a memory location that does not reside within a *page* not currently resident in *physical memory.* On PowerPC processors, a page fault exception condition occurs when a matching, valid *page table entry* (PTE[V] = 1) cannot be located.

Page table. A table in memory is comprised of *page table entries*, or PTEs. It is further organized into eight PTEs per PTEG (page table entry group). The number of PTEGs in the page table depends on the size of the page table (as specified in the SDR1 register).

Page table entry (PTE). Data structures containing information used to translate *effective address* to physical address on a 4-Kbyte page basis. A PTE consists of 8 bytes of information in a 32-bit processor and 16 bytes of information in a 64-bit processor.

Physical coding sublayer (PCS). Sublayer responsible for encoding and decoding data stream to and from the MAC sublayer. Medium (1000BASEX) 8B/10B coding is used for fiber. Medium (1000BASET) 8B1Q coding is used for unshielded twisted pair (UTP).

Physical medium attachment (PMA) sublayer. Sublayer responsible for serializing code groups into a bit stream suitable for serial bit-oriented physical devices (SERDES) and vice versa. Synchronization is also performed for proper data decoding in this sublayer. The PMA sits between the PCS and the PMD sublayers. For fiber medium (1000BASEX) the interface on the PMD side of the PMA is a one-bit 1250 MHz signal, while on the PMA's PCS side the interface is a ten-bit interface (TBI) at 125 MHz. The TBI is an alternative to the GMII interface. If the TBI is used the gigabit Ethernet controller must be capable of performing the PCS function. For UTP medium, the PMD interface side of the PMA consists of four pair of 62.5-MHz PAM5 encoded signals, while the PCS side provides the 1250-Mbps input to a 8B1Q4 PCS.

Physical medium dependent (PMD) sublayer. Sublayer responsible for signal transmission. The typical PMD functionality includes amplifier, modulation, and wave shaping. Different PMD devices may support different media.

Physical memory. The actual memory that can be accessed through the system's memory bus.

Pipelining. A technique that breaks operations, such as instruction processing or bus transactions, into smaller distinct stages or tenures (respectively) so that a subsequent operation can begin before the previous one has completed.

Precise exceptions. A category of exception for which the pipeline can be stopped so instructions that preceded the faulting instruction can complete and subsequent instructions can be flushed and redispatched after exception handling has completed. See *Imprecise exceptions.*

Primary opcode. The most-significant 6 bits (bits 0–5) of the instruction encoding that identifies the type of instruction.

Program order. The order of instructions in an executing program. More specifically, this term is used to refer to the original order in which program instructions are fetched into the instruction queue from the cache.

Protection boundary. A boundary between *protection domains*.

Protection domain. A protection domain is a segment, a virtual page, a BAT area, or a range of unmapped effective addresses. It is defined only when the appropriate relocate bit in the MSR (IR or DR) is 1.

Q

Quad word. A group of 16 contiguous locations starting at an address divisible by 16.

Quiesce. To come to rest. The processor is said to quiesce when an exception is taken or a **sync** instruction is executed. The instruction stream is stopped at the decode stage and executing instructions are allowed to complete to create a controlled context for instructions that may be affected by out-of-order, parallel execution. See *Context synchronization*.

R

rA. The **r**A instruction field is used to specify a GPR to be used as a source or destination.

rB. The **r**B instruction field is used to specify a GPR to be used as a source.

rD. The **r**D instruction field is used to specify a GPR to be used as a destination.

rS. The **r**S instruction field is used to specify a GPR to be used as a source.

Record bit. Bit 31 (or the Rc bit) in the instruction encoding. When it is set, updates the condition register (CR) to reflect the result of the operation.

Reconciliation sublayer. Sublayer that maps the terminology and commands used in the MAC layer into electrical formats appropriate for the physical layer entities.

