LM2832 High Frequency 2.0A Load - Step-Down DC-DC Regulator

General Description

The LM2832 regulator is a monolithic, high frequency, PWM step-down DC/DC converter in a 6 Pin LLP and a 8 Pin eMSOP package. It provides all the active functions to provide local DC/DC conversion with fast transient response and accurate regulation in the smallest possible PCB area. With a minimum of external components, the LM2832 is easy to use. The ability to drive 2.0A loads with an internal 150 mΩ PMOS switch using state-of-the-art 0.5 µm BiCMOS technology results in the best power density available. The world-class control circuitry allows on-times as low as 30ns, thus supporting exceptionally high frequency conversion over the entire 3V to 5.5V input operating range down to the minimum output voltage of 0.6V. Switching frequency is internally set to 550 kHz, 1.6 MHz, or 3.0 MHz, allowing the use of extremely small surface mount inductors and chip capacitors. Even though the operating frequency is high, efficiencies up to 93% are easy to achieve. External shutdown is included, featuring an ultra-low stand-by current of 30 nA. The LM2832 utilizes current-mode control and internal compensation to provide high-performance regulation over a wide range of operating conditions. Additional features include internal soft-start circuitry to reduce inrush current, pulse-by-pulse current limit, thermal shutdown, and output over-voltage protection.

Features

- Input voltage range of 3.0V to 5.5V
- Output voltage range of 0.6V to 4.5V
- 2.0A output current
- High Switching Frequencies 1.6MHz (LM2832X) 0.55MHz (LM2832Y) 3.0MHz (LM2832Z)
- \blacksquare 150mΩ PMOS switch
- 0.6V, 2% Internal Voltage Reference
- Internal soft-start
- Current mode, PWM operation
- Thermal Shutdown
- Over voltage protection

Applications

- Local 5V to Vcore Step-Down Converters
- Core Power in HDDs
- Set-Top Boxes
- **USB Powered Devices**
- DSL Modems

FIGURE 1.

Applications Information

THEORY OF OPERATION

The LM2832 is a constant frequency PWM buck regulator IC that delivers a 2.0A load current. The regulator has a preset switching frequency of 1.6MHz or 3.0MHz. This high frequency allows the LM2832 to operate with small surface mount capacitors and inductors, resulting in a DC/DC converter that requires a minimum amount of board space. The LM2832 is internally compensated, so it is simple to use and requires few external components. The LM2832 uses current-mode control to regulate the output voltage. The following operating description of the LM2832 will refer to the Simplified Block Diagram (Figure 1) and to the waveforms in Figure 2. The LM2832 supplies a regulated output voltage by switching the internal PMOS control switch at constant frequency and variable duty cycle. A switching cycle begins at the falling edge of the reset pulse generated by the internal oscillator. When this pulse goes low, the output control logic turns on the internal PMOS control switch. During this ontime, the SW pin voltage (V_{SW}) swings up to approximately V_{IN} , and the inductor current (I_1) increases with a linear slope. I_L is measured by the current sense amplifier, which generates an output proportional to the switch current. The sense signal is summed with the regulator's corrective ramp and compared to the error amplifier's output, which is proportional to the difference between the feedback voltage and V_{BFE} . When the PWM comparator output goes high, the output switch turns off until the next switching cycle begins. During the switch off-time, inductor current discharges through the Schottky catch diode, which forces the SW pin to swing below ground by the forward voltage (V_D) of the Schottky catch diode. The regulator loop adjusts the duty cycle (D) to maintain a constant output voltage.

FIGURE 2. Typical Waveforms

SOFT-START

This function forces V_{OUT} to increase at a controlled rate during start up. During soft-start, the error amplifier's reference voltage ramps from 0V to its nominal value of 0.6V in approximately 600 µs. This forces the regulator output to ramp up in a controlled fashion, which helps reduce inrush current.

OUTPUT OVERVOLTAGE PROTECTION

The over-voltage comparator compares the FB pin voltage to a voltage that is 15% higher than the internal reference V_{BFE} . Once the FB pin voltage goes 15% above the internal reference, the internal PMOS control switch is turned off, which allows the output voltage to decrease toward regulation.

UNDERVOLTAGE LOCKOUT

Under-voltage lockout (UVLO) prevents the LM2832 from operating until the input voltage exceeds 2.73V (typ). The UVLO threshold has approximately 430 mV of hysteresis, so the part will operate until V_{IN} drops below 2.3V (typ). Hysteresis prevents the part from turning off during power up if V_{IN} is non-monotonic.