Referenced bit. One of two *page history bits* found in each *page table entry.* The processor sets the *referenced bit* whenever the page is accessed for a read or write. See also *Page access history bits.*

Reservation. The processor establishes a reservation on a *cache block* of memory space when it executes an **lwarx** instruction to read a memory semaphore into a GPR.

Reservation station. A buffer between the dispatch and execute stages that allows instructions to be dispatched even though the results of instructions on which the dispatched instruction may depend are not available.

RISC (reduced instruction set computing). An *architecture* characterized by fixed-length instructions with nonoverlapping functionality and by a separate set of load and store instructions that perform memory accesses.

S

Secondary cache. A cache memory that is typically larger and has a longer access time than the primary cache. A secondary cache may be shared by multiple devices. Also referred to as L2, or level-2, cache.

Set (*v*)**.** To write a nonzero value to a bit or bit field; the opposite of *clear.* The term ‘set’ may also be used to generally describe the updating of a bit or bit field.

Set (*n*)**.** A subdivision of a *cache*. Cacheable data can be stored in a given location in one of the sets, typically corresponding to its lower-order address bits. Because several memory locations can map to the same location, cached data is typically placed in the set whose *cache block* corresponding to that address was used least recently. See *Set-associative*.

Set-associative. Aspect of cache organization in which the cache space is divided into sections, called *sets*. The cache controller associates a particular main memory address with the contents of a particular set, or region, within the cache.

Slave. The device addressed by a master device. The slave is identified in the address tenure and is responsible for supplying or latching the requested data for the master during the data tenure.

Snooping. Monitoring addresses driven by a bus master to detect the need for coherency actions.

Snoop push. Response to a snooped transaction that hits a modified cache block. The cache block is written to memory and made available to the snooping device.

Stall. An occurrence when an instruction cannot proceed to the next stage.

Sticky bit. A bit that when *set* must be cleared explicitly.

Superscalar machine. A machine that can issue multiple instructions concurrently from a conventional linear instruction stream.

Supervisor mode. The privileged operation state of a processor. In supervisor mode, software, typically the operating system, can access all control registers and can access the supervisor memory space, among other privileged operations.

Synchronization. A process to ensure that operations occur strictly *in order*. See *Context synchronization* and *Execution synchronization.*

Synchronous exception. An *exception* that is generated by the execution of a particular instruction or instruction sequence. There are two types of synchronous exceptions, *precise* and *imprecise*.

System memory. The physical memory available to a processor.

T

Time-division multiplex (TDM). A single serial channel used by several channels taking turns.

Tenure. The period of bus mastership. For the e300, there can be separate address bus tenures and data bus tenures. A tenure consists of three phases: arbitration, transfer, and termination.

TLB (translation lookaside buffer). A cache that holds recently-used *page table entries*.

Throughput. The measure of the number of instructions that are processed per clock cycle.

Transaction. A complete exchange between two bus devices. A transaction is typically comprised of an address tenure and one or more data tenures, which may overlap or occur separately from the address tenure. A transaction may be minimally comprised of an address tenure only.

Transfer termination. Signal that refers to both signals that acknowledge the transfer of individual beats (of both single-beat transfer and individual beats of a burst transfer) and to signals that mark the end of the tenure.

U

User mode. The operating state of a processor used typically by application software. In user mode, software can access only certain control registers and can access only

user memory space. No privileged operations can be performed. Also referred to as problem state.

V

Virtual address. An intermediate address used in the translation of an *effective address* to a physical address.

Virtual memory. The address space created using the memory management facilities of the processor. Program access to *virtual memory* is possible only when it coincides with *physical memory.*

W

Way. A location in the cache that holds a cache block, its tags, and status bits.

Word. A 32-bit data element.

Write-back. A cache memory update policy in which processor write cycles are directly written only to the cache. External memory is updated only indirectly, for example, when a modified cache block is *cast out* to make room for newer data.

Write-through. A cache memory update policy in which all processor write cycles are written to both the cache and memory.