CURRENT LIMIT

The LM2832 uses cycle-by-cycle current limiting to protect the output switch. During each switching cycle, a current limit comparator detects if the output switch current exceeds 3.25A (typ), and turns off the switch until the next switching cycle begins.

THERMAL SHUTDOWN

Thermal shutdown limits total power dissipation by turning off the output switch when the IC junction temperature exceeds 165˚C. After thermal shutdown occurs, the output switch doesn't turn on until the junction temperature drops to approximately 150˚C.

Design Guide

INDUCTOR SELECTION

The Duty Cycle (D) can be approximated quickly using the ratio of output voltage (V_O) to input voltage (V_{IN}) :

$$
D = \frac{V_{OUT}}{V_{IN}}
$$

The catch diode (D1) forward voltage drop and the voltage drop across the internal PMOS must be included to calculate a more accurate duty cycle. Calculate D by using the following formula:

$$
D = \frac{V_{\text{OUT}} + V_{\text{D}}}{V_{\text{IN}} + V_{\text{D}} - V_{\text{SW}}}
$$

 V_{SW} can be approximated by:

$$
V_{SW} = I_{OUT} \times R_{DSON}
$$

The diode forward drop (V_D) can range from 0.3V to 0.7V depending on the quality of the diode. The lower the V_D , the higher the operating efficiency of the converter. The inductor value determines the output ripple current. Lower inductor values decrease the size of the inductor, but increase the output ripple current. An increase in the inductor value will decrease the output ripple current.

One must ensure that the minimum current limit (2.4A) is not exceeded, so the peak current in the inductor must be calculated. The peak current (I_{LPK}) in the inductor is calculated by:

$$
I_{LPK} = I_{OUT} + \Delta i_L
$$

FIGURE 3. Inductor Current

$$
\frac{V_{IN} - V_{OUT}}{L} = \frac{2\Delta i_L}{DT_S}
$$

In general,

 $\Delta i_L = 0.1 \times (I_{\text{OUT}}) \rightarrow 0.2 \times (I_{\text{OUT}})$

If Δi_1 = 20% of 2A, the peak current in the inductor will be 2.4A. The minimum guaranteed current limit over all operating conditions is 2.4A. One can either reduce Δi_L , or make the engineering judgment that zero margin will be safe enough. The typical current limit is 3.25A.

The LM2832 operates at frequencies allowing the use of ceramic output capacitors without compromising transient response. Ceramic capacitors allow higher inductor ripple without significantly increasing output ripple. See the output capacitor section for more details on calculating output voltage ripple. Now that the ripple current is determined, the inductance is calculated by:

$$
L = \left(\frac{DT_{\rm S}}{2\Delta i_{\rm L}}\right) \times (V_{\rm IN} - V_{\rm OUT})
$$

Where

$$
T_{\rm S} = \frac{1}{f_{\rm S}}
$$

When selecting an inductor, make sure that it is capable of supporting the peak output current without saturating. Inductor saturation will result in a sudden reduction in inductance and prevent the regulator from operating correctly. Because of the speed of the internal current limit, the peak current of the inductor need only be specified for the required maximum output current. For example, if the designed maximum output current is 1.0A and the peak current is 1.25A, then the inductor should be specified with a saturation current limit of > 1.25A. There is no need to specify the saturation or peak current of the inductor at the 3.25A typical switch current limit. The difference in inductor size is a factor of 5. Because of the operating frequency of the LM2832, ferrite based inductors are preferred to minimize core losses. This presents little restriction since the variety of ferrite-based inductors is huge. Lastly, inductors with lower series resistance (R_{DCB}) will provide better operating efficiency. For recommended inductors see Example Circuits.

INPUT CAPACITOR

An input capacitor is necessary to ensure that V_{IN} does not drop excessively during switching transients. The primary specifications of the input capacitor are capacitance, voltage, RMS current rating, and ESL (Equivalent Series Inductance). The recommended input capacitance is 22 µF.The input voltage rating is specifically stated by the capacitor manufacturer. Make sure to check any recommended deratings and also verify if there is any significant change in capacitance at the operating input voltage and the operating temperature. The input capacitor maximum RMS input current rating (I_{RMS-IN}) must be greater than:

$$
I_{RMS_IN} \sqrt{D \left[I_{OUT}{}^2 (1-D) + \frac{\Delta i^2}{3} \right]}
$$

Neglecting inductor ripple simplifies the above equation to:

$$
I_{RMS_IN} = I_{OUT} \times \sqrt{D(1 - D)}
$$

It can be shown from the above equation that maximum RMS capacitor current occurs when $D = 0.5$. Always calculate the RMS at the point where the duty cycle D is closest to 0.5. The ESL of an input capacitor is usually determined by the effective cross sectional area of the current path. A large leaded capacitor will have high ESL and a 0805 ceramic chip capacitor will have very low ESL. At the operating frequencies of the LM2832, leaded capacitors may have an ESL so large that the resulting impedance $(2\pi fL)$ will be higher than that required to provide stable operation. As a result, surface mount capacitors are strongly recommended.

Design Guide (Continued)

Sanyo POSCAP, Tantalum or Niobium, Panasonic SP, and multilayer ceramic capacitors (MLCC) are all good choices for both input and output capacitors and have very low ESL. For MLCCs it is recommended to use X7R or X5R type capacitors due to their tolerance and temperature characteristics. Consult capacitor manufacturer datasheets to see how rated capacitance varies over operating conditions.

OUTPUT CAPACITOR

The output capacitor is selected based upon the desired output ripple and transient response. The initial current of a load transient is provided mainly by the output capacitor. The output ripple of the converter is:

$$
\Delta V_{\text{OUT}} = \Delta I_{\text{L}} \left(R_{\text{ESR}} + \frac{1}{8 \times F_{\text{SW}} \times C_{\text{OUT}}}\right)
$$

When using MLCCs, the ESR is typically so low that the capacitive ripple may dominate. When this occurs, the output ripple will be approximately sinusoidal and 90˚ phase shifted from the switching action. Given the availability and quality of MLCCs and the expected output voltage of designs using the LM2832, there is really no need to review any other capacitor technologies. Another benefit of ceramic capacitors is their ability to bypass high frequency noise. A certain amount of switching edge noise will couple through parasitic capacitances in the inductor to the output. A ceramic capacitor will bypass this noise while a tantalum will not. Since the output capacitor is one of the two external components that control the stability of the regulator control loop, most applications will require a minimum of 22 µF of output capacitance. Capacitance often, but not always, can be increased significantly with little detriment to the regulator stability. Like the input capacitor, recommended multilayer ceramic capacitors are X7R or X5R types.

CATCH DIODE

The catch diode (D1) conducts during the switch off-time. A Schottky diode is recommended for its fast switching times and low forward voltage drop. The catch diode should be chosen so that its current rating is greater than:

$$
I_{D1} = I_{OUT} \times (1-D)
$$

The reverse breakdown rating of the diode must be at least the maximum input voltage plus appropriate margin. To improve efficiency, choose a Schottky diode with a low forward voltage drop.

OUTPUT VOLTAGE

The output voltage is set using the following equation where R2 is connected between the FB pin and GND, and R1 is connected between V_{Ω} and the FB pin. A good value for R2 is 10kΩ. When designing a unity gain converter (Vo = $0.6V$), R1 should be between 0 Ω and 100 Ω , and R2 should be equal or greater than 10kΩ.

$$
R1 = \left(\frac{V_{OUT}}{V_{REF}} - 1\right) \times R2
$$

 $V_{REF} = 0.60V$

PCB LAYOUT CONSIDERATIONS

When planning layout there are a few things to consider when trying to achieve a clean, regulated output. The most important consideration is the close coupling of the GND connections of the input capacitor and the catch diode D1. These ground ends should be close to one another and be connected to the GND plane with at least two through-holes. Place these components as close to the IC as possible. Next in importance is the location of the GND connection of the output capacitor, which should be near the GND connections of CIN and D1. There should be a continuous ground plane on the bottom layer of a two-layer board except under the switching node island. The FB pin is a high impedance node and care should be taken to make the FB trace short to avoid noise pickup and inaccurate regulation. The feedback resistors should be placed as close as possible to the IC, with the GND of R1 placed as close as possible to the GND of the IC. The V_{OUT} trace to R2 should be routed away from the inductor and any other traces that are switching. High AC currents flow through the V_{IN} , SW and V_{OUT} traces, so they should be as short and wide as possible. However, making the traces wide increases radiated noise, so the designer must make this trade-off. Radiated noise can be decreased by choosing a shielded inductor. The remaining components should also be placed as close as possible to the IC. Please see Application Note AN-1229 for further considerations and the LM2832 demo board as an example of a four-layer layout.

Calculating Efficiency, and Junction Temperature

The complete LM2832 DC/DC converter efficiency can be calculated in the following manner.

$$
\eta = \frac{P_{OUT}}{P_{IN}}
$$

Or

$$
\eta = \frac{P_{\text{OUT}}}{P_{\text{OUT}} + P_{\text{LOS}}}
$$

Calculations for determining the most significant power losses are shown below. Other losses totaling less than 2% are not discussed.

Power loss (P_{LOSS}) is the sum of two basic types of losses in the converter: switching and conduction. Conduction losses usually dominate at higher output loads, whereas switching losses remain relatively fixed and dominate at lower output loads. The first step in determining the losses is to calculate the duty cycle (D):

$$
D = \frac{V_{\text{OUT}} + V_{\text{D}}}{V_{\text{IN}} + V_{\text{D}} - V_{\text{SW}}}
$$

 V_{SW} is the voltage drop across the internal PFET when it is on, and is equal to:

$$
\mathsf{V}_{\mathsf{SW}} = \mathsf{I}_{\mathsf{OUT}} \times \mathsf{R}_{\mathsf{DSON}}
$$

 V_D is the forward voltage drop across the Schottky catch diode. It can be obtained from the diode manufactures Electrical Characteristics section. If the voltage drop across the inductor (V_{DCR}) is accounted for, the equation becomes:

$$
D = \frac{V_{\text{OUT}} + V_{\text{D}} + V_{\text{DCR}}}{V_{\text{IN}} + V_{\text{D}} + V_{\text{DCR}} - V_{\text{SW}}}
$$

The conduction losses in the free-wheeling Schottky diode are calculated as follows:

$$
P_{\text{DIODE}} = V_{\text{D}} \times I_{\text{OUT}} \times (1-D)
$$

Often this is the single most significant power loss in the circuit. Care should be taken to choose a Schottky diode that has a low forward voltage drop.

Another significant external power loss is the conduction loss in the output inductor. The equation can be simplified to:

$$
P_{IND} = I_{OUT}^2 \times R_{DCR}
$$

The LM2832 conduction loss is mainly associated with the internal PFET:

$$
P_{\text{COND}} = (I_{\text{OUT}}^2 \times D) \left(1 + \frac{1}{3} \times \left(\frac{\Delta i_{\text{L}}}{I_{\text{OUT}}} \right)^2 \right) R_{\text{DSON}}
$$

If the inductor ripple current is fairly small, the conduction losses can be simplified to:

$P_{\text{COMP}} = I_{\text{OUT}}^2$ x R_{DSON} x D

Switching losses are also associated with the internal PFET. They occur during the switch on and off transition periods, where voltages and currents overlap resulting in power loss. The simplest means to determine this loss is to empirically measuring the rise and fall times (10% to 90%) of the switch at the switch node.

Switching Power Loss is calculated as follows:

$$
P_{\text{SWR}} = 1/2(V_{\text{IN}} \times I_{\text{OUT}} \times F_{\text{SW}} \times T_{\text{RISE}})
$$

$$
P_{\text{SWF}} = 1/2(V_{\text{IN}} \times I_{\text{OUT}} \times F_{\text{SW}} \times T_{\text{FALL}})
$$

$$
P_{SW} = P_{SWR} + P_{SWF}
$$

Another loss is the power required for operation of the internal circuitry:

$$
P_{Q} = I_{Q} \times V_{IN}
$$

 I_{Ω} is the quiescent operating current, and is typically around 2.5mA for the 0.55MHz frequency option.

Typical Application power losses are:

 $\Sigma P_{\text{COND}} + P_{\text{SW}} + P_{\text{DIODE}} + P_{\text{IND}} + P_{\text{Q}} = P_{\text{Loss}}$ $\Sigma P_{\text{COND}} + P_{\text{SWF}} + P_{\text{SWR}} + P_{\text{Q}} = P_{\text{INTERNAL}}$ $P_{\text{INTERNAI}} = 339 \text{mW}$

Thermal Definitions

 T_J = Chip junction temperature

 T_A = Ambient temperature

 $R_{\theta\text{JC}}$ = Thermal resistance from chip junction to device case $R_θ$ _A = Thermal resistance from chip junction to ambient air Heat in the LM2832 due to internal power dissipation is removed through conduction and/or convection.

Conduction: Heat transfer occurs through cross sectional areas of material. Depending on the material, the transfer of heat can be considered to have poor to good thermal conductivity properties (insulator vs. conductor).

Heat Transfer goes as:

Silicon \rightarrow package \rightarrow lead frame \rightarrow PCB

Convection: Heat transfer is by means of airflow. This could be from a fan or natural convection. Natural convection occurs when air currents rise from the hot device to cooler air.

Thermal impedance is defined as:

Thermal Definitions (Continued)

$$
R_{\theta} = \frac{\Delta T}{Power}
$$

Thermal impedance from the silicon junction to the ambient air is defined as:

$$
R_{\theta JA} = \frac{T_J - T_A}{Power}
$$

The PCB size, weight of copper used to route traces and ground plane, and number of layers within the PCB can greatly effect $R_{\theta JA}$. The type and number of thermal vias can also make a large difference in the thermal impedance. Thermal vias are necessary in most applications. They conduct heat from the surface of the PCB to the ground plane. Four to six thermal vias should be placed under the exposed pad to the ground plane if the LLP package is used.

Thermal impedance also depends on the thermal properties of the application operating conditions (Vin, Vo, Io etc), and the surrounding circuitry.

Silicon Junction Temperature Determination Method 1:

To accurately measure the silicon temperature for a given application, two methods can be used. The first method requires the user to know the thermal impedance of the silicon junction to top case temperature.

Some clarification needs to be made before we go any further.

 R_{AJC} is the thermal impedance from all six sides of an IC package to silicon junction.

 $R_{ΦJC}$ is the thermal impedance from top case to the silicon junction.

In this data sheet we will use $R_{\Phi\text{JC}}$ so that it allows the user to measure top case temperature with a small thermocouple attached to the top case.

 R_{Φ J_C is approximately 30°C/Watt for the 6-pin LLP package with the exposed pad. Knowing the internal dissipation from the efficiency calculation given previously, and the case temperature, which can be empirically measured on the bench we have:

$$
R_{\Phi JC} = \frac{T_J - T_C}{Power}
$$

Therefore:

$$
T_{j} = (R_{\Phi JC} \times P_{LOSS}) + T_{C}
$$

From the previous example:

 $T_i = (R_{\Phi JC} \times P_{INTERNAL}) + T_C$

$$
T_j = 30^{\circ} \text{C/W} \times 0.339 \text{W} + T_{\text{C}}
$$

The second method can give a very accurate silicon junction temperature.

The first step is to determine $R_{\theta JA}$ of the application. The LM2832 has over-temperature protection circuitry. When the silicon temperature reaches 165˚C, the device stops switching. The protection circuitry has a hysteresis of about 15˚C. Once the silicon temperature has decreased to approximately 150˚C, the device will start to switch again. Knowing this, the $R_{\theta JA}$ for any application can be characterized during the early stages of the design one may calculate the $R_{\theta JA}$ by placing the PCB circuit into a thermal chamber. Raise the

ambient temperature in the given working application until the circuit enters thermal shutdown. If the SW-pin is monitored, it will be obvious when the internal PFET stops switching, indicating a junction temperature of 165˚C. Knowing the internal power dissipation from the above methods, the junction temperature, and the ambient temperature $R_{\theta JA}$ can be determined.

$$
R_{\theta JA} = \frac{165^{\circ} - Ta}{P_{INTERNAL}}
$$

Once this is determined, the maximum ambient temperature allowed for a desired junction temperature can be found.

An example of calculating $R_{\theta JA}$ for an application using the National Semiconductor LM2832 LLP demonstration board is shown below.

The four layer PCB is constructed using FR4 with $1/2$ oz copper traces. The copper ground plane is on the bottom layer. The ground plane is accessed by two vias. The board measures 3.0cm x 3.0cm. It was placed in an oven with no forced airflow. The ambient temperature was raised to 126˚C, and at that temperature, the device went into thermal shutdown.

From the previous example:

$$
P_{\text{INTERNAL}} = 339 \text{mW}
$$

$$
R_{\theta J A} = \frac{165^{\circ}C - 126^{\circ}C}{339 \text{ mW}} = 115^{\circ} \text{ C/W}
$$

If the junction temperature was to be kept below 125˚C, then the ambient temperature could not go above 86˚C.

> T_i - ($R_{\theta JA}$ x P_{LOS}) = T_A 125˚C - (115˚C/W x 339mW) = 86˚C

LLP Package

FIGURE 4. Internal LLP Connection

For certain high power applications, the PCB land may be modified to a "dog bone" shape (see Figure 6). By increasing the size of ground plane, and adding thermal vias, the $R_{h, A}$ for the application can be reduced.

LLP Package (Continued)
